In one study of personal explicit theories, Runco and colleagues asked creativity researchers to rate behaviors that were the most important for recognized creative achievement. Motivational behaviors received the highest ratings, with problem finding and questioning skills rated next most important, and adaptive cognition the third most important. The researchers were also asked about developmental influences on creativity. Here education and learning received the highest ratings, with Cultural and Social Factors and Family and Early Background receiving lower ratings. The final question to the researchers asked about important topics for future research. The rankings of these indicated that actual creative behavior, motivation and drive, imagery, imagination, and creative products are of critical interest.

Interestingly, the differences in the ratings of researchers who had experience teaching creativity courses and those who

had published a book or article, and of those who had not, were very slight. Additionally, only slight group differences were found for ratings of important research topics. There were a few differences in the interests (i.e., writing and music) of the researchers which were related to selected ratings of creative achievement variables and important research topics.

Conclusions

Even with some group differences (including those implied by a comparison of characteristics across studies), there is some consensus about certain correlates of creativity. The characteristics Artistic, Capable, Clever, Curious, Imaginative, Individualistic, Intelligent, Wide Interests, Inventive, Original, and Resourceful are the most commonly recognized, for example. In a sense, these may be considered the core characteristics of the creativity complex.

The inclusion of Intelligence in that list may come as a surprise. Yet it may be that creativity does require some basic information processing skill. The relationship between creativity and intelligence is often described as a threshold, with some of the latter necessary for the former, but beyond a low level, the two are unrelated.

Alternatively, it may be difficult to justify the inclusion of Intelligence in the implicit theories of creativity. It suggests a lack of discriminant validity (creativity being just another sign of intelligence). This is, however, an inherent feature of

implicit theories: They differ from explicit theories. Moreover, explicit theories may not be able to justify implicit theories. If they could, there would be no reason to examine implicit theories. As it happens, implicit theories of creativity do differ from explicit theories in several ways, and they should be examined and respected. They tell us how people in the natural environment really think about creativity.

Glossary

Commedia Dell'arte A popular form of theater in Europe in the sixteenth through eighteenth centuries. Although the basic plot was worked out in advance, most of the dialogue was improvised on stage.

Ethnography of speaking A branch of linguistic anthropology that studies the improvisational creativity of folklore performers.

Method acting A type of theater rehearsal that requires the actor to improvise a character's behavior, as a way of better understanding the character's psychology.

Developed in New York City, method acting was based on the theories of Russian director Konstantin Stanislavsky.

Motivic improvisation In musical improvisation, the use of a set of motifs – melodic fragments between 4 and

10 notes in length – as the basic building blocks of an improvised melodic line. The same motifs may be used in many different songs, resulting in improvisations that have no necessary relationship to the original melody.

Oral tradition In contrast to written tradition. Oral tradition includes all of the performances that are important to a society but are not written down. Oral tradition is particularly important in nonliterate societies, and can include religious rituals, stories, jokes, political oratory, and theater.

Paraphrase improvisation In musical improvisation, an elaboration of a basic melodic line, using embellishments or rhythmic changes, such that the original melody remains recognizable.

Introduction

Since the 1950s, creativity researchers have focused on product creativity – the creativity that results in the masterpieces of Western art, or the grand theories of science. Improvisation is a relatively new topic for creativity research, only beginning to receive attention in the 1990s. Two unique characteristics of improvisation have led to this increased focus.

First, in most creative domains, the creative process results in a *product*, such as a painting, a scientific article, or a musical score. Unlike product-oriented creativity, the goal of improvisational performance is to entertain an audience by exposing them to the creative process itself. Because the performance is live, in front of an audience, there is no opportunity for reflection or revision in the creative process. The audience observes the creative process in action. In a sense, the creative process is the creative product.

Second, almost all improvisations are performed by an ensemble, and require collaboration among all of the performers. For example, in a small jazz group with four to six musicians, no one musician can control or conduct the performance. Instead, all of the musicians have to listen closely to one another, responding to each other in a give-and-take that many jazz musicians call a 'conversation.' A jazz performance is a collaborative, group improvisation. Improvisational theater is also an ensemble art. An improvisational theater troupe typically has between five and eight actors. During a scene, no single actor takes on a director's role and guides the performance. Instead, the dialogue is collaboratively created, from line to line, as the actors respond to each other's words on the spot. Like jazz, improvisational theater is a collaborative, group improvisation.

These two unique characteristics make the study of improvisation potentially valuable for the study of creativity more generally. For example, improvisation gives the researcher an opportunity to observe the creative process in action, potentially providing insights about the creative process more generally. In creative domains that result in creative products – like art and science – the creative process usually takes place in isolation, in a studio or a laboratory. It can take months or years before the final product is completed. This isolation and the long time period make the creative process difficult for researchers to study directly. But with improvisational performance, the creative process occurs on stage, in front of the audience.

In addition, because collaboration is central to improvisational performance in both music and theater, improvisational performance can help creativity researchers understand how collaboration influences the creative process in all domains. For example, most modern scientific laboratories involve the efforts of many top scientists, Ph.D.-level researchers, and graduate assistants. Conducting a scientific experiment is a highly collaborative endeavor. In a broader sense, an entire scientific discipline evolves and grows as a result of collaborations – ideas and theories published, rejected, and elaborated in the pages of journals, constant emails across the country among leading researchers, grant proposals accepted, edited, and revised by committees of experts in Washington. Although the collaborations of stage performers are obviously very different, some aspects of improvisational performance may be common to all collaborations.

In recent European history, improvisational performance is relatively unusual, because our performance traditions have emphasized the composer and the playwright. In Western music, we have a long tradition of scored music – written by

a composer and later performed by a professional musician. This tradition extends at least back to the medieval period. In Western theater, we have an even longer tradition of scripts that are written by a playwright and then later directed and performed by professional actors. Since the nineteenth century, all of our serious, high-art performance forms have been scored or scripted, and improvisational performance has generally been associated with uneducated or rural subgroups. Examples include the fiddle dances of Ireland and the blues and jazz of African Americans. Partly because of these cultural and economic associations, improvisational performance has faced an uphill battle to gain respect in mainstream culture.

The current predominance of scored music and scripted theater makes it hard to imagine a time when *all* performance was improvised. But of course, this was the case at the beginning of human culture, when writing systems had not yet been developed. The idea that a composer would write down a score for later performance is a relatively recent innovation in human history. Yet, human societies have always had musical and ritual performances, *oral traditions* that were passed from one generation to the next. And until at least the late medieval period, many European actors remained illiterate, and stage performances retained improvisational elements.

Theater Improvisation

All modern theater is rooted in ancient, prehistoric ritual performances. These performances, since they predate literacy, were essentially improvisational. Of course, some rituals are more structured and repetitive than others; nonetheless, all rituals that are not scripted display variation from one performance to the next. Contemporary anthropologists, who study verbal ritual performance around the world, have documented variations even in the most sacred rituals. For example, in many performance traditions only experienced elders have acquired the skills required to speak at important rituals. But even after a lifetime of performing prayers, incantations, and sermons, an examination of different audiotapes always shows differences between performances.

These observations have led to a revolutionary change in the way that folklorists conduct their research. For decades, until the late 1970s, folklorists were primarily concerned with discovering traditional folklore – stories, prayers, jokes, games, songs, dances – and transcribing the words as they were told or sung. In many cases, there was a very real concern that this folklore would die along with the sometimes elderly people who were the only performers.

But there was always a problem with the approach of trying to identify *the* correct, official version of a song or a story. The problem is that these traditions are *oral traditions*; they are almost never written down. Every performance of a North Carolina tall tale or an Appalachian fiddle tune is a little different. Folklorists initially viewed this as an annoying problem. Their goal was to write down the correct version of the story, ritual, or game, but each time they observed a performance, it was different. In the 1970s, a branch of linguistic anthropology, called the *ethnography of speaking*, began to accept that oral traditions are not fixed and verbatim, like the performances of a literate culture. Instead, these anthropologists

realized that oral folklore is an improvised tradition. Trying to identify the source text was no longer the goal. Instead, these researchers began to study the improvisational creativity of the performer, and began to emphasize the ways that folklore was a living, practiced tradition.

History in Europe

These realizations have recently begun to change the way early European theater is analyzed. Modern theater is often traced to a popular form of entertainment, called the *commedia dell'arte*, a partially improvised genre of plays originating in sixteenth-century Italy and thriving for the next 200 years throughout Europe. The *commedia* is a classic example of an oral performance tradition. Theater historians have long guessed that the early actors were not literate, and no one has ever found a script for a *commedia dell'arte* performance. Instead, what historians have found are rough outlines of plot, with brief descriptions of the characters. The actors could easily memorize these rough outlines, called *scenarios*, but all of the dialogue was improvised in front of the audience. The success of a *commedia dell'arte* performance depended on the actor's improvisational creativity.

The improvisations were guided by the scenario, which specified the characters of the play, an outline of the plot, the order of entrances and exits and the action for each scene, and summarized important conversations and monologues. These scenarios always used the same stock characters, and each character was always performed by the same actor. This allowed the actor to refine his performance, and allowed him to develop portions of speeches and dialogue that worked well. Each actor memorized particularly successful monologues, called *lazzi*, that he could fall back on if necessary.

Commedia is the kind of theater one would expect when most actors are unable to read. Even though many things are decided in advance, this early form of improvisation displays the key features of all improvisation: The dialogue is not scripted, but is improvised anew in each performance; and the performance is collaborative, with the final performance emerging from the creative improvisations of many actors.

Literacy became more widespread in Europe during the same years that improvisation was fading out of our performance tradition. Over the 200-year period that *commedia dell'arte* was popular, literacy became much more common among actors, and the scenarios developed into more highly scripted plays. By the nineteenth century, this form of early improvisation had been largely replaced by scripted theater.

In an interesting parallel development, during the same period, improvisation became less and less accepted in musical performance, as well. Composers began to write much more detailed scores, leaving less room for embellishment and improvisation. Musicians were expected to stick to the score, and improvisation was restricted to an optional *cadenza* at the end of a piece (see below). The influence of increasing literacy on these changes has recently received increasing attention from historians, literary theorists, and psychologists.

Recent History

Character improvisation was an important rehearsal technique for the Russian director Konstantin Stanislavsky. In character

improvisation, actors improvise a monologue, going beyond the script to better understand the character. Influenced by Freud's psychology of the unconscious, Stanislavsky taught his actors to emphasize the feelings, moods, and expressions of a character, so that the performance would seem more authentic. Stanislavsky called this new technique *psychological realism*. Stanislavsky's techniques have been influential for decades, leading to *method acting* and the *New York school* of actor training. Many contemporary theater and movie directors use character improvisation. But these improvisational techniques are used only in the privacy of rehearsal.

In a parallel development in France, the influential director Jacques Copeau began to transform French theater by drawing on improvisation and by reviving the techniques of the *commedia dell'arte*. His vision for *la comédie nouvelle* (the 'new comedy') was based on improvisation, and his innovations in training and directing influenced almost every modern theater group, including those in England and the United States. In 1913, Copeau was the first to use semi-structured *improvisational games* in rehearsals, drawing on his insight that children's games are fundamentally improvisational.

The first theater to improvise dialogue on stage was the 'Theater of Spontaneity,' created by Moreno in Vienna in 1923, and which performed to rave reviews in New York a few years later. Despite Moreno's initial success in New York, this innovation did not catch on. Contemporary American improvisational theater – using many techniques originated by Moreno in the 1920s – are usually traced to Chicago in the 1950s. In addition to Moreno's techniques, Chicago-style improvisational theater drew on a series of games developed for children's peer play. These games were developed by a drama teacher, Viola Spolin, in the 1930s and 1940s. Her son, Paul Sills, used these games to found the first improvisational comedy group, The Compass Players, at the University of Chicago in 1955. The Compass later evolved into the well-known improv group, The Second City, the model for the popular TV show *Saturday Night Live*.

Classic Chicago improv performances begin with the stage lights up and the ensemble standing on an empty stage. They ask for a suggestion from the audience – a location, a relationship, a problem. After repeating the suggestion to be used, the actors immediately begin improvising a dialogue based on the suggestion. Nothing is planned in advance – they develop characters, plot lines, and dramatic tension as they go along.

Since its origins in the 1950s, improvisational theater has grown dramatically in Chicago and in other urban centers. With this growth has come a remarkable variety of styles and approaches to improvisation. These styles can be grouped loosely into two main approaches. The most well-known groups perform short *games*, five minutes or less, which start from one or two audience suggestions. There are dozens of different games widely used by improvisational ensembles; each game is distinguished by a unique set of constraints on how the performance will proceed. A common game is Freeze Tag.

After asking for an audience suggestion, perhaps a location or a starting line of dialogue, two performers begin to improvise a scene. The actors accompany their dialog with exaggerated gestures and broad physical movements. The audience is instructed to shout 'freeze' whenever they think the actors are in interesting physical positions.

Immediately, the actors must 'freeze' themselves in position. A third actor then walks up to these two and taps one of them on the shoulder. The tapped actor leaves the stage, and the new actor must take his place, in the same position, and then begin a completely different scene with her first line of dialogue, playing on the ambiguities inherent in the physical relationship of the frozen actors.

A second style of performance is referred to as *long-form improv*. The ensemble asks for an audience suggestion, and then begins to improvise a one-act play which typically lasts for 30 minutes without interruption. These performances often are so good that many audience members assume a script is being followed. Yet this is never the case with authentic improv groups. The actors work very hard to avoid repeating even brief segments of a performance from a prior night. Long-form improv is less focused on comedy than are game performances, instead focusing on character and plot development.

Using Improvisation to Develop Scripts

Many directors and playwrights have begun to use ensemble improvisation in their rehearsals, as a way of collaboratively developing new script ideas. Their belief is that by freeing the natural creativity of the actors, a more believable drama can result. They also believe that the 'group mind' is capable of creative innovations that may be more inspired than even the most creative playwright's imagination.

There are two parallel traditions. In Britain, the director Mike Leigh has been using improvisation to develop plays since the mid-1960s. He later shifted to movie producing, and his innovative technique has led to several award-winning and popular movies. For example, his 1996 film 'Secrets and Lies' won the Best Director award at the Cannes film festival.

In 1959, The Second City theater formed in Chicago, and from the beginning they used improvisation during rehearsal to develop their comedy scripts. Although this group originated live improvisation, today their shows consist almost exclusively of scripted sketch comedy. However, they continue to teach and use improvisation as a technique for developing comedy scripts.

Conclusion

In conclusion, improvisation has always been an important component of theater performance. In a preliterate era, in the early roots of European theater, improvisation was a necessary skill for any performer. And since Stanislavsky and Copeau transformed modern theater, improvisation has become more and more central to theater training and performance. In historical perspective, the last few centuries of European theater have been perhaps the least improvised theater performances that any society has ever created.

Musical Improvisation

For most of history and in all cultures, musical performance has been improvised. The style of musical performance that has been predominant in the West for several centuries – European art music like the symphony, which is elaborately

scored by a composer and then performed by noncomposing musicians – is found in only a few cultures. A partial list of musical traditions in which improvisation is a key element would include, at a minimum, many genres of Indian music, the Arabic *maqam*, the Persian *dastgah*, African drum ensembles, Indonesian gamelan, flamenco, European baroque and organ music, American jazz and rock, and folk musics throughout Europe. In fact, almost all of the world musics that have been documented by ethnomusicologists and folklore researchers contain elements of improvisation. Nonetheless, most of Western musicology has focused on composition and written scores, and performance as a whole has been neglected.

Certain stereotypes follow from this bias toward composition: improvisation is spontaneous, primitive, and natural; composition is calculated, sophisticated, and artificial. For example, a common misconception about improvisation is that the performers are playing without any preparation. But there is always some musical structure, and ‘improvisation’ can refer to many different types of music, ranging from relative freedom to relative fixity. For example, many people think that jazz musicians simply play whatever comes into their heads, in contrast to the years of training and practice that classical musicians go through. Recent research, by psychologists and musicologists both, has demonstrated what jazz musicians have known all along: playing jazz well takes a lifetime of learning, and requires discipline, rehearsal, and preparation.

Only a few cultures have the ‘composer – score – performer’ division found in Western music. A relatively small percentage of musical traditions use any notational system. Even in musical traditions that have notational systems, the written notations are often only rough guidelines for a performance, with the expectation that a trained performer will improvise on the basic form of the piece. And in many musical traditions, these notations are not composed by anyone – they are transcriptions of traditional pieces that have been performed for generations.

Even early European composers did not have to write down every note, because they could assume that all performers were talented improvisers. Improvisation flourished in the music of the Baroque period. For example, most Baroque scores used a partially improvised system known as *basso continuo*, with a notated bass line and chords. The keyboard player was expected to use this shorthand notation to improvise the accompaniment. Along with this improvised accompaniment, the solo instrument that performed the melody was also expected to employ extensive variation and ornamentation of the written score. Even after the Baroque period, improvisation survived in the *cadenza*, a short section at the end of a movement where the composer would indicate that the performer should improvise. This provided the performer with an opportunity to demonstrate virtuosity. Improvisational and compositional creativity often went together – many famous European composers were also talented improvisers, including Mozart, Bach, Handel, and Beethoven.

Musicologists distinguish between two types of improvisation. The first is *paraphrase improvisation*, the ornamental variation of a written melody, such that the melody remains recognizable. The performer is allowed only minor *embellishments* on a standard

melody, and the variations that are allowed are limited in number and must be placed in certain standard parts of the melody. An example of improvised embellishment is the performance of the melody of a Baroque composition, where the performer was expected to vary and embellish the written melody.

In paraphrase improvisation, we often say that the performer is *improvising on* the basic song. Although the song remains recognizable, each performance is clearly unique and different. But it turns out that not all cultures share this idea of improvisation; in some traditions that use extensive embellishment that we would call paraphrase improvisation, musicians of that tradition feel that they are performing the ‘same song’ each time, even though tape recordings clearly show the differences. The ethnomusicologist Bruno Nettl wrote about a Persian *dastgah* performer, who was asked to comment on the differences between two performances of the same *dastgah*. He denied there was a difference. When the researcher played the two tapes for him, pointing out the differences, the musician admitted the differences, but claimed they were not significant – that the essence of the song was the same. It seems that different musical traditions have different concepts of ‘sameness.’ These differences could be related to musical literacy – with our notational system, we believe that ‘the same’ means note-for-note verbatim.

In the second type of improvisation, *motivic improvisation*, the musicians arrive at the performance with a repertory of patterns – called *licks* or *motifs* – stock phrases that the musicians then combine and draw on in each of their song performances. The set of patterns can be specified by the musical tradition, or may be the shared repertory of a single group or a single musician. For example, the jazz saxophonist Charlie Parker created his own repertory of about 100 motifs, each of them between four and ten notes in length. In Javanese *gamelan*, a much smaller set of motifs is specified by the musical tradition, and the same patterns are used by many different groups.

In motivic improvisation, the creative challenge for the performer is to artfully weave together the motifs, molding them into a coherent whole. Different traditions vary in the rules for combining motifs, and in the degree of melodic creativity and variation that performers can use to connect motifs. Charlie Parker typically improvised completely new melodic material in between his standard motifs; the Javanese *gamelan* performer is not permitted to insert any new material, but must use only the motifs specified by the tradition.

Within a culture’s musical tradition, the motifs and their style of combination tend to be similar in both composed and improvised performance. Typically, the set of motifs used in a culture’s improvised performances is less extensive than that same culture’s composed music.

In the United States today, musical improvisation is almost exclusively associated with blues and its descendants, jazz and rock. These are all examples of motivic improvisation. American jazz is one of the most highly developed genres of improvisation; musicians must go through years of intensive training and apprenticeship. Many do not reach their peak until middle age, with decades of performing experience behind them. Jazz requires of the performer a deep knowledge of complex harmonic structures, and a profound familiarity with the large body of *standards* – pieces that have been played by jazz

bands for decades. Standards are typically based on the 32-bar pop song, with four subsections of 8 bars each. Usually one or two of the 8-bar sections is repeated, resulting in song forms such as 'aaba,' a song where the first 8 bars are the same as the second and fourth 8 bars. A standard is outlined on a *lead sheet*, a shorthand version of the song, with only the melody and the chord changes written. None of the musicians' parts are notated explicitly; all of the musicians have to improvise their own parts, around the outline that is represented by the lead sheet. After playing through the verse and chorus once or twice, the band then moves into the improvisational portion of the performance, taking turns soloing over the basic song form. Although these ensemble improvisations can diverge dramatically from the original melody, all of the players in a virtuoso ensemble remain connected to the basic outline of the song.

There are other ways that preparation helps to structure a jazz performance. Most jazz performers use private rehearsals as an opportunity to develop *licks*, personal motifs that can be inserted into a solo for a wide range of different songs. Still, the choice of when to use one of these motifs, and how to weave these fragments with completely original melodic lines, is made on the spot. In group rehearsals, jazz groups often work out ensemble parts that can be played by the entire band at the end of a solo. If listeners have never heard the musician or the band before, they will generally not be able to detect which portions of the song are completely new that night, and which portions have been rehearsed or played before.

These examples reveal an important property of all musical improvisation: no performer ever makes up everything from scratch every time. There is a constant balance between preparation, tradition, and spontaneous creativity. No matter how spontaneous it sounds, there is always some structure that holds the performance together and guides the musicians. The completely spontaneous creation of new forms through free improvisation, without any preexisting framework, is quite rare in jazz and worldwide. Even the least-structured genre of jazz, called *free jazz*, often depends on themes, motifs, and other prearranged schemes such as the sequence of soloists.

Anthropologists have studied performance genres from around the world, and have found that there is no sharp line between completely scripted performance and completely free improvisation. Even cultures that have no notation system for music often have multiple genres of performance, each defined by style, rhythm, and melodic regularities. Most cultures have genres that are quite rigid, and are supposed to be performed essentially the same way each time, as well as other genres that are extremely open to improvisational creativity, even demanding improvisation from the performers. Cultures with a range of genres include the Plains Indians, various Eskimo tribes, and Yemeni Bedouins. In these cultures, musicians and nonmusicians alike are quite aware of the different types of creativity required in each genre. The more structured genres generally require more preparation and memorization; the more improvised ones require more spontaneous skill. The worldwide existence of highly structured musical genres suggests that 'composed' songs predated the first invention of written notation, although the origin of these traditional songs will never be known.

Jazz demonstrates almost all of the characteristics of improvisation. First, it depends on a complex balance of structure and free improvisation. Second, jazz is an ensemble art form. Perhaps the defining feature of jazz is the musical conversation on stage. Each musician must listen intensely to the other members of the band, both to coordinate with them, but also to draw inspiration from their last melodic phrase or rhythmic pattern, and to incorporate those musical statements into their own evolving part. In the best jazz performances, this conversation results in a constant give and take between the musicians. A collaborative performance emerges from the improvisations of all of the musicians working together, a performance that no one musician could have controlled or predicted.

Summary

Improvisation is present in all creativity. For example, a painter is constantly responding to his canvas and oils as he is painting. More importantly, each step of the painting changes the artist's conception of what he is doing – the first part of a painting often leads to a new insight about what to do next. Fiction writers are constantly interacting with the story as they write. A character or a plot line frequently emerges from the pen unexpectedly, and an experienced writer will respond and follow that new thread, in an essentially improvisational fashion. Most television comedy writing is collaborative and improvisational, with plot twists and bits of dialogue emerging during discussions with a writing team.

Improvisation is most essential in performance creativity, because unlike the painter or the writer, performers do not have the opportunity to revise their work. Where the improvisations of the painter can be painted over or discarded, and the writer has the power of a word processor to generate the next draft, the improvisations that occur on stage are exposed to the audience. As a result, the audience observes the creative process in action, sharing in every unexpected inspiration, but also in those disappointing attempts that fail. Even the most famous artists often destroy or paint over a significant number of their canvases, but these aborted attempts are generally lost to history, and not available for study. Improvisational performance is the creative process made visible, and as such it can teach us about the creative process in general.

The collaborative nature of improvisational performance also makes it a promising field of study for creativity researchers, because collaboration is important in most creative domains. In a biographical and interview study of creative partnerships, Vera John-Steiner demonstrated the ways that collaboration enhanced creativity, in fields as different as physics, writing, and dance. Michael Farrell demonstrated the important role played by creative circles in many artistic fields, including nineteenth century French impressionists, the Fugitive poets, and the Inklings, the British group that included novelists J. R. R. Tolkien and C. S. Lewis. Keith Sawyer demonstrated the improvisational nature of the collaborations behind many business, scientific, and technological innovations. These collaborations range from the group work that goes on in the laboratory to informal conversations over late-night coffee.

In business teams, innovation often emerges from collaborations that are essentially improvisational – in that the team does not know in advance where their creative discussions will lead. Gay Lemons studied seven individuals who had used improvisational techniques in business policy, early childhood education, jazz and dance, as well as improv theater. She found several central elements of improvisation across these domains that paralleled creative thinking more generally: communication, teamwork, emotional expression, challenge, safety, self-actualization, and joy. The creative interactions of a jazz or theater group are much easier to study than many of these other collaborations, since the analyst can hear and transcribe how this interaction affects each performer's creative process. Studying improvisational performance could potentially help creativity researchers better understand all group collaborations.

Modern European performance traditions have been the least receptive to improvisation of all the world's cultures, and this bias against improvisation is found in both the theater and musical communities. Improvisation has often been considered to be a less refined, 'popular' or 'folk' genre, and all of these terms tend to devalue improvisational creativity, relative to composed or scripted performance. Because most creativity researchers are also European, they have tended to focus on these more highly valued performance genres. As anthropologists, ethnomusicologists, and cross-cultural researchers begin to join in the study of creativity around the world, improvisation will become an increasingly important part of the field of creativity research.

Glossary

Fixation A persistent block to memory or problem solving.

Illumination A sudden unexpected insight into a problem solution.

Implicit Without conscious awareness.

Incubation A temporary break from creative problem solving that can lead to insight.

Insight A deep understanding that sometimes occurs all at once.

Mental set An approach to solving a problem that causes fixation.

Set-breaking Discarding a fixating mental set, using a new approach.

Historic Cases of Incubation

Of the many celebrated anecdotes that describe historically important ideas that appear to have been the result of incubation, it is sometimes difficult to separate fact from fiction. Nonetheless, there is an interesting consistency among these stories, threads, or elements that resonate with commonplace experiences of ideas that seem to flash spontaneously into mind, unheralded by a succession of incremental steps, and that seem to occur outside of the typical workplace. For example, there is the story of Archimedes, a great mathematician, who was trying to determine the volume of a highly irregular solid, namely, the crown of his cousin, King Hiero of Syracuse. Archimedes began as most of us might, trying to reduce the volume into set of regular solids, such as sphere or rectangular block, but after many long and fruitless hours, he found that task to be impossible. Importuned by his friends to go to the baths, he went to the public baths, leaving the problem behind – or so he may have thought. As he lowered himself into the bath water, Archimedes realized that the water his body displaced was equal to the volume of his body; therefore, the crown's volume could be determined by measuring the volume of water it displaces when submerged – the displacement principle. Archimedes is said to have raced through the streets when he realized his discovery, naked from the bath, shouting, "Eureka! I have found it!"

Henri Poincaré, the brilliant polymath who made important contributions to mathematics and physics, and whose work served as the foundation for the theory of relativity and chaos theory, had at one time been working on a problem dealing with Fuchsian functions. At an impasse for many days, Poincaré was stepping onto a bus on a vacation when he suddenly realized that these functions were the same as another set of transformations in non-Euclidean geometry, an insight that allowed him to solve the problem that had him stumped. Once again, it is noteworthy that the sudden unexpected insight did not occur when Poincaré was at work on the problem, but rather occurred when he was away from the task. This is a hallmark of incubation effects. Other famous historic cases of incubation effects include Kekulé, whose insight about the ring-like structure of benzene supposedly came while he was dozing

before a fireplace, Nobel Laureate Kary Mullis, whose insight about the polymerase chain reaction (PCR), a method for replicating and amplifying DNA, came to him as he was driving along a highway one evening, and NASA engineer James Crocker, whose insight about how a spacewalking astronaut could repair the Hubble Space Telescope occurred while he was taking a shower during a break. These historically significant anecdotes, and many others, serve as an important backdrop for the understanding of this mysterious phenomenon, and they may provide important clues as to the causes of incubation.

Mundane Incubation

Because of the impressive nature of historic cases of unexpected illumination, or incubation effects, people usually associate the phenomenon of incubation with insights of larger-than-life qualities. It doesn't take a lot of self-monitoring, however, to begin noticing cases of incubation effects in everyday life. Mundane types of problems, whether they deal with one's home, relationships, work, or recreation are often facilitated by taking a break from the problem, especially if solutions to these everyday problems are not found during one's preliminary attempts to solve the problems.

Theories of Incubation

Because people have recognized their own unexpected moments of inspiration throughout history, there has been a historical progression of explanations of incubation effects [Table 1](#). Since classical times, the notion became popular that magical spirits called the *Muses* visited individuals unpredictably, through their minds, provoking unexpected inspirations for amazing and new creative ideas. These inspirational Muses, conceived as sisters, were entities external to the people visited by these magical beings. A genius, according to this view, was not someone with a personally powerful intellect, but rather someone with the luck to have a Muse who lived close by.

As knowledge supplanted magical explanations, the notion of an unpredictable and inexplicable inspirational power

Table 1 Theories of incubation effects

Conscious Work	Intermittent conscious work during the incubation period.
Recovery from Fatigue	Recovery from fatigue built up during the preparation period of problem solving.
Forgetting Inappropriate Mental Sets	Inappropriate initial strategies and responses are forgotten over time or with changes in one's mental set.
Remote Association	Unusual responses emerge because common responses have been exhausted.
Opportunistic Assimilation	Remaining sensitive to information related to unsolved problems, one assimilates chance environmental events into problem solving during the incubation period.
Unconscious Work	Associations made among ideas in one's unconscious or recognized in spontaneous environmental events.

shifted from something external to an internal ability of individuals. A creative genius was a rare individual with inexplicable mental powers. Most people believed, and many continue to believe that creative genius reflects a special personal mental power, an incomprehensible ability, and probably not subject to scientific examination.

Changes in this view can be traced to a scientific description of the process of creative problem solving by Wallas in 1926. According to Wallas, the process of solving creative problems began with *preparation* (materials, knowledge, and information seemingly relevant to the problem are fore-grounded, and common approaches and solutions are examined), followed by *incubation* (following an impasse, or fixation, the problem is put aside), then *illumination* (a sudden inspiration or insight, the 'aha' experience), and finally, *verification* (checking the efficacy of the insight). For the first time, a logical sequence of cognitive states and operations, rather than an inexplicable magical force, was used to describe the experience of unexpectedly realizing the solution to a problem. On the one hand, this list of problem solving stages was an important step forward in terms of explaining this mysterious phenomenon. On the other hand, the term was not clearly explained, and the use of the expression *incubation* has been a drawback in terms of understanding the phenomenon.

Unconscious Work

The very term *incubation* implies both a phenomenon that people experience, and a mechanism for what causes the observed experience. This is an unfortunate conflation because, although there is ample evidence that the phenomenon actually occurs, there is little or no evidence for the mechanism that many people suppose is the cause of incubation effects. *Incubation* refers to an artificial means of supporting the development of a fragile developing system, such as the development of an infant born before reaching full term, or an egg after being laid (e.g., by a hen) before hatching. When an egg farmer places a freshly laid egg in an incubator, the unseen insides develop, bit by bit, out of sight, until at long last, miraculously, a live chick emerges where once had been only albumen and a yolk. This unseen development has served as an analogy for the notion that unconscious processes in the mind develop insightful ideas bit by bit, out of sight of the conscious

mind, until at long last, miraculously, an insight emerges into consciousness. The analogy is a compelling one; unfortunately, there is no scientific evidence that unconscious cognitive processes autonomously put together the necessary steps for the emergence of an insightful idea.

Opportunistic Assimilation

The *opportunistic assimilation* hypothesis is, in part, a variation of the *unconscious work* explanation of incubation effects. This explanation has multiple components. First, it states that when someone has repeatedly tried to solve a problem, but experienced repeated failures, then that person's cognitive representation of the problem becomes *sensitized* to stimuli in the environment that are related to that unsolved problem. That is, the unsolved problem gathers enough mental energy that, although it is not activated enough to be consciously on one's mind, it is just barely below the threshold of conscious awareness. This sensitization is the result of emotional experiences associated with repeated failures, such as frustration or desire. The next component of this explanation is the random or serendipitous encounter one has with a stimulus in the environment that is related to the eventual solution to the unsolved problem. When, by blind luck, one stumbles across a related stimulus, it triggers activation of the sensitized problem, bringing it to conscious awareness. Now, when the relevant stimulus is apprehended and considered in association with the unsolved problem, it can be used as a helpful hint that provides insight into a possible solution to the problem. Thus, one can opportunistically assimilate this serendipitously encountered hint with the unsolved problem, yielding a novel solution to the problem.

Conscious Work

Another explanation of incubation effects is the *conscious work* hypothesis. This rather mundane, yet plausible idea is that people spend periods of time consciously working on unsolved problems, yet people forget those episodes of work, even though the progress on the problem has advanced. Eventually, enough piecemeal progress on the problem is made that a final step brings one to the solution. Because the previous episodes of conscious work are forgotten, realization of the solution comes as a surprise, and the problem solver may attribute their progress to unconscious processes. This type of explanation is referred to as *incremental*, because progress toward the solution is made in discrete increments or steps.

Recovery from Fatigue

A different explanation of incubation effects is the *recovery from fatigue* theory. This rather straightforward idea states that when people are fatigued, their tired minds are not up to the task of solving a difficult problem. After a break, they are mentally refreshed, and better able to solve difficult problems. This clear explanation has some support; clearly refreshed minds will be better able than tired ones to solve difficult problems. On the other hand, many experiments have controlled for mental fatigue, and have shown that neither fatigue, nor relief from fatigue are necessary for incubation effects to occur.

Forgetting Fixation (also, Set-Breaking)

The *forgetting fixation* theory of incubation effects, also known as the *set-breaking* theory, takes a quite different approach from most explanations of incubation. Whereas most theories focus on what processes can add to one's progress and bring a problem solver closer to a solution, the forgetting fixation theory focuses on how a problem solver can disengage from counterproductive activities. Forgetting fixation is a type of creative destruction; that is, this theory posits that for incubation to help, one must destroy or abandon work on unproductive ideas. This explanation states that incubation periods do not really have the effect of moving the problem solver in the right direction; rather, such breaks allow the problem solver to stop moving in the wrong direction.

Fixation refers to a block or impediment to successful problem solving, usually because one is stuck on inappropriate ideas or problem solving approaches that are doomed to fail. *Set* refers to a readiness or preparedness to do something, as in the phrase 'ready, set, go!' One can be set to remember an episode from one's past, set to perceive an ambiguous picture in a certain way, or set to solve a problem with a particular mental strategy. The last of these has been referred to as a *mental set*, such as a series of mathematical operations for solving a certain type of problem. A mental set can be very useful and efficient when one is solving many problems that can be solved with the same set of operations; in such circumstances, one can mindlessly reapply the same formula, again and again, using little mental effort. The upside of mental sets is that it is economical in terms of mental resources, freeing such resources to be used on activities other than solving repetitive problems. The downside of using mental sets is that they can prevent people from seeing more elegant solutions to problems, and worse, their mindless and automatic use can prevent people from solving problems that require creative solutions.

The forgetting fixation theory attributes incubation effects to cases in which time away from unsolved problems allows people to break out of fixating mental sets; hence, the term *set-breaking*. A mental set is a type of cognitive structure, consisting of a collection of operations that are automatically reapplied to new problems. This automatic engagement of mental operations is referred to by cognitive psychologists as *implicit*, which means a cognitive process that occurs without conscious awareness, such as a habit or a skill that has been acquired through practice. The implicit use of a mental set can occur because the set was used recently, frequently, and/or if the set was previously associated with the same context in which a problem occurs. If the implicit use of a mental set is caused by recent use of that set, then time away from the problem may help one forget that set of mental operations. If the engagement of a mental set is due to its association with a particular context, then changing contexts might likewise facilitate forgetting to use the fixating mental set. In either case, time away from a fixated problem, particularly if one shifts contexts, might lead to an incubation effect by helping the problem solver forget and break out of the fixating mental set.

When simplified, the logic of the forgetting fixation explanation is very compelling. A problem can be classified as one of three types: (1) a problem can be immediately solved by the

problem solver; (2) A problem can never be solved by the problem solver; or (3) a problem potentially can be solved, but it cannot be immediately solved. Only problems of the third type are candidates for incubation effects. Therefore, one might ask what makes a problem of the third type difficult or impossible to solve in one's initial attempts? A likely answer is *fixation*, that is, a cognitive impediment to successful completion of a task. Therefore, forgetting fixation, or at least temporarily keeping incorrect answers and inappropriate approaches out of mind, can cause an incubation effect, facilitating resolution of unsolved problems by escaping from counterproductive efforts.

Empirical Research on Incubation Effects

For decades, many popular psychology books, as well as introductory psychology textbooks cited the dissertation experiments of Silveira in 1971 as evidence that incubation is a real phenomenon. Few of these references, however, noted that only one of Silveira's two reported experiments found a reliable effect of incubation, and that experiment was never replicated by another scientific study. When Olton reviewed all of the published experiments that studied incubation in 1979, he found no reliable, replicated evidence of the effect, numerous failures to find incubation effects, and furthermore, Olton presented a new experiment that also failed to document an incubation effect. Thus, early attempts to study incubation effects scientifically were not particularly reliable, making the phenomenon seem more like a mythical fantasy than a real phenomenon.

Forgetting Fixation Research

The first replicated experimental findings of incubation effects to be published were reported by Smith and Blankenship in 1989, who used the forgetting fixation theory to guide their experimental methodology. These experiments, and many others to follow, found that if fixation is experimentally induced, then incubation periods reliably relieve this experimentally caused fixation (e.g., Kohn and Smith, 2009, 2010; Smith and Blankenship, 1989, 1991; Vul and Pashler, 2007). In these published experiments, fixation was induced before people had their initial attempts at problems. Typically, the experimental participants are presented with information that deceptively resembles problem solutions, but which are really wrong answers.

These scientific studies show that incubation effects are likely to occur for people who are fixated. That is, when problem solvers are stuck on wrong answers and inappropriate approaches, taking a break from the problem increases the likelihood that the solution will be discovered. On their own, problem solvers might find themselves fixated on inappropriate solutions to a problem. The key to these experimental studies of incubation, however, is to experimentally cause fixation. That way, it is much more certain that experimental participants will experience fixation. Following the experimental induction of fixation, we can be more certain that periods of incubation, where the problem is temporarily put aside, will help forgetting the initially induced fixation.

An example of forgetting fixation experiments from Smith and Blankenship in 1991 can help illustrate this experimental methodology. Smith and Blankenship showed their participants numerous Remote Associates Test (RAT) problems. Each problem consists of three words, such as *APPLE – HOUSE – FAMILY*. The problem can be solved by thinking of a single solution word that forms a common two-word phrase or a compound word when that solution word is combined with each of the three problem words. The solution to the example problem is *TREE*, which links to each of the three problem words: *APPLE–TREE*, *TREE–HOUSE*, and *FAMILY–TREE*. To induce fixation before participants saw this problem, they were shown inappropriate associates of the problem words, such as *APPLE–PIE*, *HOUSE–BOAT*, and *FAMILY–REUNION*. When participants first saw *APPLE–PIE*, *HOUSE–BOAT*, and *FAMILY–REUNION*, and then tried to solve the *APPLE – HOUSE – FAMILY* problem, they did poorly, indicating that induction of fixation with the inappropriate associates was successful. After this fixation was observed on participants' initial test of the RAT problem, a second opportunity to solve the problem was given. The second attempt was either immediately after the first attempt (the No Incubation treatment), or after 15 min had passed (the Incubation treatment). Smith and Blankenship found an incubation effect; the initially unsolved problem was more likely to be resolved after an incubation period, as compared to the No Incubation control condition. Importantly, this incubation effect was not found when there was not a fixation treatment before the first attempt. This study, and others (e.g., Kohn and Smith, 2009, 2010; Smith and Blankenship, 1989; Vul and Pashler, 2007) show that incubation effects can be scientifically demonstrated if fixation is initially induced.

The forgetting fixation theory has been supported by experimental research on incubation effects, not only in problem solving, but also in recovering blocked memories. For example, Smith and Vela showed in 1991 that when memories of a list of pictures has become blocked or fixated on one recall test, more initially blocked memories can be recovered on a second recall test if the second test follows an incubation interval. In another study, Choi and Smith showed in 2009 that if an initial attempt to remember a general knowledge question fails, and the participant feels as if the correct answer is on the tip of their tongue (referred to as a *tip-of-the-tongue* or *TOT* state), then the answer is more likely to be accurately recalled if a subsequent recall attempt is made not immediately, but rather after an incubation period. Finally, Leynes, Rass and Landau showed in 2008 that a powerful implicit or unconscious memory blocking effect (e.g., Smith and Tindell, 1997) disappeared after an incubation period of 72 hours. These memory experiments provide further support for the forgetting fixation hypothesis of incubation effects.

Opportunistic Assimilation Research

The *opportunistic assimilation* theory of incubation effects focuses on taking advantage of stimuli that one encounters some time after putting aside an initially unsolved problem. This theory states that when people must postpone goals of solving unsolved problems, or remembering things they could not initially recall, they form a plan to be sensitive to anything they later encounter that might be related to those postponed

goals. The key to this opportunistic notion is that one must be prepared to notice things encountered by chance that might be useful in terms of fulfilling postponed goals. For example, Patalano and Seifert showed in 1997 that when experimental participants were given the problem of finding a way to remove a ring stuck on one's finger, and given the hint that Vaseline might be useful for the problem, they were especially likely to notice an incidental mention of Vaseline stored under the sink.

Interestingly, these participants were not very likely to notice other things that might solve the problem, such as soap or butter, which can also act as lubricants. In other experiments, however, when participants were given the 'Vaseline' hint, they also received the hint about the general use of the Vaseline, namely, to serve as a lubricant. Given this more abstract hint, participants were likely to notice the mention not only of the specific lubricant, Vaseline, but they also noticed other lubricants, such as butter (Seifert and Patalano, 2001). These experimental studies show that when problem solvers are prepared to notice specific things needed for solving problems, they may be limited to those specific objects, but when they are sensitized to notice a more general category of needed objects, then they are more likely to benefit from unanticipated stimuli that are serendipitously encountered. Importantly, this sort of *prepared mind* may benefit from chance encountered things even after an initially unsolved problem has been put aside, thereby triggering an incubation effect.

Principles of Incubation

It is clearly true that incubation effects are *multiply caused*. That means that there are many causes of incubation effects, and furthermore, that different cases of incubation effects occur for different reasons. Scientific studies show clearly that incubation periods can allow initial fixation to be forgotten, or escaped. Other experimental studies show that when people are frustrated in their preliminary attempts to solve problems, they remain sensitive to stimuli related to the problem, and serendipitously encountered hints can trigger incubation effects. Furthermore, recovering from mental fatigue after a rest can cause incubation, and conscious work that is forgotten may appear to cause incubation effects. Finally, combinations of these factors are also likely the multiple causes of incubation effects that people experience.

Understanding incubation effects requires that we understand the fixating effect of mental sets. It is important to be able to recognize when one is fixated, because that is the time to put the problem aside, at least temporarily. By recognizing one's own fixation and taking a break, people might be able to stop blocking themselves. The absence of fixation, however, is not sufficient for successful incubation, even if it is necessary. Stopping one's counterproductive work is essential for incubation, but there remains the issue of which direction will lead to a solution. Although there is no clear answer to this question, it is nonetheless clear that stimuli that are related to the fixated problem can sometimes provide useful hints. Therefore, carrying your troubles around with you, especially in new contexts, can sometimes trigger new and useful ideas.

An important principle to keep in mind for understanding incubation effects has been referred to as TANSTAAFL, an

acronym that stands for *There Ain't No Such Thing As A Free Lunch*. There is a widespread notion that incubation effects are not the results of hard work; that is, the myth that incubation results from essentially effortless unconscious cognitive processes. Nothing could be further from the truth. Incubation requires hard work. First there must be the initial preparation, where the problem solver tries all of the solutions that are at hand. Then, one must recognize one's impasse, and put the problem out of mind, while paradoxically remaining sensitive to stimuli and ideas that might be related to the unsolved problem. Finally, the problem solver must maintain a prepared mind, considering newly encountered stimuli and ideas to see if they shed any new light upon the fixated problem. With luck, vigilance, and hard work, an incubation effect might be achieved.

Summary and Conclusions

Incubation is a phenomenon that definitely does exist, both in laboratory experiments, and in historic cases. There has never been any reliable evidence that autonomous unconscious processes cause incubation effects. Incubation is multiply caused; contributing factors include forgetting fixation, sensitization to hints in serendipitously encountered the environment, and sometimes repeated bouts of conscious work in contexts not associated with fixated approaches.

Innovation

M Mayfield, Texas A&M International University, Laredo, TX, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Actor network theory (ANT) A systems theory originally developed by Bruno Latour to explain how innovation occurs in scientific settings, and then later expanded to a more general systems theory. This theory posits that system elements only have meaning based on their purpose in a given system, and that all elements require equal study to understand how the system operates.

Creativity The generation and development of new useful ideas.

Innovation Creativity purposefully applied to solving a given problem. Such an application can be applying a

completely new idea to the given problem or applying an existing innovation in a new setting.

Levels of analysis A term denoting a study's focus on different societal groupings. The usual groupings in relation to innovation are individual, team, organizational, industrial, and societal.

Systems theory A holistic approach to understanding elements and their interrelationships. This method contrasts with other world views by positing that a given element can only be understood by examining the other factors that the element interacts with, and its larger environment.

Defining Innovation

Innovation, as with creativity, is a driving force of the twenty-first century. Increasingly the world economy is shaped and improved by individual and organizational innovations. With material production and service being continually reshaped by competitive forces, there is a constant need for new business methods and innovations. And the pressure for innovation extends beyond the business sphere into all arenas. New innovations are being used to improve social issues, medical technology, environmental problems, and many other aspects of modern life. The world is placing an increasing emphasis on understanding and promoting innovation. An indication of this importance is that by late 2009 there were over 11000 books and 180000 articles with innovation in their titles: publications from across all academic disciplines. However, this plurality of interest means that developing a consensus innovation definition is difficult, with each area (and often each writer) using a slightly different meaning.

However, a core innovation meaning has emerged: it is the purposeful realization of applied creativity. As such, innovation is a special type of creativity, and it is also the recognition of how to implement a creative idea to solve a concrete problem. Innovation is both contained within the larger construct of creativity and afforded a special place in the study of creativity as an entity that extends beyond creativity. Nevertheless, the dividing line between creativity and innovation will always be fuzzy – drawing a firm boundary between the two is difficult in any given situation. In order to reduce this ambiguity, the remainder of this section will provide an expanded examination of innovation's meaning and characteristics.

Innovation Characteristics

The major characteristic that gives innovation its unique characteristic in the field of creativity is that innovation is purposeful: the innovation fulfills a specific need. Where creativity can occur spontaneously and simply for the joy of being creative,

innovation achieves some end or solves some problem. Therefore, the first criteria in determining if a creative act can also be classified as an innovation is if it fulfills a need or improves a situation beyond the need to be creative. As such, innovation can only truly be recognized retroactively – a creative act that attempts to fulfill a need but does not do so is not an innovation. Also, innovation may occur either through a deliberate act or through serendipity. That is to say that the creative act may be undertaken to solve a specific problem beforehand, or it may be later recognized that the creative idea can be used to answer some existing dilemma. In either case an innovation occurs when the creative act is able to solve some problem because it can be used to fulfill a need.

An example of both characteristics occurred with Pfizer. Chemists were working with a chemical compound (Sildenafil) to treat angina. This treatment proved to be ineffective – thus it was not an innovation. However, it was discovered that this chemical was effective in treating male erectile dysfunction, and very successfully marketed as Viagra. Thus, the unexpected use of the drug lead to it becoming an innovation.

The second innovation characteristic is one that moves it beyond creativity: innovation is both the development of new ideas and the adoption of new ideas. Creativity is usually only considered to occur when a new idea is developed. This idea may (and usually is) based on existing ideas, but the idea must in some way be unique. However, innovation can occur when someone adopts an existing idea that is new to the person, organization, or society. Thus, a surgical technique's first use within a hospital is an innovation for that hospital, even if the technique has been used (even widely used) in other hospitals. It may seem that at some point such adoption must stop being considered an innovation – if you are the last person on earth to use sticky notes to keep reminders on, it hardly seems that doing so is an innovation. But such is not the case. When a person or organization applies an idea to a problem for the first time, innovation occurs for that entity. The idea adoption process and the outcomes from adopting the idea all remain virtually the same for the last adopter to implement the idea as the first adopter to implement the idea.

Thus for each adopter it is an innovation. Taking the narrower view that innovation only occurs the first time (or even the first few times) an idea is applied to a problem seems to be artificially and unnecessarily restrictive. With this characteristic, innovation incorporates the concepts of everyday creativity and garden variety creativity – where creativity is not confined to new, unique, and exceptional ideas.

Another reason for including existing idea adoption in innovation's definition is that it recognizes how innovation diffuses through the wider environment. This recognition plays two roles in understanding innovation. The first role is to better our discernment of how innovations are transmitted. Innovations travel through a network of adopters and observers. Without such a network, innovation cannot occur. (This idea will be expanded upon again later in this article.) The second role is to expand our understanding of how innovation can be viewed. It goes beyond the person (or persons) who developed the initial creative idea. It includes those who recognize the idea can be used to fulfill their own needs. This characteristic goes back to innovation's core definition of applying a creative idea to solve a problem. While duplicating an existing idea may not be creative, applying it to a problem you face (even if others have also applied it to the same problem that they face) can be considered to be an innovation. So switching to fluorescent light-bulbs in your house because you saw the energy savings from a neighbor's change would be considered an innovation.

Innovation Types

This innovation aspect raises the idea of different innovation types. One innovation type – the rarest – is an innovation completely new to the world: the creative idea had not been applied to the given issue in any way. However, more commonly, innovations are new to a specific group, but not completely new. In this situation others have previously applied the innovation, but the innovation can be considered to be new to another group. Such innovations can be when technology is transferred from one nation to another (as with Asian nations adopting US developed chip fabrication processes), to a new industry (the adoption of computer financial management from the banking sector to all other industries) or new to an organization or work group (such as when GM adopted Japanese quality management methods). All of these applications would be innovative for the new set of adopters, though the innovation could be long standing to other adopters.

As alluded to in the previous paragraph, innovation occurs at different levels of societal groupings; when describing or defining innovation, the level at which it occurs must be considered in the definition. The most commonly studied groupings in terms of innovation are the individual, team, organizational, industry, and societal levels. While there are differences in how innovation is developed, transmitted, adopted, and implemented at each of these levels, there are also many meaningful similarities across these levels. Therefore, it is useful to take a systems approach to innovation so that cross-level or homologous similarities can be discovered and understood by looking for repeating innovation patterns at each level. Along this multilevel approach, it is also important to understand that innovation is a system process rather than a stand-alone phenomenon.

By definition, innovation changes its surrounding environment (if only to solve the problem it is applied to). In changing the environment an innovation will spur new innovations: innovation is a process. Such environmental spurs can come from a change in an organization's own needs after the innovation, or from an organization's innovation creating a need for change in other organizations. A systems view of innovation gives insights into innovation's feedback loop property. Unfortunately, such a systems approach has largely been neglected in innovation writing, but more recent work has begun to explore the larger systems nature of innovation development and dissemination.

Innovation Defined

Based on this discussion, innovation can be defined by recognizing the following characteristics. It is the realization of a creative idea being applied to an existing problem. This application may be either of a new idea or the adoption of an existing idea. Innovation can be either completely new or new to the adopting entity. There are different societal groupings or levels at which innovation can occur, and there are similarities and differences in the adoption process across these levels. And finally, innovation must be viewed as a systems process where the creative idea is shaped by the environment, and the environment is changed by the innovation.

With this innovation definition established, the rest of the article will provide information on what factors affect innovation at different levels, the major innovation outcomes, more information on the systems approach to innovation, and a conclusion that will provide suggestions on our understanding of innovation's future.

Innovation Factors

To better understand innovation, it is useful to examine the factors that can promote or hinder innovation. While the phenomenon of innovation is still not completely understood, at this point there is much consensus about what factors should be studied, and even how these variables are expected to affect innovation. As stated earlier, most innovation factors fall into one of four categories based on its grouping focus or level of analysis. These levels are individual, team, organizational, industrial, and societal.

Levels of Innovation

In addition to studying a level by itself, there is also interest in how factors at one level affects innovation at another level. The study of factors in this manner can be either through an atomistic or hierarchical perspective. Under the atomistic perspective, factors are considered to be the building blocks of events at a higher levels of analysis. Thus, individual innovation propensity would be studied in terms of how it affects team innovation. The hierarchical perspective (the more common perspective) instead examines how a higher level's characteristics influences innovation at a lower level. Thus an organization's resources would affect a team's innovation output.

It is important to approach innovation at multiple levels for two reasons. First, there is good evidence that some innovation factors operate differently at different levels of analysis. Therefore, one should not simply apply (successful) innovation methods from the team level to an organizational or individual level. On the other hand, there are also many similarities between the innovation process at multiple levels. For example, available resources and communication between entities is necessary for successful innovation at all levels. By noting these similarities, one can become more aware of the innovation process, and develop new means to enhance innovation.

Individual Level Factors

While the individual perspective provides valuable insights into the innovation process, innovation is less of an individual phenomenon than creativity. Correspondingly, less research has been done at this level than the other levels. Innovation is an interactive phenomenon: it usually requires more than one person to occur. Thus the individual level seems to have had less interest for the researcher who studies innovation and the practitioner who must nurture innovation.

The individual level, though less well studied, is the base from which innovation arises. It is thus both the foundation for the atomistic perspective, and does not lend itself to a larger hierarchical analysis. From this level, individual factors include both elements that are inherent in the person and elements from the surrounding environment that affect a person's innovation. Individual factors that have been found to be related to individual innovation include cognitive ability, personality, mood states, motivation, and job characteristics.

Individual core characteristics and innovation

An individual's cognitive ability provides the foundation for his or her innovative capabilities. Such cognitive abilities include intelligence, perseverance, creative thinking ability, and even pattern recognition. Cognitive ability refers to the functioning usually considered to be a person's mental faculties. In general, the higher an individual's cognitive abilities, the more able that person is to develop innovations and implement innovations from other sources. Leonardo da Vinci and Michaelangelo are perhaps the exemplars of strong cognitive abilities being linked to great innovations.

People with certain personality types have also been found to be more innovative. Those with a more creative personality tend to be more innovative as well. Characteristics that predispose one to innovation include openness to new ideas, perseverance, self-confidence, tolerance of ambiguity, independence, and originality. There are also personality traits that reduce a person's propensity for innovation. These include authoritarianism and being rules oriented. Personality, like cognitive ability, is thought to be a relatively stable aspect of a person, and thus not very amenable to alteration. While there are ways to improve both aspects, intervention techniques are usually aimed at other individual level characteristics.

Individual state and job characteristics and innovation

Such characteristics include mood states, motivation, and job characteristics. These characteristics are highly interrelated in terms of innovation, and best discussed together. Mood states

are transient feelings a person has about his or her surroundings and circumstances. (While such mood states can persist for extended periods of time, they are far less fixed than an individual's personality.) More positive mood states are associated with higher levels of innovation. Motivations are the rewards that drive a person to act. For example, workers are more likely to be innovative if there is a quarterly award for innovative practices. In addition to such external rewards, people that have an internal motivation for success and have a high level of personal initiative are more likely to be innovative. Job characteristics are the work features and a person's perceptions of those work features that affect a worker. Job characteristics that are associated with higher innovation are high autonomy, support for innovation, moderate job demands, low job dissatisfaction, good communication channels, and leadership support and guidance.

The last factor, leadership support and guidance, needs to be discussed further. This individual level aspect is also a bridge between the individual level and the team level. While a leader's support for innovation will impact an individual's innovation, it will also have a similar effect on other team member's innovation, thus creating similarities between team members. The leader also acts as a bridge between team members and the larger system in which the individual and team are embedded. Such a function occurs when a leader directs a team to focus on developing strategically mandated projects, and when the leader requests needed resources from higher management. As such, leadership acts across the individual and team level.

Team Level Factors

In contrast to the individual level, the team level seems to be one of the more natural groupings for examining innovation. The richness inherent in this grouping occurs because innovations most often arise at this level – with teams being used to develop creative outflows into innovation specifics. As stated earlier, innovation most often occurs through the interactions between individuals rather than as an individual phenomenon. The factors that seem to be most relevant for innovation at the team level include team processes, climate, structure, input variables, member characteristics, and team leadership.

Team process variables and innovation

Team process variables have been found to have the strongest link to innovation. Teams that possess more appropriate processes show much higher innovation rates than those lacking such processes. Many of these processes are similar to the individual personality characteristics at the individual level. These processes include having support for innovation among team members, and being task oriented. Task orientation acts to focus worker creativity onto appropriate tasks, while team support acts through developing norms as well as a focusing role.

Team climate and innovation

Team climate – analogous to job characteristics or mood state at the individual level – is also positively related to innovation. The more positive a team's climate, the greater the likelihood for development and adoption of innovation. However, team climate goes beyond members feeling that the team is a good

work group to be in. Climate also incorporates how open the team is to new ideas, tolerance for conflict, innovation norms, and participation expectations. In short, team climate is the set of norms for team member work behaviors. When GM initially opened the Saturn auto manufacturing plant, much work was done to ensure positive team climates among the various work groups. This initial set-up proved successful in that Saturn vehicles consistently ranked high in quality and customer satisfaction – outcomes that can be partially attributed to work team supported innovation.

Team structure and innovation

Team structure is the specific flow and interactions that occur between team members. In general, greater flow and interactions between team members fosters increased innovation. It should be understood that team structure plays a greater role in the team innovation process than this simple statement makes apparent. Team structure shapes the types and methods of innovation that occurs in a team. It tends to remain stable despite turnover in team members. Team structure can be viewed as the skeleton on which other team processes are built. In order to substantially change innovative process within a team, great care must be made to change the team structure. The Firefox browser's success can be partially attributed to such a change. The browser improved markedly – both in terms of overall quality and new innovative features – only after team structure changed from a more top down, centrally controlled model at Netscape to the decentralized, developer and user controlled model now in place.

Team input variables and innovation

Team input variables are also important for team innovation, though these variables do not seem to be as strong as process variables. Such variables include available resources, information, and exposure to external ideas. While all of these factors are important to innovation, teams that have more positive levels of the preceding factors will tend to compensate for lower input variables, while it will be difficult to make up for a deficit in the other factors by simply increasing inputs. Many organizations have made the mistake of increasing inputs but not changing team process, climate, or structure. Usually, innovation increases will not be sufficient to offset the extra resources applied in the attempt to improve outcomes.

Other team characteristics and innovation

Other important factors include team member characteristics and team leadership. Team member characteristics are much the same as already covered under individual factors; with teams composed of more innovative team members having increased team innovation. In addition, there are benefits to be had from increased team diversity, and when members with minority positions are willing and able to voice their dissent. This process can be seen when teams select a Devil's Advocate to purposefully challenge dominant positions. In this situation, everyone must be more creative to support their positions, group think is less likely (which also promotes innovation), and new ideas can occur from the enforced examination of all ideas. Team leadership operates through two means. Leaders act to motivate and inspire team members, and leaders with a more participative style that are open to

team member ideas tend to have more innovative teams. Team leaders also provide a communication channel, access to outside resources, and appropriate direction for applying creativity to organizationally relevant issues. As such, leaders provide a linking pin role between the team and the organization in which the team forms a part of.

Organizational Level Factors

Organizational factors are among the most studied innovation elements. Part of the reason for this plethora of information is that organizational level innovations are the most visible. However, there is also a strong argument for this level being truly the most active of innovation levels. Going back to the article's innovation definition including adoption as well as development, one can see that organizations have many peers where innovation observations can be made, and then decisions about which ones to adopt can be judged against peer success. Regardless of the reasons, many organizational elements have been identified that are related to an organization's innovation, and these factors often include innovation adoption issues.

Highly related organizational characteristic

Some of the strongest organizational characteristics that improve innovation are increased specialization, external communication, functional differentiation, and technical knowledge resources. As can be seen, many of these factors are similar to team and individual level factors that promote innovation with knowledge, communication, and idea diversity appearing in some form at all levels. Similarly, centralization is one of the strongest organizational inhibitors of innovation. This characteristic also shows similarities to how authoritarian leadership can inhibit innovation at the team level, and rigidity of thinking can diminish it at the individual level. A common thread among these characteristics appears to be that the influx of new ideas coupled with the ability and opportunity to act on them promotes innovation at all levels. Such seems to have been the case with Japanese manufacturing firms after World War II. In this situation, the firms readily adopted new manufacturing ideas, and worked to train and empower employees to implement these ideas in novel ways to recover from wartime devastation.

Moderately related organizational characteristic

Organizational level characteristics that have shown more moderate relationships with innovation include administrative intensity (the amount of personnel devoted to accomplishing administrative work relative to the total workforce), and managerial attitude toward change. Perhaps most surprising is that professionalism, slack resources, and internal communication have generally been found to have only weak relationships with organizational innovation. Such findings are especially unexpected in terms of slack resources and internal communication. Prior thought – and findings at other levels of analysis – had generally indicated that increased resources and communication provided a good basis for increased innovation. While there is a positive relationship at the organizational level, the strength of these relationships is less than what is expected.

Other organizational characteristics

Other organizational factors that affect innovation include structure (with more flexible structures producing more innovation), strategy (with strategic alignment being important for successful innovation), market orientation (with more market oriented organizations being more likely to develop and adopt new innovations), resources devoted to innovation (in contrast to general slack resources), and culture (with more organic cultures being more innovative). Organizational factors that have been found to be unrelated to innovation include formalization, top managerial tenure, and vertical differentiation.

Organizational demographic variables and innovation

Firm size has been found to be related to innovation adoption. And since this organizational aspect has been discussed so vigorously, more attention needs to be devoted to it in this article. A long-standing debate has been if firms become more or less innovative with increased size. The argument for a positive relationship has been that larger firms have increasing resources to devote to innovation, and also face increased competition that requires more innovations. The counter argument is that increased size leads to greater wasted resources and increased administrative barriers to innovation adoption and implementation. While this issue is complex and fraught with many exceptions, in general, studies have shown that larger firms are more likely to generate more innovations. Apple, IBM, and Google all show this phenomenon, with each company being responsible for a vast number of innovations in the IT sector.

Larger firms are especially likely to adopt IT innovations, possibly because managers see IT technology as one way to cope with the increased administrative complexity brought about by increased firm size. Many organizations adopted the practice of having managers use pagers to contact them when needed regardless of their location. This practice evolved into using cell phones and e-mail for distributed communication methods. While these practices have created problems with work-family life balances, they have also been useful for increasing manager efficiency and accessibility.

An organization's life-cycle stage can also play an important role in how innovation is encouraged. Organizations in the earlier life-cycle stages are more open to a wide variety of innovative types, but generally have fewer resources to encourage such innovations. Organizations in the later life-cycle stages tend to encourage a narrower set of innovation types, but also have more resources available to devote to the implementation of these creative ideas.

Several other organizational characteristics have also been found to be related to innovation. Higher levels of the following organizational demographic characteristics have been found to be positively associated with greater innovation: firm age, complexity, capabilities, specialization, formalization, organizational resources, and interfunctional coordination. In addition, there are management characteristics that are positively associated with innovation: greater management training, more managers with professional degrees, and having an innovation champion. Organizational culture and orientation characteristics that have been found to specifically enhance innovation include the following: diversification (having workers with many different backgrounds and varied

workplace projects), clan culture (characterized by tight knit work relationships and high levels of positive workplace interactions), customer orientation, competitor orientation, and openness to change. Also, successful past innovations tend to promote future innovations, while network capability and team communication promote the diffusion and adoption of innovation.

Organizational moderator variables and innovation

Several important moderators have emerged that need to be considered. The type of organization has been shown to be a strong moderator of organizational innovation. These moderators do not simply alter the degree of innovation in an organization, but change the relationship between organizational characteristics and innovation. The most important organizational classification types include manufacturing versus service organization, and for-profit versus nonprofit organization.

In manufacturing organizations, innovation is enhanced through work standardization while increased direct supervision decreases innovation. In service firms, there is no link between these two variables and innovation. Similarly, formalization and centralization enhance innovation in for-profit organizations, but seem to have no effect in nonprofit organizations.

There is also evidence that organizational culture moderates the relationship between other organizational characteristics and innovation development and adoption. This moderator effect is in addition to the direct effect that an organization's culture can have on innovation. However, there is still much debate and study needed to fully realize how culture moderates these relationships. Still, highly creative organizations often take extra steps to maintain a creative culture. For example, the *Mad Magazine* publisher and editor William Gaines once took his entire staff to Puerto Rico to convince their one subscriber there to renew his subscription. While this trip was unlikely to have been directly cost effective, it was a way to keep up an atmosphere of creativity and innovation among his workers.

An innovation's characteristics also has an effect on how likely an organization is to adopt the innovation. Innovations that are more compatible with an organization's mission or existing product line are more likely to be adopted. Similarly, innovations that are expected to provide the organization with a relative advantage have a higher chance of adoption. Conversely, complex innovations are less likely to be adopted.

There are also many factors that, often unexpectedly, are not related to adoption rates. These factors include cost, trialability (how well an innovation can be used on a limited basis before full adoption), observability (how completely an innovation can be viewed before adoption), communicability (how easily an innovation can be described before adoption), divisibility (the ability to try small or limited parts of an innovation), profitability, and social approval (how well the innovation's adoption will be perceived by organizational members and external stakeholders).

Industry Level Factors

While there is obviously industry-wide development and adoption of new innovations, factors at this level have been less well studied than at the organizational or team levels. However,

there are some useful findings about what type of industries are more likely to use and rely on innovation for their operations. Factors that have emerged from these findings include industrial age, the industry's technological dependence, required infrastructure investment, and the industry's technological turbulence. These factors will be briefly outlined in the following subsections.

Industry age

Industrial age seems to be negatively related to innovation. New innovations are most prevalent near the beginning of an industry's creation and growth. While this observation seems to be relatively stable across a broad array of existing industries, the causes for this phenomenon are still unclear. One possibility is that most major innovations are only possible during the early stage of an industry. As the industry matures, the opportunities for discovering new innovations decreases. Similarly, as industries mature, existing organizations may invest more in infrastructure, and find it increasingly difficult to adopt new innovations when they become available. It is also possible that a feedback loop is at play. As fewer organizations adopt new innovations, there becomes less competitive pressure for other organizations to be innovative. As such, there would be an increasing decline in overall innovation.

Technological dependence

The more technologically dependent an industry is, the more likely that the industry will be more innovative. While there is a bit of circular reasoning in this observation (technologically dependent industries are more innovative, and industries whose firm's competitive success depends on innovation are more technologically dependent), the statement has a strong intuitive appeal. When industries grow and thrive based on their technological capabilities, firms in the industry must strive to find new ways to innovate. What may not be as obvious is that success can come from sharing innovations between competitors more than keeping these innovations secret. An example of this phenomenon is the computer industry which makes many technological advances available to all members. This sharing of innovation then allows for greater interoperability and standardization between different IT aspects, thus increasing the utility, demand, and growth of all components.

Infrastructure investment

Required infrastructure investment within an industry can be either positively or negatively related to industry innovation. Higher levels of required investment can hamper innovation by creating greater barriers to entry and change within the industry. Such barriers can make innovation more difficult, and thus favor organizations that do not innovate through being able to redirect their resources to other organizational operation areas. However, these required high investments can also lead to industry members developing innovations to lower the needed infrastructure costs, and allowing the early innovation adopters to reap high initial returns. Such events have happened during the 1970s when mini-mills were introduced by Japanese steel companies, and in the printing industry today which is outsourcing much of its physical printing to China at lowered cost.

Environmental turbulence

Organizational level innovation also has a weaker effect on firm performance in technologically turbulent environments than in calmer environments. While this observation could also appear under the innovation outcomes section, it is important to discuss it in this section for the possibilities it brings up. Turbulent environments may suppress this relationship because innovations have less chance to be successful when the environment is uncertain. It can be unclear how well an innovation will solve a problem when one is uncertain of what the problems are. However, turbulent environments may also force all competitors to be more innovative to cope. In turn, this higher level of innovation continually changes the industry's environment, thus reinforcing the environmental turbulence – an example of the feedback loop inherent in the innovation process.

Societal/Cultural Level Factors

At the highest level of analysis are societal or cultural factors that influence innovation. Less work, and thus diminished understanding, exists for factors at this level. This paucity of research might arise from the difficulty of comparing innovation factors across nations, as would be necessary for most research at this level. However, evidence does show that higher levels of competition, environmental turbulence, and urbanization all improve innovation. Similarly, higher unionization levels in a society has been found to reduce innovation. The number of patents granted within a society seem to have weak or mixed effects on innovation. Patents do not seem to be useful in predicting cross-national innovation, but this effect may be moderated by industry. Within the pharmaceutical industry the number of existing patents have been found to be positively related to innovation. In other industries patents seem to hinder innovation. The reason for this variance is unclear, but it appears that other industries use patents to create idea monopolies and barriers to innovation exchange. The pharmaceutical industry seems to have developed a system where patents provide clear information on drug creation so other firms can build new research on this work.

Fortunately, national culture factors are becoming more prominently studied, and there appears to be cultural differences that strongly affect innovation. Higher individualism, lower power distance (a view that there should be a certain level of equality between people in different work positions), and lower uncertainty avoidance (a greater willingness to take risks) are related to increased organizational innovation. The area of innovation transfer has also been studied internationally, though specific and stable findings about these factors has yet to emerge.

Innovation's Effects

Innovation is an interesting phenomenon in its own right, but most often the purpose of studying innovation is to try and improve some organizationally or societally desirable outcome. As such, there is much interest in the effect of higher levels of innovation. Most people agree that increased innovation is a desirable state of affairs at all levels, and for most all

affected parties. In some ways, this belief is almost a tautology. By definition innovation is an applied solution to some problem, therefore greater innovation should lead to improved outcomes. However, this belief has been confirmed by observations. While there exists much work on how innovation affects a broad range of life factors – such as quality of life, environmental shaping, and societal development – the most consistent findings have been in the area of organizational performance. As such, this section will focus on this outcome.

Performance and Innovation

Performance is perhaps the most highly studied innovation outcome, and findings have shown a strong link between the two across a wide swath of performance measures. At the firm level, higher levels of innovation increase financial performance, stock prices (for publicly traded corporations), and the perception of organizational performance. There is also evidence that innovation has a long lasting impact on firm performance, with greater innovation today leading to increased future performance.

This relationship is stronger when the innovations are more relevant to firm strategy. There may also be an increasing need for organizations to focus on product innovation rather than service innovation, as there seems to be a trend in diminishing returns between new service innovation and better firm performance. This trend may be because there is an increasing ease of other organizations observing and adopting similar service innovations, while there are legal and sometimes physical barriers to prevent such adoptions of new product innovations. There also seems to be a decreasing link between new-to-firm innovations and organizational performance. However, the link between new-to-market innovations still seems to be strong. This trend indicates that there may be increasing benefits for organizations to invest in research and development in attempts to bring out innovations ahead of competitors.

Innovation as a Systems Process

As has been discussed throughout this article, innovation depends on a larger system to occur and be transmitted to other entities. Therefore, innovation can only be fully understood in a systems context. Even more than creativity, innovation requires a network of elements to be successful, and these elements must also be included as part of the innovation process. While much progress has been made to place innovation in a systems context, most people continue to view innovation and innovation factors as stand-alone entities. Fortunately, a consensus is emerging concerning what elements should be included in our understanding of an innovation systems view.

The Environment–Innovation Interrelationship

The first part of this systems view is that an innovation and its environment are inextricably related. The environment will provide the impetus for an innovation, resources for developing innovations, and limit what innovations are possible at a

given time. In turn, innovations can change their environment through such means as altering the competitive landscape, shifting resource allocation and availability, and creating new innovation opportunities. Another generally agreed upon aspect of this system view is that innovation relies on some form of transmission channel in order to bring in new ideas, and transmit innovations to other system members.

Actor Network Theory and Innovation

One of the most advanced descriptions of innovation as a systems process has been developed by Bruno Latour in his actor network theory (or ANT for short). This theory was developed based on his observations of French science researchers and how they conducted their work. From his observations, he realized that innovation was embedded within a network of human and nonhuman participants that all must be considered to be part of an indivisible whole. He also posits that most system theories unnecessarily give human actors precedence in their system descriptions, and will under-rate the importance of nonhuman elements. For instance, scientific journals are often ignored in the examination of the innovation process. However, such journals are necessary for the researchers to both obtain information for their creative work, and to transmit their innovation to other parties.

Latour asserts that – in such a case – not only are journals necessary elements in the system, but the researchers would not be researchers without such mechanisms. All elements, therefore, must be considered simultaneously in the ANT framework. While the practical implications of the ANT system model have not fully been delineated, it holds great promise for better understanding how the innovation process works.

The Innovation Systems Model: Our Current Understanding

The development of a full innovation systems model is still in the early stages, but there has been more consensus on how an innovation process model can be viewed. The following is a brief outline of this model.

1. An environmental impetus for an innovation occurs. This impetus can be a change in the surrounding environment that presents a problem or opportunity, or simply the recognition of a gap between existing and desired conditions.
2. This impetus must find creative receptivity so that some actor within the system can become aware of the need and possibility of a creative development. There may also be a garbage can effect where an impetus triggers the use of an existing creative spark to fulfill the need.
3. The creative idea must be developed into an innovation, and this development has to be supported by the environment through available resources including support and materials.
4. The innovation must then be accepted by appropriate parties within the system (though innovations may lie dormant for extended periods of time).
5. The innovation will be diffused through a network, and adopted by appropriate parties. The party that originally

developed the innovation may see advantages to either keeping the innovation exclusive or allowing other parties to adopt the innovation. In turn, the other parties may seek to incorporate the innovation, neutralize the original parties ability to implement the innovation, or counter the innovation through some other innovation.

6. The new innovation will alter its environment, thus leading to the need for a new generation of innovations (either in response to environmental changes, or by freeing up resources to develop new innovations).

Conclusions

This entry has presented an overview of our current understanding of innovation, the innovation process, factors that promote or hinder innovation, and how innovations affect their environment. Innovation is a specific type of creativity: creativity that is applied to solving some given problem. Also, innovation cannot be viewed as an independent event. It is part of a larger system process that creates a feedback loop and the necessity of new generative innovations. Another important aspect to understanding innovation is that it occurs at different levels throughout society. Innovation at each of these levels has similarities and unique characteristics, but understanding innovative output and processes must take into consideration the level at which the innovation occurs.

With this recap, what can be understood about innovation in the twenty-first century? From this review there appears to be a few characteristics of innovation that are common at all levels. To promote innovation at all levels there must be resources made available specifically for developing innovation, innovation must be encouraged by the wider system, effective communication is necessary between appropriate parties, and there needs to be a strong leadership role to nurture innovation and provide a guiding vision to focus the innovation. Barriers to innovation at all levels appear to be inflexibility and a fear of change.

For organizations to successfully promote and develop innovations, there will have to be an alignment between the organization's goals and mission and its attempts to implement innovations. Such linkage has to be accomplished through individuals, and this requirement means a well developed and articulated human resources strategy and plan. While it can be easy to focus on the hardware aspect of innovative advancement, the human side is the true driver of the phenomenon.

There also seems to be a potential shift in the national sources of innovation. For most of the modern era, the western world has driven most large innovations with new forms of society, government, organizations, and industrial advancements. However, with the opening of the twenty-first century, there seems to be a shifting of innovation to the eastern world. With nations like China, Taiwan, and Japan devoting much of their national resources to education institutions and corporate research, many of the factors that promote innovation are being put in place in these nations. In contrast, the western nations seem to be more reluctant to place long-term investment in such projects. At this point it is unclear what the long-term behaviors of all parties

will be – the western world still has far more resources that can be placed into innovation promoting activities. Increased diversity in ideas can only be beneficial for all parties in terms of increasing innovation.

Perhaps the most basic observation is that innovation will continue to drive our civilization's growth and advancement for the foreseeable future, and the rate of innovation is expected to continue increasing. With this observation, however, it must be pointed out that not all innovations are beneficial for society, and that most all major innovations have unforeseen consequences that can create seriously detrimental outcomes. The innovation of using oil products as a fuel has allowed humanity to make tremendous strides forward. It would not be an exaggeration to say that this innovation has advanced our civilization more than most any other application of a creative idea. However, as this innovation has become more widespread, we are realizing that it also has serious negative effects on our environment, and that new innovations are necessary to counter these negative effects. What is less clear is what long-term effects these new innovations will have.

With this observation in mind, there is a need to place greater emphasis on both developing methods for examining possible consequences of innovations and the ethics of implementing innovations. While no perfect solution exists for determining unintended consequences from innovations, scenario planning as developed by Shell Oil provides a useful tool for this purpose. Similarly, Donella Meadows' Twelve Leverage Points model provides another way to predict the scope of effect an innovation might have. By using these tools we might be able to better understand the consequences of an innovation and determine what the ethical boundaries are of using or not using it.

Glossary

Illumination Conscious realization of how to solve a problem or how to understand the problem properly; usually quite sudden and emotional.

Incubation A stage of problem solving during which the conscious mind does not work on the problem; used to be accounted for in terms of implicit processing.

Problem A situation characterized by one's inability to find a way between the initial states of affairs (i.e., data) and the

desired state of affairs (i.e., goal, solution); one knows what is needed but does not know how to get it.

Problem representation The way people understand the main features of the problem, particularly what the difficulty comes from, and what the obstacles are to achieve the goal.

Restructuring Conversion of the previous problem representation into a new one.

Insight is a sudden realization of the essence of a complex, paradoxical, or not well-understood situation, particularly the essence of a problem at hand. Insight is not synonymous with working out a solution to the problem; rather, it consists in understanding the gist of the problem through discovering its hidden structure. In problem solving, insight usually occurs after the preparatory stage, often following an 'incubational break,' and results in deep understanding why the problem is 'problematic.' In other words, insight produces realization of what the difficulty comes from, what the obstacles are to a good solution, and why the previous attempts to solve the problem were futile. Insights like that may be false and misleading, if based on inappropriate or incomplete data, but nevertheless they produce the unique (sometimes deceptive) feeling of understanding the essence of the problem. Besides problem solving, insight occurs in learning, where it produces deep understanding of a difficult subject matter, and in reception of creativity, where it leads to the realization of what is the message of the creative artwork. A particular example of insightful reception of one's creativity is the act of understanding a joke. According to Arthur Koestler, every act of creation includes an element of beauty (ah!), an element of wisdom (aha!), and an element of humor (haha!). Although in particular cases these elements occur in specific proportions, it is always possible to investigate production and understanding of humor instead of studying the whole creativity. Analogically, it is possible to examine insightful problem solving in laboratory settings, with the use of relatively simple tasks, to replace studying deep insights in science or technology, providing that such simple tasks are good models of serious and difficult problems taking place in mature creativity.

The Nature of Insight

The Gestalt psychologists introduced the term insight at the beginning of the twentieth century. It was put forward in opposition to the trial-and-error account of learning and problem solving, a stance advocated by the behaviorists. According to Wolfgang Köhler, Kurt Koffka, and Max Wertheimer,

problem solving should not be described as a process of incremental increase of habit strength because people (and great apes as well) sometimes work on problems that are impossible to solve through continuous acquisition of learned skills. Such problems supposedly require fundamental change in the way they are perceived. Restructuring of problem perception occurs on the basis of already acquired knowledge but requires additional new elements and – this is particularly important – new arrangement of these elements. The problem before the solution is a 'bad' (i.e., incomplete or inelegant) figure, whereas after the solution it becomes a 'good' figure. In other words, problem solving is a process of conversion of a 'bad' figure into a 'good' figure through adding some lacking elements, along with rearrangement of all the elements of the problem (both 'old' and 'new') into a plausible structure.

Max Wertheimer described a little girl who was taught to estimate the area of a rectangle by counting the number of small squares into which the rectangle was divided. This counting-the-squares method was pretty successful in every instance of a rectangle but appeared inadequate in the case of a parallelogram. The girl was unable to find the area of a parallelogram until she realized a new possibility. She asked for scissors, immediately cut off the triangular part of the parallelogram, and put it at the appropriate place on the other side of the figure. In this way, she obtained a rectangle, whose area was easy to estimate with the already acquired method of square counting. This example epitomizes all-important aspects of insight: The 'old' solution does not work anymore. The impasse is therefore inevitable. After some break, a new solution appears, which is quite unexpected. The new solution consists in the use of old knowledge completed with new elements. And, most importantly, the new solution is based on the essential change of the problem perception.

Laboratory studies of insight cannot rely on realistic difficult tasks, like scientific problems; therefore, some relatively simple but tricky tasks are usually explored. For instance, a task may consist in deciphering the meaning of an expression, such as 'poPPd.' The expected answer to this rebus, 'two peas in a pod,' requires not only perfect knowledge of idiomatic English but also specific mindset and – maybe – an ability to read the

intentions of the experimenter. Insight tasks may be nonverbal as well, such as a series of various 'matchstick problems.' For example, a person may be asked to compose four unilateral triangles out of six matchsticks; the solution seems impossible until one realizes that he/she is supposed to build a pyramid. Or, a person may be asked to convert an equation expressed in Roman numerals, for example, $IV=III-I$, into the correct version using just one stick, that is, $IV-III=I$. Such tasks, though appealing to one's mental flexibility and the ability to overcome fixed mindsets, require some specific skills, like spatial imagination (pyramid) or knowledge of Roman numerals (equation). If so many factors count, validity (i.e., what is actually measured) and reliability (i.e., how well is it measured) of such tasks appears as serious methodological issues.

Stellan Ohlsson introduced a task that proved to be quite popular and useful in the studies on insight (Figure 1). It is a much more advanced and difficult version of the problem that was solved by the little girl, described by Max Wertheimer. The task is to find the sum of the areas of square ABCD and parallelogram EBGD, given that $AB=a$, and $AG=b$. We know very well that the area of a square is obtained by multiplication of the length of its two edges, which is easy. We also may remember that the area of a parallelogram is obtained through multiplication of the length of its base by the length of its height, but the latter value is not provided (the former is possible to deduce). However, the solution is immediately worked out as soon as one realizes that the needed sum of areas is obtained through moving the triangle DCE upwards (or the triangle ABG downwards), so as to compose two big triangles, and eventually one big rectangle, whose square is easily computed as a times b . Although this task requires basic mathematics, its difficulty results from the necessity in perceiving it in a new and unconventional way rather than from complex mathematical reasoning.

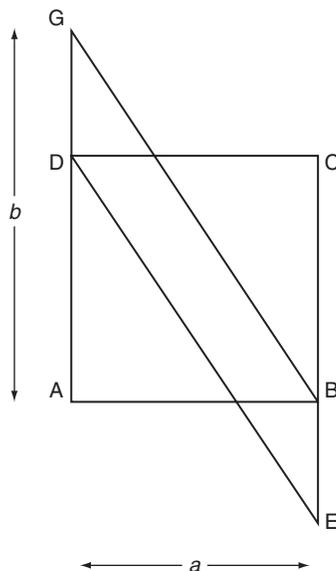

Figure 1 Given that the line $AB=a$ and the line $AG=b$, find the sum of areas of square ABCD and parallelogram EBGD (Ohlsson, 1984).

The Features of Insight

Suddenness

Insight is usually experienced as sudden and unexpected. Eminent creators, on the basis of their introspective analyses of the creative processes, often report these feelings. Introspection lacks objectivity, but if the phenomena under consideration are subjective by nature, it must not be ignored as a source of relevant data. The empirical psychology argues that similar phenomena take place in controlled experimental settings, too. Psychologists also try to answer the question why insight is experienced as sudden and unpredictable.

Investigations on suddenness are based on the technique called 'feeling of knowing.' People are presented with an intellectual problem and asked to judge their subjective feeling of being close to the solution. They may use a 1–10 point scale where '1' means 'I'm at the starting point' and '10' means, 'I know how to solve it.' It usually appears that this subjective feeling of knowing rises only 10–20 seconds before emergence of the actual solution. People are quite unable to discern any symptoms of the upcoming solution during the earlier stages of the process of thinking. It also appears that the feeling of knowing may rise quite evenly in the case of regular algebraic problems but not in the case of insight problems. The latter usually produce irregular curves of changes of the feeling of knowing (i.e., with many ups and downs). If the problem solver is eventually successful, the curve rises steeply during a few final judgments but not earlier. This pattern of relationships suggests that insightful problem solving typically results in a solution that is unpredictable for the problem solver, and the process of looking for solution is interpreted as 'catastrophic' or lacking continuity.

Malcolm Westcott demonstrated the phenomenon of discontinuity in the studies on 'intuitive leaps.' Participants were presented with a series of numbers ordered according to some principle, for example, 4–5–3–6–2–7–1–?. Their task was to decide which number is supposed to replace the question mark if the underlying principle is valid. Some people were ready to make a decision only after two or three elements of the series, whereas others needed more time for that. The former apparently made their choices on the basis of quick, spontaneous speculations, rather than elaborated deductions. In follow-up studies participants were encouraged to guess the elements of series as soon as possible. It appeared that those who were inclined to make such 'leaps' scored higher on the independently administered battery of insight problems. Therefore, such 'intuitive leaps' may be interpreted not only as an illustration of discontinuity in problem solving but also as a model of intuitive processes in high-level creativity.

Where does the subjective feeling of suddenness of insight comes from? According to Graham Wallas, the author of the 'theory of incubation,' suddenness of insight results from the unconscious nature of creative processes. If a creative idea is 'incubated' in the unconscious parts of the mind, its eventual appearance must be unpredictable and entirely unexpected for the consciousness. This theory, although very popular and influential, was questioned by the proponents of the so-called 'nothing special' approach. According to Robert Weisberg, creative processes do not differ in kind from less creative functions

of the mind. Particularly, they have nothing to do with unconscious 'incubation,' because they rely on the incremental process of accumulation of knowledge. The creative process supposedly consists of consecutive trial and errors, being usually very long, full of pauses, and tiresome. If a particular trial appears successful, a person may have an impression of unexpectedness of the creative idea. But this is just an illusion, coming from large number of previous unproductive attempts.

Incubational Break

Even though the theory of unconscious incubation is questioned for a lack of empirical evidence, there are good reasons to ask about possible benefits of breaks in the creative process. The occurrence of such breaks is unquestionable. For instance, Catherine Patrick observed painters during their work and concluded that the process of drawing a picture is discontinuous in nature. The artists usually start with an initial idea, which is seemingly abandoned and replaced by alternative options. However, the original idea tends to reappear from time to time, and the whole process of creation makes the impression of being abundant with breaks and pauses.

Five hypotheses have been formulated to explain the effect of incubational break.

1. The hypothesis of unconscious activity of the mind, although formulated more than 100 years ago, still has its proponents. If this stance makes any sense, an incubational break must be long enough in order to allow the unconscious mind to work out a tenable solution.
2. It is claimed that a break allows renewal of energetic resources because creative work may be prolonged and exhaustive (so-called 'fatigue-dissipation hypothesis'). This viewpoint is somewhat opposite to the unconscious thinking hypothesis, as it amounts to the conclusion that nothing particular happens during the break.
3. A break supposedly allows redirection of attention from futile ideas and misleading aspects of the problem perception to some new and more promising pieces of information. According to this explanation, people must change their activity during the break, possibly to something completely unrelated to the original problem, because otherwise the effect of attention redirection cannot be obtained.
4. A break probably leads to elimination of ineffective mindsets, false assumptions, and other symptoms of mental rigidity. If this hypothesis makes sense, it should not be important what type of activity takes places during the incubational break because its beneficial effects result from mere flow of time.
5. It is claimed that something particular must happen during the break, namely, a new piece of information is perceived which serves as a source of inspiration and therefore leads to a new and productive idea. For instance, a person reads relevant literature or discusses the problem with other people, and thanks to such events, assimilates new and productive pieces of knowledge. Sometimes the process of assimilation is subtle enough to prevent any conscious realization of the actual sources of inspiration. For instance, a person perceives an analogical solution in some area that is distant and seemingly irrelevant to their problem.

In such cases, inspiration works without conscious realization of the source of a new idea, although one's mind must be prepared for assimilation of relevant information.

Some of the above-sketched hypotheses have been verified experimentally. For instance, Roy Dreistadt demonstrated that short (eight minute) incubational breaks alone did not improve performance on an insight problem solving test but helped to assimilate pictorial analogies that were dispersed in the lab and served as 'hints' to the participants. People who saw these hints but had no opportunity to take a break obtained lower scores. These results favor the fifth hypothesis, according to which the break does not work as such but serves as an opportunity to assimilate some new relevant information. More recently, Eliaz Segal asked students participating in his study to solve the problem of the parallelogram (Figure 1). Participants were given a short (four minute) or a long (12 minute) break, during which they solved crosswords (a demanding activity) or leafed through newspapers (a nondemanding activity). There was also a group with no break allowed. It appeared that the break resulted in increased proportion of correct answers but its duration did not matter. It was also demonstrated that the demanding activity during the break was more beneficial than the less demanding one. It is therefore possible to conclude that:

1. incubational breaks work;
2. the unconscious activity of mind probably does not take place (duration of breaks is irrelevant); and
3. breaks allow redirection of attention from irrelevant aspects of the problem to the relevant ones (demanding activity is beneficial).

Restructuring

The notion of restructuring is crucially important for the original Gestalt account of insight. However, the Gestalt psychologists did not develop any mature theory of restructuring, sometimes over-relying on metaphors like 'replacement of figure with background' or 'seeing the problem from another perspective.' More elaborated models of restructuring have been worked out by cognitive psychologists and cognitive scientists in the last three decades.

According to Stellan Ohlsson, people typically attempt to solve problems through retrieving relevant knowledge from their long-term memory, while elements of the mental representation of the problem serve as retrieval cues. In 'normal problem solving' such a strategy may turn out to be successful but if a problem is tricky or unusual, a person runs into an impasse. In order to break the impasse, a person needs to restructure their mental representation of the problem. Instead of trying to find a way between the initial state of affairs (i.e., the problem) and the attempted goal state (i.e., a solution), one aims at constructing a new problem space, where both the initial state and the goal state are either changed substantially or replaced by entirely new structures. In consequence, restructuring means that a new problem arises in one's mind, with new initial data, new goals, and new constraints. When such a change is completed, the transformed mental representation of

the problem works as a fresh source of retrieval cues, thanks to which some relevant data, already stored in the long-term memory, can be used in a productive way.

Ohlsson improved the Gestalt theory through identifying three separate types of restructuring: elaboration, reencoding, and constraint relaxation. Elaboration consists in adding new elements to the original mental representation, so as to make it complete. For instance, the problem of the parallelogram (Figure 1) is easily solved if one adds new elements to its original representation, namely, two big triangles ABG and DCE. The original representation involves the square and the parallelogram, whereas the transformed representation consists of just two triangles. Reencoding amounts to sticking a new label to some old elements of the problem, which usually require that these elements be included into another category. For example, the rebus 'poPPd' ('two peas in a pod') is solved only if one includes two capital letters (PP) into one category, and three lowercase letters (pod) into another category. In other words, the solution requires that the already encoded elements be encoded again in this entirely new way, because particular letters must be treated as independent words instead of parts of words. The third mechanism, constraints relaxation, consists in abandoning, or at least lessening, some impediments, rules, or obstacles that previously seemed unconditional. For example, if the task is to compose four unilateral triangles with the use of six matchsticks, one has to abandon the tacit and false assumption that all triangles must be located on the same plane. Only after such relaxation is accomplished, one is able to build a pyramid of six matchsticks.

The Cognitive Mechanisms of Insight

Selectivity

Janet Davidson and Robert J. Sternberg proposed the selectivity theory of insight. According to the authors, insightful problem solving does not differ in kind from 'regular problem solving.' What makes a difference amounts to selectivity with which otherwise regular mental processes are executed. There are three types of selectivity that the authors believe are important for insight: selective encoding, selective comparison, and selective combination.

Selective encoding consists in taking into account some pieces of information that, though present in the perceptual field, were hitherto ignored as irrelevant. Alternatively, selective encoding may consist in ignoring some elements of the problem as irrelevant, although they tended to be treated as rather important. These two aspects of selectivity take place mostly in perception but may also occur in remembering and concept formation. Louis Pasteur's discovery is a good example of selective encoding. Pasteur noticed that grapes with broken skin quickly staled, whereas grapes with whole skin preserved their freshness for a long time. These facts were well known to everyone but only Pasteur understood that broken skin is a gateway open for microbes. In consequence, he was able to formulate the germ theory of fermentation.

Selective comparison amounts to discovery of relations between new facts and previously acquired pieces of knowledge. Thanks to such comparisons people can achieve new solutions through analogical transfer of knowledge. They use

already acquired knowledge to work out novel ideas, which are 'borrowed' from other schemas, or even other domains. Davidson and Sternberg illustrated this phenomenon with an anecdote about Archimedes, who had to find out if the king's crown was made of genuine gold. He knew the specific weight of gold but was unable to determine the irregular crown's volume. Fortunately, he noticed that the human body, which is also irregular in shape, elevated water if sunk in a bathtub. As soon as he discerned the analogy between the irregular human body and the irregular crown, he knew the solution: immerse the crown into water, measure the volume of water pressed up by the crown, which is equal to the volume of the crown, calculate the expected weight of the crown if it was gold, and – finally – compare the expected and the actual weight of the crown. Although anecdotal, this story epitomizes numerous examples of analogical transfer in science and technology.

Selective combination is a process through which people connect dispersed, seemingly unrelated pieces of knowledge into sensible, meaningful structures. Construction of scientific theories often matches this pattern. For example, Charles Darwin sketched the theory of evolution through connecting numerous facts from botany, paleontology, ornithology, and other domains of natural sciences. He provided an explanatory pattern thanks to which all these facts appeared understandable and meaningful. Sometimes selective combination leads to transformation of the old theory rather than construction of a new one but in every case this process requires that seemingly unconnected facts and observations be composed into a new and elegant configuration.

Simplification

Creativity is often impeded by the fact that problems that require new and productive approaches are incredibly complex in nature. The amount of data that have to be taken into account in order to construct a cognitive representation of the problem may give the impression of being too large for the human mind, particularly in science and technology but also in some domains of artistic creativity. Great creators undoubtedly possess enormous cognitive skills but nevertheless the complexity of problems they have to deal with does not seem compatible with the capabilities of any human mind. The disparity between what has to be done and human mental capabilities seems particularly severe in reference to working memory. This module is specialized in current information processing, so-called mental combinatorics, and it is severely limited in capacity. It is estimated that working memory can keep only about four separate chunks of information simultaneously. Four pieces of information may not be enough for economical shopping, not to mention insightful problem solving.

Herbert Simon was aware of the problem of disparity; therefore, he developed a theory of scientific insight whose main message amounts to the thesis that scientific problems must be substantially simplified in order to be solvable at all. Simplification is possible thanks to two independent processes: familiarization and selective forgetting. Familiarization is a long process of getting acquainted with all-important aspects of the problem. The situation is analyzed from many different perspectives. Also, many different ideas emerge how

to solve the problem, but all of them turn up to be false or incomplete. During this lengthy and 'intimate' contact with the problem, its structure is constantly changing. In particular, a person is able to perceive the problem from a very high level of abstraction, or – if necessary – with subtlety typical of perception at the lowest possible level of abstraction. In other words, the problem may look either simple or complicated, depending on the level of abstraction. In addition, during familiarization the elements of the problem are packed into 'mental parcels,' that is, they are composed in chunks defined on the basis of either content or association with other elements. In consequence, the problem gets more and more simplified although it is not deprived of important, building elements.

Simultaneously, selective forgetting allows the disposal of those elements of the problem that are not important, or even misleading. In every scientific problem, there are many pieces of data that are superfluous, redundant, or meaningless. It would be very advisable to get rid of them as soon as possible, if only one could tell which elements are actually misleading. Fortunately, the long process of deliberation about the problem makes such decisions easier, because what seems important at the beginning may lose importance later on, and *vice versa*. The mechanism of selective forgetting is especially beneficial from this point of view because it eliminates unnecessary elements of the problem quite automatically. We just do not remember some pieces of knowledge anymore, so we do not have to decide at the conscious level what is relevant and what is not.

Familiarization and selective forgetting may take a very long time but as soon as the problem is simplified enough, the solution appears as if unexpectedly. According to Herbert Simon's theory, unexpectedness is just a side effect of simplification of the problem structure, which is possible thanks to two independent but mutually supportive processes: familiarization and selective forgetting.

Assimilation

Assimilation is a process through which new elements are introduced into the cognitive representation of the problem. New pieces of knowledge are absorbed from the environment thanks to the ability of the properly prepared mind to exploit helpful external cues.

Colleen Seifert and her colleagues proposed a theory of insight based on the notion of opportunistic assimilation. According to this stance, the creative process starts with 'confrontation with the problem,' that is, with numerous attempts to understand the problem and to find a plausible solution. Striving for a new and valuable outcome is likely to result in a number of failed attempts so any serious creative work requires long-term commitment and strong motivation. When the impasse occurs, the human mind uses so-called failure indices in order to mark components of the unsolved problem in the long-term memory store. Thanks to these failure indices, the human mind remembers its fiascos: it is quite easy to remember that one was not successful and to retrieve required elements of the unsolved problem. The failure indices make one's mind rather vigilant, or 'hyper attentive,' to pieces of information that might be helpful in working out a solution.

The confrontation with the problem, the following impasse, and setting up failure indices, supposedly take place in the preparation phase of creativity. Then, the incubation period follows, which is characterized by a lack of any observable problem solving activity. This phase is very important, though, not because of hypothetical unconscious mental activity but because of increased tendency of the well-prepared mind to absorb relevant data from the environment. Siefert et al. do not agree with Simon's hypothesis about selective forgetting, nor with the argument that an incubational break alone is sufficient for success. Rather, they argue that the previously prepared mind is very sensitive to those elements of external stimulation that may be a source of relevant information. The mind takes a chance provided by the environment. External cues appear accidentally but their being utilized is the effect of the formerly performed job of confrontation with the problem, establishing failure indices, and making the mind well prepared for taking an opportunity to exploit relevant environmental cues. The experience of illumination, being a culmination of the creative process, results from unexpected 'opportunistic assimilation' of external cues that happen to be crucially important for finding a solution to the previously unsolved problem.

Conclusions

Insight is undoubtedly a pivotal moment of the creative process, so understanding insight results in better understanding creativity. The scientific study of insight brought about interesting theories, as well as valuable empirical evidence. However, there seems to exist a serious disparity between real-life insights, for example, in science and technology, and so-called insight tasks widely employed in laboratory studies. Future advances in the theory of insight seem to depend on the researchers' ability to unify the experimental laboratory studies with *in vivo* observation of genuine creative processes.

Intelligence (as Related to Creativity)

R J Sternberg, Oklahoma State University, Stillwater, OK, USA

J C Kaufman, California State University at San Bernardino, San Bernardino, CA, USA

© 2011 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by Robert J Sternberg, volume 2, pp. 81–89, © 1999, Elsevier Inc.

How are intelligence and creativity related? The question is important because, in our schools, we seem to value intelligence over creativity, but in life, creativity is at least as important because it involves adapting to the novel situations that can lead people either to great success or stunning failure. Not only is the relationship important for theoretical reasons, it also has tremendous applied value in the schools, workforce, and our every day lives.

The roots of creativity as a scientific discipline are planted in the intelligence literature. Many of the earlier scholars (such as Francis Galton, Lewis Terman, Alfred Binet, and Charles Spearman) who considered and discussed creativity were more primarily focused on intelligence. Indeed, it was an intelligence researcher, J. P. Guilford, who first publicly recognized the need for an independent study of creativity.

Guilford placed creativity into a larger framework of intelligence in his Structure of Intellect model. He attempted to organize all of human cognition along three dimensions. The first dimension was called 'operations,' and simply meant the mental processes needed to complete almost any kind of task, such as cognition. The second dimension, 'content,' referred to the general subject matter, such as words. The third dimension, 'product,' represented the actual products that might result from different kinds of thinking in different kinds of subject matters, such as writing. With five operations, four contents, and six products, Guilford's model had 120 different possible mental abilities. Indeed, he later expanded the model to include 180 different abilities, although the 120 abilities model is the one more often studied.

One of Guilford's operations (or thought processes) was divergent thinking – analyzing one's response to questions with no obvious, singular answer. Such questions might include "What would happen if we didn't need sleep?" This work, followed up by other researchers (most notably E. Paul Torrance), has often been used as a measure of creativity. Two of the most common ways of scoring these tests are fluency (the total number of responses given) and originality (how unique are the responses).

Theories of Intelligence which Encompass Creativity

Guilford placed creativity within the context of an intellectual framework. In doing so, he was the first of many to consider creativity to be part of intelligence. Some theories of intelligence include creativity as a subcomponent. Undoubtedly, the theory of intelligence that is most often applied to IQ tests is the CHC (Cattell–Horn–Carroll) theory, a combination of two earlier theories. The Cattell–Horn theory initially proposed two types of intelligence, crystallized (Gc) and fluid (Gf). Gc is what a person knows and has learned, whereas Gf is how a

person handles a new and different situation (i.e., problem solving). Horn expanded the theory to include more dimensions (known as Broad Abilities). Carroll's theory proposed a hierarchy of intellectual abilities. At the top of the hierarchy is general ability; in the middle of the hierarchy are various broad abilities (including learning and memory processes and the effortless production of many ideas). At the bottom of the hierarchy are many narrow, specific abilities such as spelling ability and reasoning speed.

The combined CHC theory incorporates both the concept of a general intelligence (all of the different aspects of intelligence are considered to be related to a common 'g', although this aspect is not often emphasized) and the concept of many different aspects of intelligence. Ten different broad factors of intelligence are proposed. These include Gf and Gc from the initial Cattell–Horn theory. They also include Gq (quantitative knowledge, typically math-related), Grw (reading and writing), Gsm (short-term memory), Gv (visual processing), Ga (auditory processing), Glr (long-term storage and retrieval), Gs (processing speed), and Gt (decision speed/reaction time). Of these 10, only 7 are directly measured by today's intelligence tests: Gq and Grw are in the domain of academic achievement, and, therefore, are measured by achievement tests, and Gt is not measured by any major standardized test. Intelligence tests may indirectly measure some of these other skills, however. For example, intelligence tests indirectly measure achievements in various areas. The Stanford–Binet 5 and the Woodcock–Johnson–Revised were the first intelligence tests to be built on Gf–Gc theory. Today, nearly every major intelligence test is founded either explicitly or implicitly on the current version of the theory, namely, CHC.

Although in the early stages of the Cattell–Horn Gf–Gc theory, Gf (fluid intelligence) was hypothesized to be strongly linked to creativity, such a relationship is no longer explicitly part of the CHC theory. The current model, based on factor analytic studies by Carroll and others, includes originality/creativity as a component of long term storage and retrieval (Glr). The most recent presentations of CHC theory argue that some Glr narrow abilities impact such creativity-relevant abilities as divergent production, ideational fluency, or associative fluency. In the detailed description of the model, connection is the only mention of creativity, originality, or divergent thinking. Fluid intelligence (Gf) is discussed in terms of its relationship to problem-solving and coping with novel problems (both considered to be highly related to creativity), yet the emphasis is on Glr.

Martindale proposed a differential relationship between Gs (processing speed) and creativity. According to Martindale's theory, people who are creative are selective with their speed of information processing. Early in the creative problem-solving stage, they widen their breadth of attention, allowing

a larger amount of information to be processed (and thereby lowering their speediness). Later, when the problem is better understood, their attention span is shortened and their reaction time is quicker. This theory is reminiscent of Sternberg's distinction between global and local planning: According to Sternberg, brighter people spend more time in initial global planning so that later they do not have to spend as much time in local planning.

Some have argued that the current CHC model short-changes creativity. Placing all references to creativity and originality under *g* seems quite narrow. The ability to draw selectively on past experiences is essential for creating something new. But the connection between fluid intelligence and creativity is minimized in new conceptions of the model. A theory of intelligence that has recently been applied to school admissions is Sternberg's theory of successful intelligence. This theory comprises three 'subtheories': a *componential subtheory*, which relates intelligence to the internal world of the individual; an *experiential subtheory*, which relates intelligence to both the external and the internal worlds of the individual; and a *contextual subtheory*, which relates intelligence to the external world of the individual. The componential subtheory specifies the mental mechanisms responsible for planning, carrying out, and evaluating intelligent behavior. The experiential subtheory expands on this definition by focusing on those important behaviors that involves either adjustment to relative novelty, automatization of information processing, or both. The contextual subtheory defines intelligent behavior as involving purposeful adaptation to, selection of, and shaping of real-world environments relevant to one's life.

The experiential subtheory is directly related to creativity. Sternberg's application assessments of creativity to admissions data increased prediction of college success beyond that obtained with standard admissions tests; in addition, ethnic-group differences were significantly reduced. Gardner's well-known theory of multiple intelligences does not specifically address creativity. However, his eight intelligences (interpersonal, intrapersonal, spatial, naturalistic, linguistic, logical-mathematical, bodily-kinesthetic, and musical) certainly seem to apply to creativity. Gardner has used case studies of eminent creative individuals to argue that creative people can shine as a function of embodying different intelligences. For example, he selected Freud as an example of intrapersonal intelligence; Einstein to represent logical-mathematical intelligence; Picasso, spatial intelligence; Stravinsky, musical intelligence; T. S. Eliot, linguistic intelligence; Martha Graham, bodily-kinesthetic intelligence; and Gandhi, intrapersonal intelligence (naturalistic intelligence had not been added at this time).

Another theory of intelligence that incorporates creativity is Luria's neuropsychological model. Like the CHC model, Luria's model is frequently applied to intelligence tests. This model has three functional units; the first unit is responsible for focused and sustained attention. The second functional unit receives and stores information with both simultaneous and successive (or sequential) processing. Simultaneous processing involves integrating chunks of information together, largely in parallel; chunks are synthesized together simultaneously, much as one might appreciate a painting all at once. Successive processing is interpreting chunks of information

separately, in sequential fashion, much as when one listens to a news broadcast reporting successive stories.

The third functional unit is responsible for planning, decision-making, and self-monitoring behavior. It is this last ability, planning, that has been hypothesized to be related to creativity. For example, studies have found that planning-oriented cognitive styles were strongly linked to creative productivity. Also, people who spent time planning and replanning a project were more productive and more creative.

Theories of Creativity that Encompass Intelligence Systems Theories

In recent years, there has been an emphasis on creativity theories that incorporate factors that are interrelated. Some of these theories emphasize issues such as the environment or evolution and are less relevant here. Other theories emphasize a confluence of different elements and include intellectual and cognitive abilities in the equation. One such theory is Sternberg and Lubart's 'investment' theory of creativity, in which the key to being creative is to buy low and sell high in the world of ideas. In this model, a creative person is like a talented Wall Street investor. A successful creator will generate ideas that may be initially unpopular or underappreciated (as in buying stocks with low price-earnings ratios), yet will persist and convince others of the ideas' merits. The creator will then know when to move on to pursue other ideas (as in selling high, when one divests oneself of stocks).

According to this model, six main elements contribute to creativity: intelligence, knowledge, thinking styles, personality, motivation, and the environment. Intelligence contributes using three elements drawn from Sternberg's triarchic theory (later expanded into the theory of successful intelligence).

The first element is synthetic ability, which is the ability to generate ideas that are novel, high in quality, and high in task appropriateness. Because creativity is viewed as an interaction between a person, a task, and an environment, what is novel, high in quality, or task appropriate may vary from one person, task, or environment to another. Central to this ability is being able to redefine problems. Creative people may take problems that other people see, or they themselves may previously have seen, in one way, and redefine the problems in a different way. This synthetic ability includes three knowledge-acquisition components. The first, selective encoding, involves distinguishing relevant from irrelevant information. Selective combination, the second, involves combining bits of relevant information in novel ways. Finally, selective comparison involves relating new information to old information in a novel way.

The second element, practical ability, is needed to communicate creative ideas to other people (i.e., 'selling' an idea). Good ideas do not always sell themselves – the creative person needs to devise strategies for and expend effort in selling those ideas.

The third component, analytical ability, is often measured by traditional intelligence tests. Yet this component is also related to creativity, as a successful creator must be able to judge the value of his or her own ideas and decide which ones to pursue. Such analytical ability can be used to evaluate

the strengths and weaknesses of the idea and determine the best steps to improve upon the idea. People who are high in synthetic ability but low in analytical ability may need someone else to evaluate and judge their work for them. People who are able incisively to evaluate their own work may be said to be high in metacognition (which is related to planning, a key component of Luria's model).

There has been some empirical work on the role of meta-cognitive abilities in creativity. Some studies have found that people who tended to produce more original responses also were better at rating their most original responses to a divergent-thinking task. In one study, people were asked to pick their best responses to a similar divergent-thinking task, and then examined whether they were more likely to choose responses that outside raters considered creative. Research found that people were able to discern their more creative responses – and that people who were more open to experience were more likely to choose accurately.

A theory of giftedness that could be argued to be a Systems theory is Renzulli's Three-Ring Model, which proposes that giftedness is at the intersection among above-average intelligence (measured traditionally), creativity, and task commitment. The circles representing creativity and intelligence overlap. Renzulli distinguishes between two types of giftedness – schoolhouse (i.e., what would be measured by an ability or achievement test) and creative-production. Examples of his components of creativity include Guilford's divergent thinking components (fluency, flexibility, and originality), and being open to new experiences, curious, willing to take risks, and sensitive to aesthetic characteristics.

Another theory that views creativity as a mix of different abilities is Amabile's componential model of creativity. She argued that three variables were needed for creativity to occur: domain-relevant skills, creativity-relevant skills, and task motivation. Domain-relevant skills include knowledge, technical skills, and specialized talent (i.e., a creative mathematician should know basic algebra and geometry). Creativity-relevant skills are personal factors that are associated with creativity. These skills include tolerance for ambiguity, self-discipline, and risk-taking. Finally, Amabile singles out your motivation toward the task at hand. Intelligence would primarily occur at the domain-relevant skill level.

Cognitive Theories of Creativity

The other group of theories that includes intellectual abilities as a key component is the set of cognitive theories of creativity. Guilford, as discussed earlier, pioneered these ideas, and his convergent versus divergent thinking dichotomy is still a key idea in creativity. Even before Guilford, however, Wallas proposed a model of the cognitive creative process. According to his five-stage model, you first use *preparation* to begin work on a problem. Next, there is *incubation*, in which you may work on other things while your mind thinks about the problem. In *intimation*, you realize you are about to have a breakthrough (this phase is sometimes dropped from the model), and then you actually have the insight in the *illumination* phase. Finally, with *verification*, you actually test, develop, and use your ideas.

More recently, the Genevieve model has two phases, generative and explorative, that are comparable to Guilford's

convergent and divergent thinking distinction. In the generative phase, someone constructs a preinventive structure, or a mental representation of a possible creative solution. For example, Elias Howe was working on his invention of the modern sewing machine. He could not quite get the needle correctly designed. Howe had an odd dream in which he was chased by savages who threw spears at him. The spears had a circle loop at the end – and Howe realized that adding the circle (or an 'eye') to the end of the needle was the solution he needed. The image of a spear with a circle at the end – the image that preceded Howe's insight – would be an example of one of these preinventive structures. They do not need to be as dramatic or sudden as the realization based on Howe's dream. Indeed, the generation of preinventive structures is only one part of the creative process, according to the Genevieve model. The thinker must then explore these different preinventive structures within the constraints of the final goal. There may be several cycles before a creative work is produced.

Although the model focuses on the creative process, most tests of the model have actually measured the creative product. In an experiment testing the model, people were shown parts of objects (such as a circle or a cube). They were then asked to combine these parts together to produce a practical object or device. The creativity (and practicality) of the items was then assessed. Interestingly, people produced more creative objects when they were told which parts had to be combined than when they could pick the parts to be combined.

Other theories have also focused on cognitive-oriented components of the creative process. Michael Mumford and his colleagues have argued for an eight-part model, focusing on problem construction, information encoding, category selection, category combination and reorganization, idea generation, idea evaluation, implementation planning, and solution monitoring. Mednick proposed the idea that creativity occurs when different elements are associated together to form new combinations. Creative individuals are assumed to be able to make meaningful, useful associations between disparate concepts and ideas to a greater extent than a relatively uncreative individual. The Remote Associates Test was developed based on this idea.

Theories on How Intelligence and Creativity Are Related

The threshold theory argues that intelligence is a necessary but not a sufficient condition of creativity. According to this view, creativity and intelligence are positively correlated up until an IQ of approximately 120; in people with higher IQs, the two constructs are said to show little relationship. The interference hypothesis suggests that very high levels of intelligence may interfere with creativity.

Empirical Work on Intelligence and Creativity

Most studies that investigate creativity and intelligence use divergent-thinking tests (such as the TTCT) or other related paper-and-pencil tests also scored for fluency, originality, or other divergent thinking-related methods of scoring. The studies have generally found that creativity is significantly associated

with psychometric measures of intelligence (especially verbally oriented measures, regardless of the type of creativity measured). This relationship is typically not a particularly strong one, although some have argued that the relationship between the latent constructs of creativity and intelligence is underestimated because the analyses only look at observable scores (i.e., performance on an intelligence test). If it were possible to get a 'true' measure of the constructs, there might be a higher relationship.

More recently, however, the threshold theory has come under fire. Some have found that the nature of the relationship was dependent on the measures used and the populations tested. Others looked at measures of fluid intelligence and creativity (as measured through divergent thinking tests) and found modest correlations across all levels of intellectual abilities. A longitudinal study of gifted (top 1%) 13 year olds revealed that differences in SAT scores – even within such an elite group – predicted creative accomplishments 20 years later. A meta-analysis of 21 studies discovered virtually no support for the threshold theory, with small positive correlations found at all levels of ability between measures of intelligence and creativity.

It is notable, however, that nearly all of these studies do not use traditional, individually administered intelligence tests. In the meta-analysis, many of the studies were more than 30 years old and, therefore, were conducted using intelligence tests that do not reflect current theories of intelligence. In addition, most of the studies used group intelligence tests. Although group intelligence tests serve a strong purpose in research studies, they are not used by most school psychologists for psychoeducational assessment.

One of the few research studies to use an individually administered, modern IQ test used the Kaufman Adolescent and Adult Intelligence Scale and a creative invention task (in which people would use shapes to create a possible object, and then name and describe their invention). They delved deeper into the intelligence–creativity relationship by specifically examining the relationship between Gf (novel problem solving) and Gc (acquired knowledge) and a measure of actual creative innovation. Gc showed the same moderate and positive relationship to creativity as past studies, mentioned previously; in contrast, Gf showed the opposite pattern. Measured intelligence and creativity were significantly correlated for the high IQ group, but they were not significantly correlated for people with average IQs. This finding implies that students who receive high Gf scores may be more likely to be creative than students who receive high Gc scores.

This study also addresses a second major weakness in this line of research: the over-reliance on divergent thinking measures as the sole assessment of creativity. Few studies have been conducted that include measures of creative personality, creative products, and creative processes (other than divergent thinking). Given the distinct characteristics of assessments in these areas, highlighted throughout this book, the threshold theory may be best viewed as largely untested.

Conclusion

Intelligence is strongly valued in schools, and there are extensive and popular measures that are often used. There are usually hundreds of empirical studies about each intelligence test. Creativity may be theoretically desired in school, but is often considered less important; some teachers may even dislike creative students. Creativity assessment is murkier than intellectual assessment. The Torrance Tests remain the most-used creativity tests despite extensive critiques.

Few studies contradict the idea that creative people tend to be fairly smart, and that smart people are usually somewhat creative. But some of the tested-and-true ideas about the specific relationship are still unclear. If the threshold theory is correct, then there may be a certain point at which being smart stops helping creativity; recent psychometric studies, however, call the existence of the threshold effect into question.

Both intelligence and creativity are essential component of learning and problem solving in everyday life. Virtually any problem, by the virtue of definition, imposes on its solver some ambiguity that needs to be overcome in order to find the solution. Some theories consider creativity to be subsumed into intelligence and others view intelligence as a core component of creativity. The need of both cognitive constructs in life, however, is undisputed.

Interest Inventories

S H Carson, Harvard University, Cambridge, MA, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Characteristics approach A method of identifying potentially gifted individuals based on how similar their interests, behaviors, and personality traits are to those of highly creative people rather than identifying them based on their previous creative achievement.

Holland codes A set of six different categories of interest based on J. L. Holland's personality research. The categories include: realistic, investigative, artistic, social, enterprising, and conventional.

Interest inventories Assessment tools that determine an individual's likes and dislikes for activities, objects,

and persons. The inventory may determine level of interest either interpersonally (compared to the interests displayed by other individuals or groups) or intrapersonally (compared to interest in other types of activities within the same individual).

Reliability The consistency of a measurement; the extent to which a construct remains stable across time and across raters.

Validity The extent to which an assessment measures what it is purported to measure; the degree to which an assessment correlates with an established measure of the construct it is supposed to be measuring.

Introduction

Interest inventories are assessment tools that determine an individual's likes and dislikes toward a variety of activities, objects, or people. Inventories may determine level of interest either interpersonally (compared to the interests displayed by other individuals or groups) or intrapersonally (compared to level of interest in other activities within the same individual) or both. Interest inventories are often used to predict present or future success and satisfaction within a specific domain of endeavor. Inventories that use *interpersonal* comparisons assume that individuals whose interests match those of a specified group will be more likely to find satisfaction in activities and careers endorsed by that group. Inventories that use *intra-personal* comparisons assume that interest in an activity or endeavor motivates the individual to pursue that interest, and may consequently equate to better performance in the specified activity. In other words, a person's interest is indicative of his or her potential in that area.

Three types of interest inventories are related to creative endeavors. The most prominent group of inventories is geared toward the assessment of possible career trajectories for adolescents and adults. These vocation-based interest inventories compute the individual's interests across different categories of activity, including creative activities, each related to a broad range of potential careers. A second smaller set of inventories measures interest in creative activities in children. These inventories are primarily geared toward identifying individuals who may show promise in creative fields such as visual art, creative writing, music, drama, and science. High scores on these measures may be used as selection criteria for programs for gifted children. A third type of inventory assesses creative interest as a measure of overall creativity for psychological research purposes. These inventories vary in their structure and method of delivery and may include items that assess creative achievement along with interest-based items.

While the three types of inventories are grouped according to the purpose for which they were developed, their functions

overlap and are not mutually exclusive; both vocational and educational inventories may be used for research, and vice versa. Because vocation-based instruments are the most widely used form of interest inventories, they will be prominently discussed.

Vocation-Based Interest Inventories

Vocational interest inventories were developed as an applied psychology tool for the purpose of career counseling. The assumption behind the use of vocational interest measures is that occupational satisfaction and performance will be determined not only by aptitude and skill, but will also be enhanced when an individual's interests are in line with the requirements of the occupation. When the environment and the individual's interests coincide, work performance and work satisfaction will be maximized.

Vocational interest inventories have a variety of uses. Because they were designed for vocational counseling, they are widely administered in high school and college career counseling settings. Most vocational inventories are suitable for use with both adolescents and adults. These inventories are also used in career transition settings, such as transitioning out of the military into civilian careers. In addition, they may be used by employers as part of a psychological testing package for potential employees. Finally, interest inventories can be used by individuals to help them determine the type of leisure activities that may balance their work life.

History of Vocational Interest Inventories

Speculation into the usefulness of interest inventories appears to have originated with E.L. Thorndike early in the twentieth century. In 1912, he reported the results of a project in which he asked 100 college undergraduates to list their interests in elementary school, high school, and college, and then to list their abilities during the same periods. Thorndike concluded

from this project that (1) interests precede abilities and (2) interests and abilities are closely related.

The prototype for the interest inventory had its beginnings after World War I at the Carnegie Institute of Technology, where Clarence S. Loakum was developing psychological tests for army use. The first widely used inventory, the Strong Vocational Interest Blank (SVIB), was developed in 1927 by E. K. Strong, Jr., to help individuals exiting the military find suitable jobs. The development of the SVIB is historically important because it is the most widely used model and the oldest interest inventory in continuous use.

The original SVIB was an inventory of items that dealt with activities, objects, and types of people that might be encountered in everyday life. Respondents indicated whether they liked or disliked each item. The original items in the SVIB were culled from a set of 1000 that had been developed by Yoakum at Carnegie. These items were submitted to samples of approximately 10000 men in some 50 occupations, and items that differentiated groups were retained in the inventory. Results of Strong's research indicated that preference for a career type also extended to a preference for specific hobbies, school subjects, and social relationships. Scores from Strong's inventory were keyed on how closely the preferences of the individual respondent matched the preferences of the vocationally distinct samples. The original inventory was not based on any specific theoretical approach, and the early versions of the instrument were developed exclusively for men. Variants of Strong's original inventory, including the recently revised Strong Interest Inventory, are still in use.

Another major influence on vocational interest inventories was the development of the Holland classification system of person and environment. In 1959, psychologist John L. Holland published the first version of his person-environment theory of vocational personalities, based on 11 years of empirical investigation. This theory suggested that both individuals and work environments can be classified into six categories, designated as Realistic, Investigative, Artistic, Social, Enterprising, and Conventional. The system of classifications, known as the Holland codes, was based on the assumption that career choice is an expression of personality (Figure 1). Thus, the six categories of personal and vocational interests represent dispositional traits of basic personality types. Holland believed that individuals who are aware of their preferred interest types can make better career choices.

Within the Holland system, the two categories of interests that are most relevant to creativity are the Artistic and the Investigative. The Artistic category includes interest in the arts, writing, music, design, and a variety of other creative endeavors. It also includes a preference for an unstructured work environment, flexible working hours, and flexible work location. The Investigative category includes interests in activities that involve observation, evaluation, and problem-solving, with relatively minimal interaction with other people. The Artistic and Investigative categories are indicative of interest in the arts and sciences respectively, and are generally taken to be measures of creative interests.

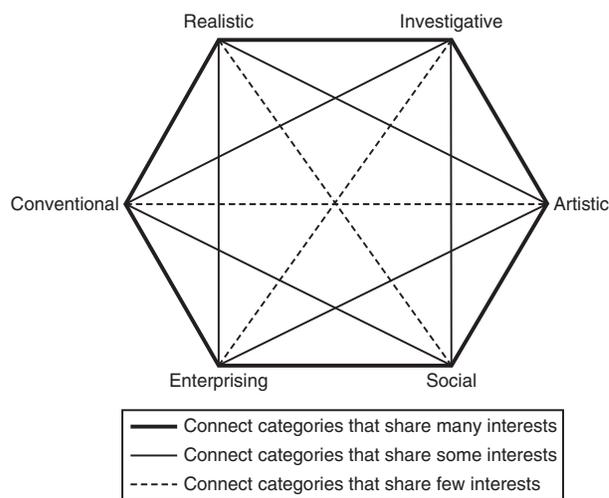

Figure 1 Holland's classification codes.

In contrast, the Realistic category of interests includes a preference for working with one's hands using tools, machines, or plants, and engaging in practical or physical tasks. It is associated with careers such as farming, transportation, and law enforcement. The Social category includes interest in working with people rather than things, as well as a desire to train, counsel, or cure others. It is associated with careers in education, applied medicine, counseling, and customer service. The Enterprising category includes interest in persuading, influencing, or directing others. It is associated with careers in sales, politics, entrepreneurship, and the law. Finally, the Conventional category of interests includes a preference for working with data rather than people or objects, and a desire for structure and working with details. It is associated with careers in accounting, business administration, banking, and finance.

Holland's research indicated that most people's interests do not fall exclusively into one category, but rather consist of blends of interests from several categories. Interests from one category will generally be dominant, with secondary interests falling within each of the remaining categories in descending order of preference. Correlations of types of interests across many samples of occupations also suggested that some interest categories are more highly correlated with each other than others. Holland arranged the six categories in a hexagon with types that tend to be more highly correlated arranged adjacent to each other. Thus, it is more likely that individuals whose primary interests are in the Artistic category will have secondary interests in either the Investigative or Social categories than in the Realistic category.

Holland's hexagon is widely employed in the vocational interest inventories available today. The Strong Interest Inventory (SII), for example, incorporates Holland's theory with Strong's original research on interests and occupations, and provides feedback to users on both the Holland codes and the occupations that are aligned with those codes.

Current Vocational Interest Inventories

Currently, there are more than 50 vocational interest inventories commercially available. Because these inventories

measure interests rather than skills or aptitudes, they are often delivered in conjunction with specific aptitude tests. **Table 1** lists examples of current vocation-based interest inventories.

The most widely used current interest inventories are those based on Strong's original 1927 instrument. The original version of the inventory has been revised by psychologists Jo-Ida Hansen and David Campbell, and several offshoots of the original Strong inventory are now available. Major changes to the original Strong inventory include the following: (a) occupations are now theoretically interpreted using the Holland codes, (b) separate inventories for males and females have been combined into a single assessment, (c) more occupations for vocational and semi-skilled workers with lower education levels have been added to the list of occupations described, and (d) inventories are now generally delivered and scored by computer rather than by hand, improving the speed and accuracy of the inventory.

A second set of vocational interest inventories that have been in use almost as long as the Strong inventories first appeared in 1934, and were developed by G. F. Kuder. The Kuder inventories differ from those developed by Strong in several ways. Unlike the Strong inventories, Kuder's original inventory was not empirically normed but was based on conceptually derived categories of interests. Rather than using the six-category Holland system as the basis of interests, Kuder conceived 10 broad interest areas: Mechanical, Computational, Scientific, Persuasive, Artistic, Literary, Musical, Social Service, Clerical, and Outdoors. Scores on the broad interest areas can be converted to Holland system scores by combining the output scores for the Artistic, Literary, and Music scales (equivalent to Holland's Artistic category) and the scores for the Clerical and Computational scales (equivalent to Holland's Conventional category). Researchers have noted the similarity between the categories in the Holland and Kuder systems, despite the very different methods of development (empirically versus conceptually driven). That two such different methodologies have yielded such similar results attests to the face validity of the interest categories.

An additional type of interest inventory was introduced by Holland himself. Whereas other inventories of the time were designed to be administered and scored by trained

professionals, Holland's Self-Directed Search (SDS) was developed to be self-administered and self-scored. Users could sum their own responses to yield scores on each of the six themes of the Holland hexagon. They could then look up a table of occupations suited to their theme scores in the manual provided with the inventory.

Although the six categories of interest described by Holland continue to be widely accepted, the careers associated with each category have changed over time. Because some career choices become outdated (such as telegraph operator) and new careers possibilities are constantly developing due to technological advances (such as IT specialist), it is necessary to update vocational interest inventories on a regular basis. For example, in the Artistic category, new careers include work in computer graphics design, internet advertising, and interactive video. In the Investigative category, new careers include developing computer systems, research using brain imaging, and research in molecular genetics.

Validity and Reliability of Vocation-Based Interest Inventories

Most popular vocational interest inventories available today appear to have acceptable validity and test-retest reliability according to published studies.

Because one of the main purposes of interest inventories is to assist in career counseling, the predictive validity of the tests is important. While there is variability across instruments, the most popular inventories have shown good predictive validity. Studies of popular inventories indicate a concordance of 50–75% between current occupations and occupations predicted by interests inventories 12–19 years earlier.

A second purpose of interest inventories is to predict future job satisfaction. One premise of the inventories is that when individual interests are matched with occupational demands, career satisfaction should improve. Several studies have investigated job satisfaction in terms of interest-occupation compatibility as measured by interest inventories. The results have been mixed. While some studies show only small associations between job satisfaction and interest-occupation congruence, other studies show that congruence is an efficient predictor of job satisfaction when between-occupation sources of variance are controlled.

A number of studies have also examined validity and reliability for interest inventories across racial and ethnic groups. The SII has shown validity in Chinese groups and Icelandic college-age groups. There is evidence for validity in college-educated groups of African Americans, Latinos, Native American and Asian Americans as well. However, it is unclear whether the validity of the inventories would extend to minority groups with lower education levels.

Most research indicates that it is preferable to use interest inventories that have been developed specifically with the group to be tested in mind. To that end, several interest inventories have also been developed for specialized groups, including picture-based inventories for groups who are illiterate, developmentally disabled or who have limited familiarity with English.

A quantitative analysis of 66 longitudinal studies conducted by K. S. Douglas Low and colleagues in 2005 examined the

Table 1 Examples of vocation-based interest inventories

<i>Name of inventory</i>	<i>Author(s)</i>
ACT Interest Inventory (ACTII)	American College Testing Program
Campbell Interest and Skill Survey (CISS)	D. P. Campbell
Career Assessment Inventory (CAI)	C. B. Johansson
Jackson Vocational Interest Survey (JVIS)	D. N. Jackson
Kuder Occupational Interest Survey (KOIS)	G. F. Kuder, E. Diamond, and D. Zytowski
Strong Interest Inventory (SII)	E. K. Strong, Jr., D. P. Campbell, and J. Hansen
Self-Directed Search (SDS)	J. L. Holland
Vocational Interest Inventory (VII)	P. W. Lunneborg

stability of interests across time as measured by popular vocational interest inventories. This review found that vocational interests remain relatively stable over time, and in fact, show even greater stability than measures of personality traits between early adolescence and early adulthood. According to this review, stability of interests rises steadily from early adolescence, and peaks in early adulthood, declining somewhat between 29 and 40. Of the six categories of interests in the Holland classification system, Realistic and Artistic interests showed the greatest stability over time. When the interest classification system developed by Kuder was examined, Artistic interests again showed the greatest stability, followed by Mechanical, Musical, and Scientific interests. The bulk of the research indicates that areas of interest, whether described by the Holland and Kuder classification systems, are stable, trait-like features within individuals.

Gender Differences in Interests

Early interest inventories were developed for men only. Specific but separate scales were later developed for women under the assumption that there was little overlap between the occupations chosen by men and women. Even when instruments that combined tests for men and women were introduced, groups such as the American College Testing Program (ACT), argued that items within certain occupation scales were still heavily weighted toward one sex or the other. The ACT asserted that interest inventories could provide a means of exploring the world of possible occupations and thus should be instruments for social change and equality in addition to providing personal information on career choice. Such a role for interest inventories would mandate that they be scored similarly for both men and women. Other researchers, including Holland, believed that interests are partially the result of the different socialization of men and women and that standardizing the scale scores for both sexes would affect the validity of the inventories. In 1981, the ACT released a unisex version of its interest inventory, in which items that substantially differentiated the sexes were removed. A recent study indicated that women who take both the ACT test and one of several other inventories based on the Holland classification system are likely to receive very different scores on the interest scales. These findings have led to a debate in vocational psychology, with some researchers applauding the unisex model and others suggesting that the removal of sex-weighted items substantially dilutes the underlying category descriptions and blurs them to the point that they no longer convey meaningful information.

Traditionally, women have shown interest in careers that are geared toward working with other people, while men have shown more interest in working with data and things. The Holland hexagon can be roughly divided in half based on a preference for working with people (Social, Enterprising, and Artistic categories) or working with things (Realistic, Investigative, and Conventional categories). A meta-analysis conducted in 2009 by Rong Su, James Rounds, and Patrick Armstrong examined studies in which over 500 000 men and women had completed interest inventories. The results indicated that there continue to be substantial differences between the interests of men and women despite the opening of many previously male-dominated occupations to women. This analysis

indicated that women across many age cohorts tended to prefer interests in the Social, Artistic, and Enterprising categories, as predicted by former research, while men overwhelmingly preferred interests in the Realistic and Investigative categories. Further, men demonstrated substantially more interest in the so-called STEM fields (science, technology, engineering, and mathematics) than women. Although there was somewhat more interest in the STEM fields in younger rather than older women, the difference was not significant enough to indicate a major trend, suggesting that differences in interest – rather than ability or opportunity – may explain the lack of parity in these fields.

In summary, vocation-based interest inventories have been in existence since the early 1900s. Most of them are commercial in nature. The main premise of these inventories is that matching individual interests to the qualities of the work environment will result in greater job satisfaction and performance. This premise appears to be empirically supported. The most popular systems of categorizing interests show substantial overlap, suggesting that the categories have validity. Current issues in the ongoing development of interest inventories include the handling of gender differences in occupational interests, the development of inventories that serve specialized groups of individuals, and the updating of job descriptions and interest items to reflect the rapidly changing technology of the twenty-first century.

Education-Based Creative Interest Inventories

As with vocation-based interest inventories, education-based inventories have a variety of uses. Understanding a child's creative interests may assist teachers in determining the best ways to help an individual child learn new material. When students can be directed toward materials that stimulate their prepotent interests, they are likely to remain engaged in school. Identifying a child's interests at an early age may also help educators and parents to guide children toward activities and educational choices that will be more rewarding for the child.

Interest inventories may also assess creative interests in children for the purpose of early identification of possible career trajectories that are impacted by educational decisions. For example, identified interests may affect a student's choice of high schools, electives, and clubs and summer programs. Results of interest inventories may also be used for early identification of creative giftedness. In some cases, inventory scores may be used as a partial basis for selection to gifted child or extra-curricular school programs. One assumption of such inventories is that the child who is interested in creative endeavors will be intrinsically motivated to take advantage of the skills and opportunities afforded by special programs, and thus will be more likely to be successful in such programs.

Many of the interest inventories designed to test children are based on the 'characteristics approach' to assessment. The assumption of this approach is that creative people share common interests, behaviors, and personality traits. Therefore, determining how closely an individual's interests match those of most creative persons is a valid way to assess creativity. Many gifted programs of the 1950s and 1960s relied on teacher

Table 2 Examples of education-based interest inventories

<i>Name of inventory</i>	<i>Author(s)</i>	<i>Age range</i>
Creative Activities Checklist	M. Runco	Grades 4–8
Creative Perception Inventory	E. P. Torrance and J. Khatena	Grades 4–12
Group Inventory for Finding Interests	G. A. Davis and S. Rimm	Grades 6–12
The Interest-A-Lyzer	J. S. Renzulli	Grades 3–12
Preschool and Kindergarten Interest Descriptor	S. Rimm	Pre-k and k

evaluations or school achievement as selection criteria. Research indicated that this form of selection lacked validity and reliability, with many potentially creative students being omitted from the selection process. Therefore, a number of psychologists have advocated for using instruments that identify creative children based on their creative interests and behaviors as well as on their school performance.

Education-based interest inventories are delivered in several formats. Inventories geared toward very young children can be completed by an observer of the child, such as a teacher or parent. Inventories for elementary school children may be picture based to account for differences in reading levels. The assessments may consist of open-ended questions ('what is your favorite activity at school?'), forced choice items ('I prefer to work alone' versus 'I prefer to work in a group'), or Likert-type items that rate activities on a never-sometimes-always scale. While most inventories are available in paper-and-pencil format, many are now available as internet programs with automatic, immediately available scoring. **Table 2** lists examples of interest inventories designed primarily for educational use.

Research using education-based creative interest inventories has reported four significant findings: first, reliability of interest inventories increases with age. Thus, instruments that assess preschoolers are less reliable than those that assess middle schoolers or high schoolers. Second, children who later enter creative occupations display interest in creative activities, such as art, writing, and investigative pursuits, early in life. Third, children who later enter creative occupations also display a wider range of interests than children who later choose less creative occupations. Finally, education-based interest inventories display greater predictive validity when used in conjunction with at least one other form of creativity assessment.

Research-Based Creative Interest Inventories

In addition to inventories measuring creative interests in children and vocational interests in adolescents and adults, a set of inventories has also been developed for use in psychological research settings. These inventories are based on the premise that future creative behavior is best predicted by past creative behavior and interest. One of the most widely replicated findings in the field of creativity research is that highly creative individuals are intrinsically motivated. Intrinsic interest in creative activity appears to be the motivating force behind much creative work. Because creative interest is necessary for high creative performance, creative interest scores are often treated as a measure of creativity.

Description of Research-Based Creative Interest Inventories

Creative interest inventories used in research are self-report measures that generally consist of checklists of activities ('I like to invent things,' 'I like to write stories'). Self-report inventories have a number of advantages over other forms of creativity measurement. First, they are quick and easy to complete. Second, they avoid the time and expense of engaging expert raters. Finally, they are suitable for internet administration, and therefore avoid the necessity of testing participants in a lab setting. Unlike the vocational and education-based interest inventories, most of the research-based instruments are not commercial in nature.

Some of the creative interest inventories developed for research combine items concerning creative interest with items assessing creative achievement. For instance, a checklist developed by researcher Dennis Hocevar for use with college-age subjects, combines items that assess participation in creative activities (e.g., 'participated in a dance workshop') with items that assess actual achievements (e.g., 'received an award for acting'). Similarly, a measure developed by Holland and Robert Nichols combines items assessing creative interests (e.g., 'drawing cartoons') with achievement items (e.g., 'invented a patentable device'). **Table 3** lists several creative interest inventories developed for research.

Relationship of Creative Interest to Other Measures of Creativity

If creative interest inventories are indeed a valid method of assessing creativity, they should demonstrate moderate correlations with other assessments of creativity. Creativity is often measured by tests of creative achievement, divergent thinking, and creative personality. In fact, several studies indicate that scores on creative interest inventories are indeed related to creative achievement in high school and college students. Creative interests in childhood predict teacher ratings of creativity in high school. Creative interests in high school predict both teacher ratings and self-report lists of creative accomplishments in college. As was indicated in research using vocational interest inventories, investigations using research inventories confirms that creative interests tend to remain stable throughout childhood and early adulthood and to predict creative pursuits in college.

Divergent thinking is a type of cognition in which the contents of memory and perception are employed to generate a large variety and quantity of solutions from an open-ended source or starting point. The ability to think divergently has been associated with creative potential; tests of divergent

Table 3 Examples of research-based creative interest assessments

Name of inventory	Author(s)	Year
ALPHA-Biological Inventory	C. W. Taylor and R. L. Ellison	1972
Biographical Inventory – Creative	A. A. Anastasi and C. E. Schaefer	1969
Creative Behavior Inventory	D. Hocevar	1979
Lifetime Creativity Scale	R. Richards, D. Kinney, et al.	1988
Potential Achievement Scales	J. L. Holland and R. C. Nichols	1964

thinking have been used as a measure of trait creativity. In general, scores of creative interest inventories do not correlate highly with measures of divergent thinking, although both types of measures have validity as markers of creative achievement. Researchers suggest that divergent thinking ability and creative interests may tap into two different facets of the creative achievement construct that, while unrelated to each other, are both necessary for high creative achievement.

Other work has demonstrated a positive and significant correlation between scores on a creative interest inventory and expert ratings of creative drawings. Inventories have also been associated with the personality trait openness to experience, the trait most predictive of creativity.

Creative interest inventories are rarely used as the sole measure of creativity in research. However, when combined with checklists of creative achievements or with other creative assessments, they may be valid indicators of creative potential.

Conclusions

Interest inventories have been constructed for a variety of purposes. Vocation-based interest inventories comprise the largest category of such assessments, followed by education-based and research-based interest inventories. Vocation inventories compare an individual's interests to those of large samples of people across many different occupations. A large body of research indicates that most interests fall into six categories that can be described as Realistic, Investigative, Artistic, Social, Enterprising, and Conventional. While interests in general are relatively stable across time, interests in the domains associated with artistic creativity are even more stable across the lifespan than most other types of interests. Stable differences in interests and careers choices also exist between the sexes. Women tend to endorse interests that include other people while men endorse interests that involve data and things. Careers

associated with creative and artistic interests are more common in women than in men.

Education-based interest inventories indicate that early childhood interests predict high school and college creative achievement as measured by teacher ratings. Creative interest inventories used in research are associated with creative achievement and creative personality measures, but only modestly associated with measures of divergent thinking. Because intrinsic motivation, or intrinsic interest in creative activities, is highly correlated with creative production, inventories that assess creative interests may be tapping into the motivational core of creative activity.

Intuition

What Is Intuition?

Intuition, in its most characteristic manifestation, occurs when a person apprehends a course of action, solution to a problem, idea, or feeling, in an immediate fashion (often in a pressure situation), without necessarily knowing from where or how the notion arose. (In this sense intuition is kindred to insight, and may be fostered by incubation – and both insight and incubation are separate topics of this encyclopedia.) However, in the case of intuition, it is logically possible that the apprehended knowledge was potentially available to the person, and stored within his or her neural makeup at all previous times. Because of the disparity between the often stimulating and rich experience of having an intuition and the relatively sparse and unsatisfying early attempts at scientific explanation of this phenomenon, many diverse and colourful views of intuition have emerged with ardent adherents to accompany each of them.

In arguably the sparsest view of intuition, people simply draw, without awareness, on their previously stored (but dormant) learning and knowledge in order to make a snap decision. This would be somewhat like the procedural knowledge of riding a bike. When we ride a bike, we don't think about all the things we have to do and know to ride, but the knowledge is there if we need to think about it.

At the opposite extreme is the view that intuition is exogenous to the individual. That is to say, that God, the universe, some other (perhaps even impersonal) force, or the situation itself imparts knowledge to a person in a discrete and mysterious way and the person can then use that knowledge to guide his or her behavior. This is actually the derivation of the word inspiration – a synonym of intuition when it is defined in this fashion. Intuition is generally regarded as a discrete, concise, and rapid acquisition of a piece of knowledge or feeling, whereas inspiration is usually prolonged, has a motivational component, and is arguably less specific. Another view of intuition that we have included under the banner of 'mystical' is the belief that the acquired piece of knowledge comes from 'nowhere.' This belief (although often latent) that the intuition came from 'nowhere' is critical to, arguably the majority definition of intuition, because, as soon as an individual believes that the knowledge is endogenous it means that the knowledge was acquired by remembering – even if the pathway to the knowledge is long forgotten.

A middle view is that the individual's neural system takes partial information from experience and the environment and generates heretofore unrealized possibilities and then selects the 'best' solution to present to consciousness. Exactly how this selection and presentation is made to consciousness remains a mystery. Of course there is also every gradation of this hypothesized continuum of views about intuition, and others that do not fit on this continuum at all. For the sake of brevity these three views are considered here as the three major views of intuition as they are broadly representative.

These three views all have relative strengths. Whereas the first view is the most amenable to scientific investigation and is supported by empirical evidence, the mystical view has been espoused by many of the world's great artists as well as scientists when they claimed to have constructed their works through intuitions and insights that were 'given' to them from something 'outside' of themselves. Whether or not their explanations are correct, any comprehensive account of creativity must be able to explain the experience reported by these creators.

The middle view is the way that some neuroscientists think the brain should work. Whilst this cannot at present be fully substantiated, there is growing empirical evidence to support the view that the brain does in fact work by constantly generating new combinations of associative neuronal firing.

The Ubiquitous Nature of Intuition

Consider the following scenario. You are buying your first home, you have selected three finalists, all of them have pros and cons and following weeks of scrutinizing research, deliberation, meetings with bank managers, meetings with architects – a decision has to be made. How do you choose? Many researchers argue that the final push to action is intuitive. That is, at the final stage, a rational deliberative decision is beyond the ken of the individual and the decision is made by attending to one's gut feeling – in other words, through intuition. This view is both abrasive and obvious at the same time. It does not seem right that important decisions in our lives are made nonrationally, but, at the same time, how else can we decide between alternatives that do not share a similar quantitative nature?

The other interesting thing about this phenomenon is that people almost always have a retrospective rationale for their decision that does not rely on intuition. For example people may firmly believe their post-hoc explanation – "The house that faced away from the sun was \$25,000 cheaper – it was better value" when in fact their decision was made because they had a moment of feeling at ease in the chosen property when standing in the sun. It appears that for the most part we are not comfortable acknowledging that we base decisions on feelings, and that intuition is an everyday practice.

Decision Making

People often make decisions without thinking about them. (It can be argued that most of our decisions are made this way.) In various experimental settings, when people are asked why they made the decision they did, they often respond that they do not know or that it seemed the 'right' thing to do, without being able to give a cogent account of a reasoning process that accompanied their answers. This process satisfies most of the definitions of intuition. What is perhaps more amazing is that

these decisions, at least under some circumstances, outperform people's conscious deliberations.

Highlighted in the previous paragraphs, the learning approach to intuition takes the view that all experience, about any and all situations, is compounded and therefore an intuition is based on a complex of all of these, often resulting in very accurate and good decisions. In this sense we may be building up potential 'intuitions' about all the experiences that we have. Thus, a novice chess player has little experience to draw on and therefore has little intuition about her moves and they are often wrong, resulting in poor playing ability. In contrast, an experienced player has a wealth of experience and can draw on many similar moves that have been successful in the past. The chess grand-master, Capablanca once said that when playing chess he sees only one move – always the best one. In other words, Capablanca did not consciously evaluate every possible move; his expertise and vast experience somehow enabled him to simply see and select the 'best' move. This statement raises many questions. First, given how poor we are at analyzing our internal workings, we must ask whether Capablanca's account is accurate. Second, is his process conscious or nonconscious? Third, if he only saw the 'best' move, by what process were all the other moves hidden? Or, inversely, how was the 'best' move revealed to consciousness? Unfortunately, although fascinating to ponder, these questions are not able to be answered without further information.

Several things need to be considered that may be weaknesses in the learning theory view of intuition. First, as mentioned before, people often do very well by acting on intuition, but in some cases they actually do better than when they make considered rational decisions. That is, their intuitive decisions outperform their choices made when they are given consideration time. This is not evidence against the learning theory approach, per se, but it does demand an explanation of the neural process that allows the best choice to be observable to consciousness whereas all the other reasoning is unconscious, as is illustrated by the Capablanca quote. That is to say, in these situations, the unconscious 'agent' that makes these decisions appears to do an exceptional job of choosing between alternatives. By what process is this 'agent' able to do this? In Capablanca's example this 'agent' is able to do this supra-rational processing at lightning fast speed. The further this line of investigation is taken the more the explanation begins to resemble the mystical interpretation of intuition.

Second, there is evidence that when the human nervous system is presented with any problem it will start generating alternatives. This may be a deeply embedded functional facility. Thus the stored knowledge of the nervous system may not be as important as its lightning fast ability to generate alternatives, perhaps without our being conscious of everything that is being generated. Some have argued that this is, in fact, the basis of creativity and the thing that separates the highly creative person from the less creative person is not their ability to generate creative ideas, (they are legion), but their ability to discriminate, and therefore act upon, the best ideas amongst all the ideas that they generate.

The study of firefighters does not provide consistent support for the view that intuition is the result of previous learning. In many emergency situations where there is too much information accruing too rapidly to process rationally,

decisions, nonetheless, still have to be made. Many studies have shown that it is better to make decisions, even when a percentage of them are wrong, than not to make decisions quickly enough or at all. Fire-fighters must rely on intuition because they simply do not have enough time to rationally consider each action they take. Studies of Australian firefighters have revealed that, in most cases, intuiting serves the fire-fighters very well. But when fire is going uphill with a breeze behind it, they (and members of the general public) systematically and drastically underestimate the speed at which the fire travels. This can lead to dire consequences. It appears that we have some sort of heuristic about the speed of fire, one that is difficult to over-ride even for firefighters who have witnessed fires moving up-hill. This evidence provides some support for the learning theory of intuition. On the one hand the fire-fighters, for the most part, seem to be using intuition as an effective tool. However, if intuition is only the accumulation of learned experience why does a persistent and stable error occur in the calculation of uphill fires despite prior experiential learning to the contrary? This provides some evidence that cognitive heuristics, that may be generalized, or 'hardwired,' play a part in the intuitive decision making process.

Are There Different Forms of Intuition?

Not surprisingly, the question of whether there are different forms of intuition can be tackled from several different perspectives – empirically, theoretically, and phenomenologically. The preceding paragraphs have suggested that, at the least, people have very different definitions of what intuition is and consequently from where it is derived. But are there different types of intuition in which individuals vary in their abilities? For instance, is there such a thing as emotional intuition, gambling intuition, mechanical intuition, artistic or scientific intuition?

It is conceivable that intellectual abilities may be less relevant for intuition than a person's interests and drives. Arguably this could be read as there being more than one form of intuition. Just as it has been argued (controversially) that there are multiple forms of intelligence operating independently of one another (practical, linguistic, spatial, musical, creative, emotional to name but a few), there may be different forms of intuition. Some people are reliably accurate at intuiting practical decisions while at the same time being unable to anticipate their partner's emotional needs. Other people can read emotional situations and intuit how best to respond with little effort yet find it impossibly hard to intuit which business opportunity is more likely to succeed or which new car to purchase. Does this justify there being different forms of intuition? People might differ in their intuitive abilities even when they do not differ in other cognitive abilities.

There is good empirical evidence that some people are very successful (and many, many more that are very bad) gamblers. Given this fact, one is faced with two possible explanations – first, the successful gamblers are just at the lucky end of a distribution of probabilities, that is somebody has to be the luckiest gambler, as evidenced by their winning streaks. Or, that successful gamblers actually have an ability that predicates that they will continue to be successful, because of something

they have learned, developed, or acquired in some fashion. Is this a form of intuition? They are, after all, trying to predict future events.

Another puzzling phenomenological argument can be made from occurrences throughout history, where people have come up with scientific theories apparently *ex nihilo* that turn out to be correct. Newton's theory of gravity is one oft-cited example of this. The pertinent point about Newton's theory is that before he espoused it, there was no such thing as 'gravity' – at least not in the mind of any human being on the planet – how on earth, pardon the pun, did he manage to come up with not only the idea, but a formula that accurately predicted the behavior of celestial bodies (previously considered inviolate and purely isolated) acting on one another? There was no precedent or prior learning in Newton's day adequate to even inform his theories.

Scientists such as Richard Feynman are famous for reliably coming up with solutions to problems that have no prior precedence, or foundation, from which they could have been built upon. The impact of these anecdotes is somewhat tempered by the fact that it is always a person who has experience in the particular field that comes up with these amazing breakthroughs; however, does this mitigate the intuitive nature of these breakthroughs?

In addition, confidence or certainty seem to mediate the form or type of an intuition or whether people consider something to qualify as an intuition at all. For example if we are absolutely certain of something we tend to regard this as 'knowledge,' even if we do not know how, or why, we came to the particular understanding. For instance, let us return to the example of riding a bike. Few people, can articulate, how to ride a bike apart from pushing the pedals (and steering the handlebars which is in large part fallacious). Yet, there is really quite a lot of knowledge that goes along with riding a bike, yet no-one really thinks they have an intuition of how to ride a bike. We are just certain that we can. We are certain that we do know all of the procedural knowledge even if we are unaware of what it is until we get on the bike. There are many other examples in the human experience which follow this pattern, such as (in some cases) religious views, political persuasion, and sexual orientation.

Can Intuition Be Learned?

It has been suggested that while some intuitions are formed by experience without formal instruction, other intuitions are learned within specific learning environments. Under this model, ability relies on both intuition and logical thought processes. Logical thought processes are a learned ability. Learning can thus be seen to influence intuitive assessments and intuitive decision making which suggests that there may be rules by which people can gain the relevant intuitions that affect or guide their behavior. From this learning approach it is implied that people have the ability to improve their intuition by attending to, learning and understanding the circumstances and environment involved in, or affected by, their decisions. Research indicates that this view is supported, at least anecdotally, within vocational domains. For instance, senior police state that 'rookies' become better officers as they develop their

intuitive abilities. This is interesting because it indicates that senior police believe that they use intuition to perform their various duties advantageously and that they also believe that this intuitive ability can be learned.

Intuition may be based upon domain – or vocation – specific latent thinking whereby our store of knowledge is somehow assembled into a framework from which a solution can be arrived at unconsciously by accessing memory and emotional pathways. This framework appears to follow some form of processing refinement as intuition is thought to improve with age and experience. Increasing knowledge, experience of diverse situations, and emotional responses each contribute to expand the framework through which intuition may result. This theory of intuition as a latent store of knowledge suggests that intuition may be underlaid by implicit, as opposed to explicit, learning processes. Again this view leaves a lot that is yet to be explained.

Further support of the theory of a store of latent, unconscious knowledge contributing to intuitive processes comes from research findings that explicitly attempting to learn a sequence may interfere with implicit learning. The more that is known about the subject or object of interest, the more information there will be available for selection.

Maintaining coherent attention toward the object of interest may allow access to implicit knowledge and, hence, the intuitive foreknowledge about the object of interest. For example, research into how mathematicians develop knowledge has shown that the majority of mathematicians interviewed state that intuition or insight is a necessary component for developing knowledge. This gives some indication that mathematicians are at least partially aware of how important implicit learning is to their discipline.

Learning and intuition can be seen as a bidirectional relationship with learning influencing intuitive abilities and intuition adding to, and expanding on, knowledge.

Neuroscientific research suggests that learning can occur via two distinct systems – a hippocampus-based system involving explicit learning and memory, and a system which is more dependent on the brain's reward mechanisms which is more implicit (and potentially intuitive). By knocking out explicit memory through the use of drugs which interfere with hippocampal processes (specifically Midazolam – a sedative), it has been demonstrated that, as a result, memory based on intuition has been enhanced. These findings suggest that implicit reward-association decisions are dissociable from explicit forms of decision making. In other words, when explicit memory is inhibited or fails, it may be useful to rely on implicitly learned memories to guide decisions and this may manifest to us as the experience of an intuition.

Intuition and Entrepreneurship

Investigations into the processes adopted by entrepreneurs conclude that there may not only be a place for thorough, in-depth research but also for intuition in risk-taking decisions. Under this model, research would allow for analysis of all the options which may then enable intuition to occur. Years of experience, expertise or extensive research may give decision-makers the confidence to move beyond speculation. It has been demonstrated experimentally that, when making decisions or trying to

come up with creative ideas, people should trust their hunches. This may be because hunches, or intuitions, might be based on past experience not consciously drawn on, or unconscious knowledge. Studies suggest that successful entrepreneurs permit themselves to depend more on their intuitive responses in order to identify and exploit opportunities. Intuition might therefore be seen to permit clarity of thought, decrease uncertainty, hasten the decision-making process, and provide valid solutions.

However, if one accepts the role of unconscious processing in intuition, over-researching and over-analyzing may hinder creativity by not permitting intuition the freedom to express itself. This counter-intuitive idea has garnered some empirical support. While it seems clear that having experience in a given field exposes one to more suitable options, it may also be that experience can be a constraining factor by limiting choices. In some situations, having little knowledge permits consideration of a wider range of possibilities. For both experts and laypersons, intuition may be aided by the process of incubation.

Entrepreneurs are inevitably exposed to both risk and uncertainty due to the fact that their endeavors are new. In this sense intuition is not simply something that entrepreneurs are forced to utilize but is probably an ability which is capable of discriminating between them. Some researchers argue that bold intuition is vital to young organizations with limited resources, and largely contributes to their ability to survive in a competitive market place.

Why Is Intuition Important for Creativity?

It has been argued that intuition is the key process by which creativity flows. Theorists who have made such bold claims often state that originality is a prerequisite of creativity and that intuition is the foundation of originality. Creativity, as a cursory investigation will reveal, is hard to define. However, some of its negative attributes are relatively easy to identify. For instance, it is often argued that if something is not original then it is not creative. It follows therefore that intuitive generativity has a good chance of being creative, because it does not follow a consciously deductive path and is therefore more likely to be original because it does not build on something that is already 'known.' If one is following a logical process then one will end up with a determined result. A facile analogy may serve to illustrate this point. Despite the quality of the end product, we would not consider someone who had painted a masterpiece using 'color by numbers' to be creative. Nor would we consider somebody who copied a masterpiece, however faithfully, to have created a masterpiece. And it is arguable whether a master themselves, having arrived upon a formula for producing beautiful work, when reenacting this formula, is actually being truly creative. Rather, we are committed to the idea, at least in the purest stance, that for artists to be creative, he or she, must be engaging in a largely intuitive process – responding to what they feel or are inspired by rather than what they know. However, this line of reasoning fails when one considers the artist who uses rational thought processes to arrive at a creative end. Such cases are common. The purist might argue that the 'creative end' in question is not truly original, or that if it is that it cannot be explained by the rational thought processes which preceded it. Such arguments

quickly end up on indefensible ground. It is easy to recognize something that is not original but very difficult to establish that something is truly original. Many theorists, since the creative process was first analyzed, have tried to avoid (or alternately highlight) these problems by suggesting that the only reliable indicator of creativity is the creative product itself. Nonetheless, a dispassionate assessment of the evidence suggests that intuition may not be necessary for creativity, even if it is considered sufficient.

It should be noted that the idea that intuition is central to creativity can be accommodated by the three major views of creativity considered in this article. Under the learning view, the artist is drawing upon all of her or his past experience, knowledge and talent, but they generate new and original work because the context, environment, and their own state are different. The neural view obviously generates new solutions by definition and the mystical view suggests that the ideas are truly novel because they are received without precedent. Many, eminent theorists (such as C. G. Jung), have stated the importance of intuition to creativity, suggesting that creativity develops from the generative interplay between intuition, the senses, feeling and thinking functions. In this respect the creative act involves the engagement of the majority, if not all, of our cognitive faculties, and intuition is a sort of fluid force that guides the action, allowing synthesis, but also the eradication of things that don't work. In a sense intuition is over-arching and constantly re-iterative. One might have an intuition that combining static knowledge with a feeling state or emotional memory will result in some creative outcome, and this can be tested again and again as the process unravels. Recent experiments have shown that intuitive perception of a future event is related to the degree of emotional significance of that event, whereby, the brain processes an emotional response that triggers cardiac involvement (and perhaps feedback), to the anticipated situation. Intuition may guide specific actions, and at the end, may provide the feelings about how successful the creative outcome is. Therefore mood may play a role in intuition.

Mood and Intuition

People differ in the way they make decisions. Some consider intuition to be an affective style of choice rather than a separate cognitive process. The role of affect in decision making literature has become increasingly important. When examining the effect of mood on intuition, it has been found that some mood states may have their effects on original insights and ideas because of enhanced cognitive flexibility, whereas others have their effects because of enhanced cognitive persistence. Positive moods relate to more creativity than negative moods, but this effect is limited to originality and fluency and has not been found to extend explicitly to intuition, insight, or flexibility.

As stated previously, studies suggest that creative people may be distinguished more by interests, attitudes, and drives than by intellectual abilities. It remains unclear whether these characteristics are consequents or determinants of creativity. Above-average, and the effective use of, intelligence, production of unusual/appropriate ideas, exceptional memory, ideational fluency, ability to synthesize disparate ideas, and general cognitive flexibility are all cognitive abilities which appear to indicate an

increased likelihood of a person being creative. (It might also be noted that they can all be construed as examples of creativity as opposed to abilities, somewhat mitigating the predictive validity of such notions). Interestingly, it is the findings regarding personality capacities that have discriminatory impact when investigating intuition and creativity. These studies suggest that a differentiating factor which specifically characterizes the creative from the noncreative subject is their relative lack of the use of repression for impulse and imagery control. It is this absence of self-defensiveness which may allow the creative subject wider access to both conscious and unconscious experiences, both of which are thought to be essential elements of intuition.

Processes Underlying Representative Views of Intuition

Under the mystical view there is not a lot that can be explained scientifically about the way in which intuition works, at least not in an internally consistent way with the paradigm. If intuition is supplied exogenously (or indeed from nowhere) then a study of the agent that supplied the intuition is required in order to elucidate the process. If one takes the view that it is mysteriously supplied, then by definition this process is ineffable and (at least mostly) unknowable. This is not to suggest that these topics are not worth pursuing, it is simply that they, like many other of humanities most intriguing questions, are not amenable to scientific practice in its current state. Indeed, a large number of scientists believe that this holds true for creativity as a whole. The result is that, at present when examining the mystical viewpoint, we are forced to rely on the anecdotal accounts of those who have received intuition or inspiration. These accounts are expansive, rich and heterogenous (and almost invariably interesting). But how is one to scientifically scrutinize these accounts? For example, what is one to do with Paul McCartney's account of how he wrote the melody for the most re-recorded song in history – *Yesterday*. McCartney apparently composed the entire melody in a dream one night. Upon waking he hurried to a piano in order to play it and thus avoid forgetting it. (For the sake of brevity, we will leave aside the process of dreaming, its purpose and creative potential, if interested see the article *Dreams and Creativity* in this encyclopedia.) His response to this event is fascinating to our topic. McCartney was initially concerned that he had subconsciously plagiarized someone else's work. He repeatedly played it to people in the music industry to see if they recognized the tune and eventually concluded that as no-one had claimed it, it must be his.

We can conclude several things from this if we take McCartney's account to be accurate. First, the song came to him as if it were from another composer (that is plagiarized). It 'felt' as though it were exogenous even though it turned out that it wasn't. Second, he was completely unaware of how (both regarding process and knowledge) he had written the melody. Third, when he sat down to manifest the creation for the first time it was complete.

It is interesting to examine how the learning theory approach might account for this anecdote. It would emphasize that McCartney had built up an extraordinary store of knowledge, feelings, and experience about musical melodies (in memory) and that these were, no doubt, drawn upon in

the composition of *Yesterday*. This assertion goes without challenge, but the learning theory approach appears incapable of explaining the motivation to action and the process by which the completely novel melody was generated, at least in this situation.

Perhaps we should turn to an examination of creative scientists, as they may have been interested in elucidating the processes by which their creative generativity occurs: amongst scientists, intuition is very often self-proclaimed as the starting point for many of their greatest scientific breakthroughs. Nobel laureates in various fields routinely explain their discoveries as starting from vague hunches, feelings, fleeting insights or 'out of the blue.' Their accounts abound with bizarre symbolism, and inchoate imagery, and indeed, ineffable experiences. What they lack is any clearer explanation of the creative process than artists are able to give us. The great discoveries are semi-explainable in some ways – they are the result of immersion in the problem field, immediate prompting by solution-oriented stimuli and are embedded in previous expert experience. Yet, although they are among the most venerated discoveries of our species, the process by which they were realized is often poorly understood, even by those that made the discoveries.

Interestingly, attempts have been made to study the phenomenological experience of intuitive creativity in an empirical manner. Generally experts within a field are selected and studied on a variety of tasks. Experts may have better mastery than lay-persons of key aspects of definable intuitive judgment such as: pattern recognition, similarity recognition, common-sense understanding, skilled know-how, sense of salience, and deliberative rationality. And often they exhibit these in laboratory settings. But, these experiments are limited by their ability to capture truly intuitive moments (as they are unpredictable) and also in their ability to study intuitions of great importance – for similar reasons.

Generative Creativity

There is emerging evidence that given any problem space the human brain will start generating possible alternative solutions. This evidence comes mainly from brain imaging studies and it is therefore hard to justify strong claims of its existence because of the correlatory nature of this evidence. However, it also accords well with anecdotal experience. Upon reflection, usually when one faces a problem it is not difficult to come up with solutions, it is simply that most of them are premature, simplistic, or wrong. The quantity of alternatives is not in question. The brain fires up enormous amounts of neural connections, combining different ideas and churning out combinations. The end result of this process may be that a lot of 'rejected' content never makes it to consciousness because it is inhibited. However, under this model it is claimed that a lot of content is generated. Creative people are seen as those who are able to take the content and assess it for what is best or most suitable for a purpose. Because this process may vary in its degree of conscious revelation it may account for the phenomenological experience of intuition. That is to say, previously unconscious ideas may bypass the normal process by which we are familiar with them entering into consciousness (whatever that may be!) and appear in consciousness apparently unbidden.

When considering the McCartney anecdote, this paradigm can partially explain the problem of why the melody was generated – the nervous system is geared to continually combine and recombine different patterns that result in an end product of ideas. However, it still cannot account for why new combinations are sought or valued, or how these neural resources are targeted and controlled. Again, it must be stressed that these areas of inquiry are in their infancy, and although it may appear we do not know much about the neural basis of intuition, we know a lot more than we did even two years ago.

No article on intuition is complete without a cursory examination of the psychic viewpoint. Way out on the fringe, some people believe that intuition is a psychic human ability that can be developed, whereby people can predict future events. Questionable empirical research has investigated this area. It has also been suggested that intuition is a psychic power that can be trained and improved. Certain parapsychologists have devoted careers to intuition training programs and the like, with results that are generally no better than chance. The most obvious value of these tests of intuition is that they are amusing. They can be easily located on the web (usually for a fee) if one is so inclined and one's putative intuitive ability can be measured. Interestingly, all of these rather dubious websites link intuition (and psychic abilities) to creativity.

Conclusion

Intuition is a fascinating and heterogeneous topic of study. There is abundant evidence that intuition is widely experienced, habitually acted upon, and extremely useful. However, people have highly different explanations about what actually accounts for the phenomenon. Previously, a considerable amount of scientists viewed the scientific study of intuition as impossible. They largely considered intuition to be a post-hoc fiction imposed upon the erratic experience of the individual and fueled by confirmation bias, Barnum effects, or other psychological phenomenon. This view has markedly changed. Increasing understanding of the human nervous system has revealed that abundant implicitly apprehended relationships affect conscious behavior (some extremists even argue that consciousness is an illusion that we experience after we have engaged in determined behavior). It is fairly safe to conclude then, (and on a sound scientific footing), that often, we act on 'good' and 'reliable' information somehow stored in our nervous system that we are consciously unaware of knowing completely, at least in the instant of action. This satisfies the most basic definition of intuition. Beyond this the neuroscience is fascinating, complex, variable and indeterminate (and advancing at an astronomical pace).

Intuition appears to be of central importance to creativity. It is likely that much creative behaviour is fuelled by experiences that are achieved when creators are engaged in – feeling, flow, disinhibition (experiences that are broadly akin to intuition), rather than consciously rational processes of method and recall and reasoning. Accordingly, what is experienced by the creative individual is commonly felt as an ineffable and inexplicable process that leads to their creative output. However, what is felt may be at odds with reality. The experience of exogenous inspiration may be a misattribution of erstwhile scientifically

explainable facts. If indeed, other worldly inspiration, was in fact, the cause of intuition, it almost follows by definition that there would not be scientifically measurable evidence to prove it. Again, this does not prove that this is (or is not) the true state of affairs.

Most people want to believe, when standing in front of their favorite painting or listening to their favorite song, that more occurred in its creation than the complex interaction of determined events. The actual works themselves appear to provide convincing evidence for more-than-rational processes. These works do more than entertain us, they move us emotionally, sometimes they make us feel connected to the universe, occasionally they even make us feel understood. There is no completely satisfactory account for how this is achieved. Within the bounds of science it would be reasonable to decide that due to a paucity of objective evidence we cannot conclude what the true nature of intuition is, nor can we determine its role in the creative process. Yet this conclusion appears to be unsatisfying to most people. If a definitive answer is desired then one must weigh up the evidence oneself, trying to reasonably balance what can be concluded from one's own direct experience with what can be considered objectively derived.

Glossary

Cognitive unconscious Sometimes called adaptive unconscious. Set of cognitive capacities that are not the result of conscious reasoning or deduction and that produces results that cannot be accounted for verbally. Examples are intuition, insight, and procedural learning. A likely explanation for these capacities is the process of pattern recognition.

Functional fixedness A category or cognitive set or mental structure that manifests in rigidity or lack of flexibility in disembodied components from a given field.

Intuition The apparent ability to know things without a rational explanation for this knowledge. In the context of invention, intuition may provide knowledge about the goodness of a proposed solution for a problem, a feeling of direction of where to search for a solution, or the awareness of an image or other type of association that hints at the structure of a solution.

Invention The creation of a new device, process, composition, or understanding. Novelty in invention can range from the improvement or variation of preexisting models or ideas, to a radical breakthrough that moves the boundaries of human experience. Generally four types of inventive products are distinguished. Technological invention, which refers to the conception of a new technological tool; scientific invention creates new understanding through the finding of patterns, regularities and mechanisms underlying phenomena in our world; artistic invention produces a new composition, in any modality, without a particular purpose or usefulness; cultural invention refers to the new habits and behaviors that appear in society that can have wide or limited spread. **Serendipity** The occurrence of a valuable or unplanned discovery, especially while looking for something entirely unrelated. This is as opposed to chance findings that are useful for the problem one is actually working on.

What Is Invention?

Definition of Invention

Invention is the creation of a new device, process, composition, or understanding. Novelty in invention can vary from the improvement or variation of preexisting models to ideas that are a radical breakthrough that shifts the boundaries of human experience. The importance of an invention can be assessed by taking three aspects into account:

1. The social impact: some invention will have little social impact, for example, a new bottle opener, whereas others, like mass production of cars, change our lives in every way.
2. The level of an invention: an invention can occur on a system level, for example, world wide web, or at a component level, for example, a new web browser. Inventions at a system level form the breeding ground for many other inventions. In art a new genre is an example of an invention at the system level.
3. Finally there is the dimension of knowledge extension, which refers to the amount of knowledge that is required to get to a certain invention. To get a first useful application in nano-technology, extensive research is required to get to the required 'what' knowledge. Getting to a new mobile phone design requires only a limited amount of 'how' knowledge.

Invention Versus Discovery

There is a longstanding debate whether creative products should be labeled as invention or discovery. A constructivist approach to the issue will argue that all knowledge is

man-made and thus should be considered invention. Other scholars have stressed the fact that new knowledge comes from the unveiling of inherent structure and possibilities and thus should be seen as discovery. Although the discussion is not settled in a deeply philosophical sense, most authors will agree that one can distinguish 'what' knowledge that is of the 'discovery-type' and 'how' knowledge of an 'invention-type.'

Products of Invention

Generally four types of inventive products are distinguished. The first one is technological invention, which refers to the conception of a new technological tool or device. These products are often commercial in nature and stem from a predetermined search to serve a practical purpose. Typically these inventions are patented.

Scientific invention refers to the finding of patterns, regularities, and mechanisms underlying phenomena in our world. Science in general is not guided by practical considerations but by the search for understanding in its widest sense. Some science may receive special funding when in areas that are expected to lead to useful inventions (e.g., microbiology).

Artistic invention has the least constraints on its products in the sense that they do not require a particular purpose or usefulness. Valued artistic invention often stems from professional activity, but unlike technological and scientific invention, is commonly produced by amateurs as well. The Internet has greatly stimulated artistic inventions (e.g., photography and blogging) since it provides a cheap means for publishing. Artistic products may have great commercial value, as can be seen for example with artists such as Damien Hirst, who sold his work for hundreds of millions of dollars at auctions and

Abba, who for several years were the biggest contributors to the Swedish GDP.

Cultural invention refers to the new habits and behaviors that appear in society. They can be of limited influence such as punk or gothic subcultures, or as widespread as environmentalism. They can be short-lived or mark an entire epoch like the Renaissance or the Enlightenment.

The distinction between these different inventive products is not absolute and they greatly influence each other. Science and technology are increasingly synergistic; often scientific invention leads to technological applications, and technological invention such as instruments, open up new areas for scientific inquiry. Artistic invention may inspire scientific invention; design synthesizes technological and artistic invention and several inventors were also artists. Technological invention such as the Internet or television can have a profound impact on the habits of our culture, and in turn culture can determine if certain artistic or scientific directions are promoted or hindered.

Invention as a Process

Many instances are known where decisive insight was reached in a single moment. Poincaré's insight into a mathematical problem he was working on while getting on the bus, Archimedes' eureka moment sitting in the bath, and Kekulé's revealing snake dream which set him on the idea of a circular structure of benzene, are examples of such insight. These insights seem to occur in idle moments that have been caricatured as the 3Bs: the bed, the bath, and the bus. These insights may be so important that an invention can be reduced to such a single moment. However, a long period of problem seeking, experimentation, searching, and many failures precede such insight and often more than one insightful breakthrough is needed. A lot of persistence is needed before such crucial understanding is turned into a fully worked out theory, useful product, or artistic realization. Darwin worked on his original idea for 30 years before he published it. An initial idea has to be developed, made into a prototype, tested, and improved before getting to a marketable product. Invention is thus the result of a long and complex process. Creators take around ten years before they produce their first major invention. The different emphasis on sudden insight versus invention as a long-term process is called the sudden-gradual controversy.

Factors Influencing Invention

Invention is not a singular event but is determined and promoted by a number of factors that operate in conjunction.

Role of Personality

Successful inventors are shown to possess a number of personality characteristics that seem to favor invention such as: passion, optimism, nonconformity, tolerance for ambiguity, and a tendency to embrace failure as a learning experience. Especially important is persistence and the capacity to delay gratification, since most inventions take many years to reach a useful,

marketable, or publishable form. On the other hand it has been argued that creative invention is in reach of everyone and several studies have shown a normal distribution of creative production and number of patented inventions. This controversy is called the special-ordinary discussion.

Role of Context

Purposes of invention vary depending on context. Invention may be driven by a specific need, for instance searching for a solution for an engine that breaks down repeatedly. But it can also stem from a general search for understanding as in fundamental science. Artistic invention may be solely for the pleasure of discovering and creating, or it could be for a commercial purpose such as a movie or theatrical production. Economically this aspect is called demand-pull where inventors respond to demands that exist in the marketplace. Other inventions are supply push, the invention is unforeseen and creates a market for itself, for example, Post-it notes. Still others are invented before there is any use, like the parachute that was invented before there were airplanes. Inventors working in an entrepreneurial context are required to produce profitable inventions, whereas inventors who work in a university setting are less so. Also the epoch we live in influences invention; da Vinci designed war engines, and recently the ecological dangers of economical progress has liberated funds for environmental studies. Thus social context influences what is fashionable, acceptable, and desirable in scientific and technological invention and, to a lesser degree in artistic invention. Finally the team context and other resources are important factors in determining the outcome of invention.

Role of Knowledge

All novelty is created through cognitive processes that build on existing knowledge. Something new may be invented through analogy, combination, or abstracting, but it always depends on existing knowledge. Effective inventors build on the knowledge that has accumulated over centuries. It is possible to invent, in the sense of creating novelty, with a limited knowledge base, but the result will usually be poor and of little use. As much as invention depends on prior knowledge it also requires stepping outside existing boundaries, and abandoning or challenging what is known. People have a natural tendency to look at problems in a habitual way and to become trapped in this conservative view, which is called functional fixedness. It is necessary to take a new approach, thinking outside the existing knowledge.

Role of Chance

Several instances are known where inventions were made by chance. The inventor was looking for something completely different but then discovered something unexpected, a phenomenon called serendipity; a famous example is the 3M Post-it notes, an unexpected application of a failed adhesive product. Errors can also lead to invention. The metallic color of plastic resulting from accidentally adding a thousand times too much of a catalyst led to the idea of exploring its metal-like properties, leading to a Nobel prize winning invention

of electrically conductive and light emitting plastic. Invention normally comes from planned activity, an inventor has a problem in mind that he wants to solve and he consciously uses a number of strategies to find a solution. Often inventors consciously expose themselves to unfamiliar perspectives or areas to be inspired by the unexpected. Other times chance has an important hand in the process, as in the well-known example of Pasteur's discovery of penicillin. But it can seldom be attributed entirely to luck, because chance favors the prepared mind, as Pasteur remarked himself. Many people may have seen the same phenomenon before, but didn't recognize its potential.

Cognitive Processes in Invention

Invention is neither a process of arduous problem solving, nor the fruit of sudden inspiration. Various processes simultaneously play an important role.

Conscious Processes

In invention various conscious steps can be identified. A first step is setting the objective or problem. In technological invention the inventor usually searches for a solution to an existing problem: how can I achieve *X*, or how can this be better, lighter, or faster? In artistic and scientific invention this phase is rather one of problem finding such as: how can I express *Y* or understand *Z*? Sometimes the major invention is in the finding of the problem itself, when discerning a problem or possibility that wasn't noticed before and that may have a very simple solution. One might think of paperclips or toilet paper, where the application is the invention rather than the product itself. The inventor will then investigate existing solutions and subsequently start generating his own ideas. The heuristics described later in this article refer predominantly to this phase. Not all ideas are useful or executable and some are better than others so that the inventor has to select from his ideas according to certain criteria of goodness. In science these will include attributes such as testability or parsimoniousness; in art originality and expressivity; in technological inventions manufacturing aspects and cost. Since no idea is ready first time around, in the final phase the inventor has to fine-tune his ideas shaping them into a useful final product.

Creative Cognitive Operations

Invention requires the creation of something new. In principle there are four cognitive operations that can be identified that create novelty. Application is the adaptive use of existing knowledge. Something already invented is adapted, or variations are introduced, to fit it to the necessities of the current context. A brilliant defense of a lawyer might be an example of such an invention; no new legal concepts are introduced, but the existing ones are used creatively to fit the case. The second creative operation is analogy, which uses transposition of a conceptual structure from one habitual context to another innovative context. Many examples can be found in chemistry and physics wherever a model is used, for example, the planetary model of the atom. In art, the importance of analogy can be found in styles like Impressionism or Surrealism that spread

to other art forms. The third operation is combination: the merging of two or more concepts into one new idea. This operation is also referred to as synthesis. Combination is especially relevant for technological invention, since many inventions are the result of bringing together existing elements in a useful and practical manner; think for instance about the manufacture of a car. In artistic invention combination can be seen when artists incorporate aspects of others' work into their own artistic styles. Finally the most radical novelty is created through abstraction. Abstraction is the invention of any structure or pattern that describes the relation between a number of different instances of a certain phenomenon. For instance young children primarily use abstraction to organize the concrete external world into interiorized mental concepts. Repeated exposure to objects leads to more abstract notions such as color, weight, or number. Abstraction is most prominent in scientific invention. A good example is Einstein's theory of relativity where the relation between time and space is redefined into a new higher abstraction in which time and space are part of the same entity.

Cognitive Unconscious

Although the effort to invent comes from a conscious determination, inventors report that many of their most important breakthroughs seem to come from processes that happen outside awareness. After conscious effort to solve the problem it is helpful to put the problem aside to allow for a process called incubation to happen, after which insight can pop up in consciousness. In the last two decades research has identified and demonstrated the importance of a number of unconscious cognitive processes which are relevant for invention. Patterns in complex data are detected unconsciously and cause procedural learning: subjects are able to decide correctly on a task without being able to give a verbal account of why or how they did it. On several complex tasks conscious reasoning has been shown to worsen people's decisions. Similarly, asking people to give a verbal account of their strategy worsened their capacity to problem solve. This interference of verbal accounts or conscious reasoning occurs especially in so-called insight problems rather than analytical problems. This makes unconscious processing especially relevant for invention, a process characterized by the occurrence of insights and lateral thinking.

Intuition

The most elusive of cognitive processes that are important for invention is intuition. Many inventors report being guided by hunches and inspirations that they cannot account for but that were absolutely essential to get to the final invention. There is no clear theory for the workings of intuition, but the most likely candidate is a process of unconscious pattern recognition. In general, some people seem to be more intuitive or rely more on intuition than others. Meyers-Briggs studies have indicated that highly creative people tend to be extremely intuitive.

However, intuition is also related to experience and expertise since experts develop a capacity for intuitive insight in their field over time.

Certainly three different types of intuition can be distinguished. The first is evaluative intuition. It tells us whether to

trust people and solutions or not. The inventor knows that he is 'on track', or that 'it doesn't feel right', or 'something is missing.' A good example is the mathematical intuition that predicts if a proof or solution can be arrived at through a certain method. A second type is directional intuition. It informs the inventor where to look for solutions. It can take the form of 'the problem must be in the ...' or 'I should look at the ...'. In working on the relativity theory Einstein started to investigate the notion of simultaneity, as if he knew that this notion would provide information for solving this problem. The wobbling movement of a soup plate fascinated the physicist Richard Feynman, but only much later did he discover that it was analogous to the atomic spin problem he was working on. Finally there is metaphorical intuition. In this type of intuition solutions come in analogical or symbolic form. The inventor spontaneously gets certain images, memories, poems, words, or even kinetic sensations that hint metaphorically at a new way of looking at the issue he is working on. Kekulé's dream of a snake that led him to hypothesize a circular structure for benzene is a famous example of this type of intuition.

Heuristics in Invention

There are a number of strategies or heuristics that inventors use to get at ideas and novelty for invention. They don't guarantee success but often lead to (partial) insights that are helpful to arrive at solutions for the inventive problem they are working on.

Subgoalting

Subgoalting refers to the breaking up of a problem into nearly independent parts that can be solved separately. This can facilitate complex inventive tasks. For instance the Wright brothers were able to achieve their flying machine by working separately on the problems of lift, control, and power. Partitioning a problem into parts can speed up invention in collaboration because it permits division of labor.

Variable and Feature Extraction

When trying to get a scientific understanding of some phenomenon, a good strategy is to identify the entities that vary. These variables often lead to vital clues to get to an invention. The inventor can now study these variables, and their covariance with other factors that may be manipulated. Especially studying extreme values of variables can provide important insights for scientific invention.

The correlate in technological invention is feature extraction. Features that may be identified are for example size, materials, and functions. This identification subsequently facilitates and systematizes operations such as elimination, adding on, combination, rearrangement, and scaling of these features. One might for instance think about the variations one could apply to the features of a chair such as number of legs, back support, adaptation possibilities in tilt and height rotations, materials or arm support. Another example of this heuristic is morphological analysis, where a system which is too complex to fully quantify first is broken down into parts; then the

system is simplified by dropping trivial components only using vital parts. The desired models or scenarios are created by only taking the contributions of the simplified system into account.

Analogizing

Searching for analogies has proven to be a fruitful strategy for invention. In order to do so inventors may deliberately read outside their field to find ideas. Other phenomena can function as metaphors for invention. Alexander Bell took inspiration from the curved spiral form in the human ear to invent his first telephone design. The concept of homeostasis was imported directly from chemical theory into family therapy. Analogy is different from similarity. Similarity refers to directly observable characteristics such as form or color; analogy to the abstract underlying structure. There is nothing similar between a musical instrumental and an atom. Yet the idea of musical intervals and harmonics served as an analogy for the quantum mechanics atomic model.

Exhaustive Search

A crude but sometimes successful strategy to get an invention is exhaustive search. It is questionable if this deserves to be qualified as a heuristic strategy but has certainly proven its worth. Edison tested hundreds of different materials to get a suitable one to serve as a glowing filament for the light bulb. Pharmaceutical companies roam the forests in search of new plant species to test for medicinal power.

Combining

Purposeful combination has led to important inventions. It may be done on a feature level like combining different functions in a cellphone, or making existing products with new materials. For instance, plastic and sophisticated polymers have been combined into products previously constructed with traditional materials such as metal, wood or glass. But also concepts and principles can be combined into new ones. For instance paleontologist Steven Jay Gould brought together the ideas of chance statistics with evolutionary theory to get to a deeper understanding of the development of life on earth. Picasso deliberately tried to incorporate primitive art in modern painting and sculpture. Two specific techniques based on this principle are homospatial thinking: imagining two or more discrete entities occupying the same space and Janusian thinking: conceiving two or more opposite or antithetical ideas, images, or concepts simultaneously. Finally there is the phenomenon of synesthesia: the interfusion of perceptual modalities such as color with sound or taste with form, which inspired artists especially poets, in their work.

Modeling

Four different types of models may be distinguished that are instrumental in invention: a physical model which displays the physical characteristics of a real object; a functional model capturing the essential operations of an object or mechanism; a theoretical model embodying the basic concepts governing

the operation of some process; and finally the imaginary model to display aspects or features of something we cannot observe directly. All models are abstractions in some way or another, which helps to understand, predict, or manipulate certain aspects of reality. Probably the most famous invention that came from a physical model was Crick and Watson's discovery of the double helix structure of DNA. Another instance was Gaudi's inverted models with strings to determine the required force of his architectural inventions. Chemistry and physics are replete with functional models that predict or describe characteristics or behavior of phenomena correctly, without having a complete understanding of the phenomenon.

Imaging

Imaging is prominent in every invention and has been equated by some authors to thinking itself. Visualizing structures or objects, fixed or in movement helps to get a deeper understanding of the workings of things, can inspire new ideas, and is a tool for testing certain aspects of inventions. The inventor may imagine how his new invention may look, its form, its color, how it will be used, how it moves, etc. A famous example of imaging are Einstein's thought experiments in which imagined traveling in trains, spaceships and on a photon helped him understand the theory of relativity. But imagining does not only refer to the visual but also to other modalities such as the auditory and kinesthetic and in rarer cases even taste and olfactory modalities. Apart from the visual modality, the kinesthetic seems especially important. This body or kinesthetic thinking is common in choreographers and sculptors. The sculpture Henry Moore said that in order to create he needed a deep feeling of the statue on a physical level, to feel the statue from within. But also in less obvious areas such as engineering and science, kinesthetic imagining has been reported as crucial. Several scientists that work on particles such as molecules, chemical reactions or atom interactions reported gaining insight by imagining physically being these particles. Cyril Smith working on metallic alloys reported that he creates a feeling of how he would behave as an alloy, how brittle, hard or conductive he would feel in a truly sensual way. Many engineers are known to imagine buildings or bridges from within, detecting design flaws from a proprioceptive and muscular sense of their structure.

Shifting Representations

Successful inventors are characterized by using a rich variety of representations to look at the problem at hand. They may draw charts, maps, and diagrams or use computer simulations; problems can be represented using colors, numbers, symbols, or mathematical equations. For instance the graphic representation of the elements in a two dimensional grid by Mendeleev was a crucial step in revealing patterns in the underlying characteristics of different atoms. Most importantly inventors shift representations swiftly to detect unnoticed possibilities, regularity and analogies. It helps to break free of fixed and conservative ways of thinking about the inventive problem one is working on. Shifts may be made from physical models,

functional or theoretical models. Inventors may also consciously try to shift perceptual modality, for instance from visual to kinesthetic or from kinesthetic to auditory. Imagining other perceptual modalities (e.g., What sound would molecules make?) can open up new ways of understanding an issue. Dimensional thinking refers to shifts in scale and dimension. The inventor can move from two-to three-dimensional representations and *vice versa*, and in some cases even higher dimensions. For instance, in understanding the structure of proteins, both second and third dimensions have been instrumental in perceiving mechanisms of protein folding. In art the effort of representing three dimensions simultaneously into the two dimensional surface led to cubism. Finally in scaling looking at objects from short and long distances can help to discover new properties or even regularities. This was the case in discovering fractal patterns in studying geographical maps at different scales.

Experimenting

Experimenting is an important tool in gathering new knowledge about phenomena. Certain aspects of reality may be manipulated in order to understand their causal influence. The simple question of 'what if,' may generate ideas and open possibilities and is the basis for trial and error learning. Variations of existing concepts and products may be tried out to get to better, faster, simpler, or cheaper products. No invention is complete when it is devised for the first time. It needs to be tested, improved and perfected to reach its final form. Numerous aircraft prototypes crashed in experiments before a proper flying one was invented. Experimenting can also be conducted in a mental way by using thought experiments. Observing can be considered an experiment without manipulation. Observation of natural phenomena, with or without the aid of instruments, can be inspirations for invention. The novelist Somerset Maugham said that it is essential for a writer to study men. The mind has to be trained to observe and detect the relevant cues from natural occurring phenomena.

Playing

Play is not only important for the infant to train and discover its capacities, but it is a creative force throughout our life. The pleasure and curiosity that are inherent to playing, motivate and inspire us to think outside the box. We experiment new things just for fun and to see what happens. Playing is a heuristic for invention since it leads the player to the unexpected. It may cause serendipitous or chance invention and lead to observations that may be instrumental in finding the way to invention. For some inventors such as Richard Feynman and Alexander Calder, play was a way of life. The mental modality of play is daydreaming.

Blockbusting

Many authors have argued that invention requires divergent or lateral thinking to break free from conventional and habitual ways of thinking. People have a natural tendency to look at

problems in a fixed way and to become trapped in a conservative view. Blockbusting is the conscious strategy to identify and overcome this functional fixedness. Key blocks are perceptual, emotional, cultural, and intellectual blocks. A typical perceptual block is stereotyping, where one can only look at something in a preconceived way. Emotional blocks can be found in the fear of failure or risk taking, and intolerance for insecurity. Intellectual blocks occur when one is too fixated on one's specialty, one type of solution, or not wanting to abandon certain dogmas or assumptions. Einstein demonstrated an intellectual block when he rejected quantum mechanics for esthetic reasons. Cultural blocks occur when an inventor does not consider solutions that are not currently fashionable or are politically incorrect. Many of the aforementioned heuristics, in one way or another, circumvent this type of block. Thus the inventor may analyze explicitly what limits he has put on the type of representation, materials, size, perceptual modality, modeling, etc.

Collaboration in Invention

Although some inventions have been conceived and executed by individuals, most inventions are done in collaboration.

Advantages of Collaboration

It is true that any idea has to rise from one mind for the first time, but collaboration is important in many ways. It offers a critical perspective, fosters spotting problems and opportunities and can promote divergent thinking. Both understanding the ideas of others, as well as the effort to explain one's ideas to others, are useful instruments to sharpen and progress in one's own ideas. The dialog between Picasso and Braque brought about cubism. In addition, collaboration can greatly increase inventive potential through the division of labor. Think for instance about the teams of the Manhattan Project that worked on developing the atomic bomb.

Types of Collaboration

Studies show that several types of collaborations can emerge. In distributive collaboration, collaboration does not go beyond the exchange of information and experience by partners who have a shared interest in a topic. Common examples are email, newsgroups, or meetings. Complementary collaboration is found in the work environment and derives from a role definition and division of labor. Finally integrated collaboration is often long-term and develops a more intimate and lasting exchange of ideas. This latter collaboration has the most potential for generating new ideas required for invention.

Roles in Collaboration

Within the collaborative process it is important to have individuals who can fulfill the following roles. Visionary roles: people with the courage and imagination to search out new problems and challenges and step out of the obvious. Often

these visionaries also possess charisma to motivate others to assist in realizing their dream. This is quite opposite to the organized and rational management role that includes planning, setting deadlines, allocation of resources and maintaining relations with funding and supervising institutional structures. Peer roles represent the horizontal relation of working together on a common issue, the exchange of ideas, critical analysis of each other's work and generation of new solutions. Leadership roles mediate between the task and team, and form a communicative factor. A specific role is the bridge role that is important when collaboration occurs at the interface between groups that have different institutional cultures. Group collaboration seems to last about ten years after which members go on solo careers (e.g., The Beatles) or regroup.

Conclusions

Invention as Indefinable

Our understanding of invention still has many gaps in large part due to some of its unconscious aspects.

A number of creative cognitive operations such as application, combination, analogy, and abstraction are known, but it may be debatable if a particular inventive product should be understood as the result of, for instance, an analogous operation or rather as a combination operation, or even if several operations were involved. We understand important characteristics of the process and heuristics that can be helpful, but many times it is difficult to understand what heuristics or processes have contributed to a particular invention. It is clear that some strategies such as imagination, Janusian, and homospatial thinking may stimulate hidden process of lateral thinking, but the process itself remains essentially hidden. Another gap in understanding is that from a number of ideas, inventors somehow consider only the most useful ideas, suggesting that there are some selection criteria at work of which little is known. Successful inventors are probably well aware of an underlying required structure they use to sieve out ideas.

Complementarity in Invention

When describing invention a number of factors appear that are complementary or dialectic in nature. Invention can be seen as a conscious process trying to solve a problem or trying to understand a phenomenon, experimenting solutions and heuristics to get to a satisfying solution. But inventors report that their most important breakthroughs seem to occur outside conscious awareness and intuitive inspiration and feel for direction are essential. Invention creates a new product or understanding but it is always based on structures of old knowledge. Invention is often a long, gradual process with sudden jumps of insight. It requires hard work and effort as well as letting go and idleness to allow for incubation to help new ideas arise. Ideas can only come up for the first time in one person, but the collaboration and human interaction is vital in promoting invention. On the one hand the inventor has to work purposefully towards a product; on the other hand periods of undirected play and distraction can promote chance findings. Invention seems to result from a

special giftedness in some, yet is also an ordinary capacity we all possess.

Invention Can Be Learned

Like any other human activity invention can be learned and optimized. Everybody can invent and practice can improve results. Inventors can work hard acquiring knowledge and skills that will enrich their base on which to build new solutions. Applying heuristics may help liberate the inventor from conventional paths opening the door to innovative and creative ideas.

Questions and conscious effort function as motivators that somehow set the cognitive unconscious at work. An inventor needs to learn how to switch productively between conscious effort and allowing time to allow for unconscious processes that require incubation. They can become more sensitive to and listen for intuitive insights. Thus a cyclical process of conscious problem finding, followed by listening for intuitive inspiration, critically working out these ideas and asking new questions can be optimized. Pattern recognition skills can be applied to the mental process itself creating meta-knowledge of the inventive process. The experienced inventor can understand something of how the interplay of all these factors can be more productive and learn over time to use all these mental tools more effectively. Various authors argue that we should not only teach existing knowledge but specifically stimulate inventive skills.

ABOUT THE EDITORS-IN-CHIEF

MARK A. RUNCO earned a Ph.D. in Cognitive Psychology from the Claremont Graduate School. His dissertation was on divergent thinking and he has studied creativity ever since. He founded the *Creativity Research Journal* over 20 years ago and remains Editor-in-Chief. He is currently the *E. Paul Torrance Professor of Creative Studies* at the University of Georgia, Athens. He is also Director of the *Torrance Creativity Center*, a *Fellow* and *Past President* of the American Psychological Association's Division 10 (Psychology of Aesthetics, Creativity, and The Arts). His textbook on creativity was released by Academic Press in 2007.

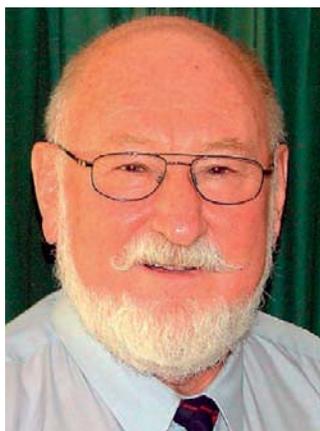

STEVEN R. PRITZKER, Ph.D., is Professor of Psychology at Saybrook University in San Francisco. He is Director of The Creativity Studies Certificate and Masters in Psychology with a Specialization in Creativity Studies. Dr. Pritzker writes both academic and popular press articles and books concerning creativity. He is a fellow and educational coalition representative for the American Psychological Association's Division 10 (Psychology of Aesthetics, Creativity, and The Arts). He serves on the editorial board of the APA journal *Psychology of Aesthetics, Creativity and The Arts*.

Dr. Pritzker is a former comedy writer-producer who worked on over 200 network television episodes including such popular shows as *The Partridge Family*, *Maude*, *Fish*, *The Hogan Family* and the Emmy winning *Mary Tyler Moore Show* and *Room 222*. He has received Emmy recognition and been nominated for the Writers Guild of America Award. Dr. Pritzker is President of Creativity Source where he consults and coaches organizations and individuals on maximizing their creativity.

ABOUT THE EXECUTIVE ADVISORY BOARD

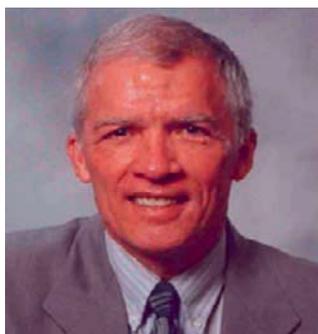

DAVID W. CHAN is a professor of educational psychology and the Program Director of the Program for the Gifted and Talented at the Chinese University of Hong Kong. He has published in areas that include stress and coping, psychopathology and health, creativity and intelligence, and gifted education and talent development.

ARTHUR J. CROPLEY spent several years as a school teacher before obtaining his Ph.D. in Educational Psychology at the University of Alberta (Canada) in 1965, and subsequently worked as a university teacher in Australia, Canada, Germany and Latvia. He retired in 1998. He is the author or editor of 25 books on creativity, lifelong learning, adaptation of migrants, and research methodology. These have appeared in English, German, Italian, Latvian, Spanish, Swedish, Norwegian, Danish, Hungarian, Korean, and Chinese. From 1989–1996 he was editor of the *European Journal for High Ability* (now known as *High Ability Studies*), published by the European Council for High Ability. He received the 1997 Creativity Award of the World Council for Gifted and Talented Children, and was elected Visiting Fellow of the British Psychological Society in 2004. In 2004 he received an honorary doctorate from the University of Latvia, and in 2008 he was made an Officer of the Order of the Three Stars by the President of Latvia, for services to higher education.

SANDRA W. RUSS, a child clinical psychologist, is a Professor of Psychology at Case Western Reserve University. She has served as President of the Society for Personality Assessment, of the Clinical Child Section of APA, and most recently, of Division of Aesthetics, Creativity and the Arts. Her research program has focused on pretend play, creativity, and adaptive functioning in children. She developed the Affect in Play Scale which assesses pretend play in children. Also, she and her students are developing a play facilitation intervention. She is author of *Affect and Creativity: The Role of Affect and Play in the Creative Process* (1993) and *Play in Child Development and Psychotherapy: Toward Empirically Supported Practice* (2004). She teaches the Child and Family Intervention course and a Psychology of Creativity course.

DEAN KEITH SIMONTON is Distinguished Professor of Psychology at the University of California, Davis. Although he earned his Harvard Ph.D. in social psychology, Simonton's research also encompasses developmental, differential, and cognitive questions. The majority of his studies apply historiometric methods to large samples of highly eminent creators. His bibliography lists nearly 400 publications, including 11 books, such as his 2009 *Genius 101*. Simonton is former president of the Society for the Psychology of Aesthetics, Creativity and the Arts (Division 10 of the American Psychological Association) and the International Association for Empirical Aesthetics. He is Fellow of the American Association for the Advancement of Science, Association for Psychological Science, International Association for Empirical Aesthetics, and nine Divisions of the American Psychological Association (1, 2, 5, 7–10, 20, and 24). His honors include the William James Book Award, the George A. Miller Outstanding Article Award, the Theoretical Innovation Prize in Personality and Social Psychology, the Rudolf Arnheim Award for Outstanding Contributions to Psychology and the Arts, APA Master Lecturer, the Robert S. Daniel Award for Four-Year College/University Teaching, and the Sir Francis Galton Award for Outstanding Contributions to the Study of Creativity.

ELLEN WINNER is Professor of Psychology at Boston College, and Senior Research Associate at Project Zero, Harvard Graduate School of Education. She received her Ph.D. in Psychology from Harvard University in 1978 working with Roger Brown on child metaphor. Her research focuses on cognition in the arts in typical and gifted children. She is the author of over 100 articles and four books: *Invented Worlds: The Psychology of the Arts* (Harvard University Press, 1982); *The Point of Words: Children's Understanding of Metaphor and Irony* (Harvard University Press, 1988); *Gifted Children: Myths and Realities* (BasicBooks, 1997, translated into six languages and winner of the Alpha Sigma Nu National Jesuit Book Award in Science); and *Studio Thinking: The Real Benefits of Visual Arts Education* (Teachers College Press, 2007, co-authored with Lois Hetland, Shirley Veenema, and Kimberly Sheridan).

She received the Rudolf Arnheim Award for Outstanding Research by a Senior Scholar in Psychology and the Arts from the American Psychological Association. She is a Fellow of the American Psychological Association (Division 10, Psychology of Aesthetics, Creativity, and The Arts) and of the International Association of Empirical Aesthetics.

JING ZHOU is Houston Endowment Professor of Management in the Jesse H. Jones Graduate School of Business at Rice University. She received her Ph.D. from the University of Illinois at Urbana-Champaign. Her current research interests include contextual factors that promote or inhibit employee creativity and innovation. She has published widely in top-tier journals in her field, and has co-edited (with Christina Shalley) *Handbook of Organizational Creativity*. Prior to joining the Jones School at Rice University, she was Associate Professor and Mays Fellow in the Management Department at the Mays Business School at Texas A&M University. She has served on editorial boards of top journals in her field, such as *Academy of Management Journal*, *Academy of Management Review*, and *Journal of Applied Psychology*. She is an incoming President of International Association for Chinese Management Research. Currently she is an associate editor of *Journal of Applied Psychology*.

PREFACE

When the first edition of *The Encyclopedia of Creativity* was published in 1999, creativity research had become broad and important enough to be treated as a legitimate field of scientific study. Since the first edition was published, interest in creativity has skyrocketed with more articles and books published than in the previous 40 years combined. This interest is an indication of the increasing complexity in our lives, where new ways of dealing with challenges on both individual and societal levels are essential. Creativity research is being conducted throughout the world in many different disciplines including psychology, arts and humanities, health sciences, education, and business. This global interest is reflected in the number of authors throughout the world who have contributed to this edition.

Some countries such as China, Korea, Singapore and New Zealand have made understanding, teaching, and encouraging creativity part of their national goals. Europe proclaimed 2009 the year of creativity. The leaders of these countries recognize that their primary natural resource is the ability of their citizens and organizations to develop new products and innovative concepts. As competition becomes more and more intense, the business community in the United States is finally accepting the concept that creativity can contribute directly to the bottom line. A recent poll of CEOs in the United States by IBM's Institute for Business Value indicated that creativity is the most important characteristic being sought in new executive hires. We have responded to the increased interest in the business community by including more entries on organizational creativity.

The *Encyclopedia of Creativity* is designed to inspire further recognition of the personal as well as professional benefits that accrue from encouraging creativity. We know, for example, that individuals who are more creative are healthier and more adaptive, and in some instances may even have a longer life expectancies. We also know that many innovations and ways of solving problems have already led to incredible benefits, such as cures for diseases, improved technologies, and higher living standards for billions of people. However, we are obviously losing a great deal of the creative potential on this planet by leaving so many of our children uneducated and unable to cope with the problems they face. Clearly we need new answers to such difficult problems as climate change, limited resources, religious and territorial conflicts, poverty, and energy.

If we want a more creative world, then we must construct an environment that allows creativity to flourish. This requires knowledge that crosses disciplines. The increased quantity and diversity of research continues for the most part to be focused on a specific area of interest. Most scientific research is still released only in academic journals. There is still not a broad cross-fertilization of knowledge that enhances the development of new ideas. One of the axioms in creativity research is that breakthroughs often occur when information or concepts from one field are applied to a different one. Darwin's theory of evolution was partially inspired by his reading Malthus' theory of population growth and Lyell on geological change. Jean Piaget, noted developmental psychologist, borrowed heavily from biology and epistemology. Freud used a medical model to understand the psyche. Our hope is that readers will roam outside their usual areas of interest in a search for new ways of thinking. The comprehensive nature of the encyclopedia offers readers the opportunity to find new perspectives, which we hope will suggest fresh insights about themselves, their work, and their place in the world.

In the first edition we stated that there was enough known about creativity that it could be integrated into every level of our educational system. Unfortunately "teaching to the test" has become more prevalent in the United States while arts programs have been all too often dropped. It is our hope that teachers at the elementary and high school level will learn about their own creativity and how to value and encourage students. It is not always an easy task, but it can help enhance and even save the lives of some creative students who are at risk.

Some progress is evident at the college and post-graduate levels where courses are taught in many schools throughout the country. There is still a tremendous need for degree earning programs and specializations in

creativity. The Torrance Center at The University of Georgia, Saybrook University, Buffalo State, and Drexel University are among the few schools that currently allow a specialization in creativity studies. By 2020 we hope that there are many more universities and professional schools which include courses and specialties in creativity studies.

Contents

Creativity is multifaceted and manifested in different ways in different domains. Moreover, there are different processes that can each lead to creative work. Thus a comprehensive *Encyclopedia of Creativity* required many different articles.

There are articles that present overviews of the research and theories about creativity from a variety of different areas:

- There are reviews of a number of domain-specific areas, such as acting, dance, expressive arts, film, food, music, religion, science, sports, theater, and writing.
- Creativity and education are examined in articles about thought processes, such as developmental trends in creative abilities and potentials, the enhancement of creativity, intelligence, knowledge, play, prodigies, programs and courses, talent and teaching creativity.
- Cognitive aspects of creativity can be investigated in articles about altered and transitional states, analogies, attention, cognitive style, divergent thinking, flow and optimal experience, metacognition, metaphors, problem-finding, problem-solving, and remote associates.
- Those interested in business and organizational creativity can view articles about advertising with art creative visuals, business/management, creativity coaching, creativity exercises, entrepreneurship, group dynamics, innovation, leadership, organizational culture, organizational development, teams, and training, among others.
- Many articles examine the creative process across domains, covering areas such as discovery, emotion/affect, gender differences, incubation, inspiration, insight, novelty and paradigm shifts.
- The complex interrelationship between society and creativity is explicitly examined in articles about awards, conformity and conventionality, the creative sector and class of society, cultural diversity, the dark side of creativity, East vs. West, networking, social psychology, war, zeitgeist, and others.
- Personal and interpersonal creativity is discussed in articles relating to collaboration, family, life stages, mentors, networking, personal creativity and self-actualization.
- Because the encyclopedia focuses on scientific information about creativity, there are also articles that discuss brain and neuropsychology, concepts of creativity, definitions of creativity, expertise, longitudinal studies, researching art, artists and art audiences, research methods, phenomenology research and qualitative research.
- Articles which look at theoretical perspectives include behavioral approaches, chaos theory, componential models, economic perspectives, the evolving systems approach, the four P's of creativity, and implicit theories.
- The creative process is examined in contrarianism, climate for creativity, discovery, dreams, heuristics, invention, motivation/drive, multiple discovery, novelty, time and rewards.
- Mental and physical health and creativity are reviewed in mental health: affective disorders, mad genius controversy, schizophrenia and psychosis, stress, suicide, and transforming illness and visual art.

Finally there are selected biographical studies selected with creativity as the key concern. The sampling of biographical subjects represents a much higher percentage of women in this second edition. Biographical subjects represent eminent individuals in different domains including composers, film directors, musicians, writers, painters, psychologists, scientists and spiritual leaders.

Audience

The encyclopedia is designed for use by students of creativity, as well as researchers, teachers, scientists, coaches and consultants, architects and designers, trainers, managers, actors, writers, directors, painters and other individuals in the creative arts, inventors, therapists and other professionals who utilize creativity in their work. Anyone who is interested in learning more about their own creativity and the creative process can benefit

from the articles presented here. Do not expect quick and easy self-help answers - individual creative growth requires work, time, serious thought and a commitment to deeper understanding of the process. And let's not forget the possibility of fun - creativity can help us experience the highest levels of involvement in work and play that ultimately leads to great joy. Readers are encouraged to follow their own interests and inclinations in exploring these volumes.

More than any other kind of book an encyclopedia is a collaborative effort. We thank our eminent panel of editorial advisors: Arthur Cropley, David Chan, Sandy Russ, Dean Keith Simonton, Ellen Winner and Jing Zhou. We also thank each of the distinguished contributors to the Encyclopedia. Finally, we appreciate the efforts of our editor, Nikki Levy, and our developmental editor Anna Gebicka. We hope this encyclopedia will not only inform but inspire readers to become more creative in their personal and professional lives.

*Mark A. Runco

HOW TO USE THE ENCYCLOPEDIA

The *Encyclopedia of Creativity* is intended for use by students, research professionals, and interested others. Articles have been chosen to reflect major disciplines in the study of creativity, common topics of research by professionals in this domain, and areas of public interest and concern. Each article serves as a comprehensive overview of a given area, providing both breadth of coverage for students and depth of coverage for research professionals. We have designed the encyclopedia with the following features for maximum accessibility for all readers.

Articles in the encyclopedia are arranged alphabetically by subject. Complete tables of contents appear in both volumes. The Index is located in Volume 2. Because the reader's topic of interest may be listed under a broader article title, we encourage use of the Index for access to a subject area, rather than use of the Table of Contents alone.

Each article contains an outline, a glossary, cross-references, a further reading list and a list of relevant websites. The outline allows a quick scan of the major areas discussed within each article. The glossary contains terms that may be unfamiliar to the reader, with each term defined *in the context of its use in that article*. Thus, a term may appear in the glossary for another article defined in a slightly different manner, or with a subtle nuance specific to that article. For clarity, we have allowed these differences to remain

so that terms are defined relative to the context of each article.

Each article has been cross-referenced to other related articles in the encyclopedia. Cross-references will always appear at the end of an entry. Where multiple cross-references apply to an article, the cross-references will be listed alphabetically. We encourage readers to use the cross-references to locate other encyclopedia articles that will provide more detailed information about a subject.

The further reading lists recent secondary sources to aid the reader in locating more detailed or technical information. Review articles and research articles that are considered of primary importance to the understanding of a given subject area are also listed. The further reading lists are not intended to provide a full reference listing of all the material covered in the context of a given article, but are provided as guides.

A select number of biographies have been included. These biographies discuss the lives of individuals famous for their creative endeavors. No living people have been included because we wanted creators whose work had stood the test of time. Although there are many individuals famous for their creative pursuits, you may not find coverage of your favorite here. Inclusion is not intended to be a judgment on the impact or value of these individuals or their creations.

Janusian, Homospatial and Sepconic Articulation Processes

A Rothenberg, Harvard University, Canaan, NY, USA

© 2011 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by Albert Rothenberg, volume 2, pp. 103–109, © 1999, Elsevier Inc.

Glossary

Analogic reasoning Drawing of inferences or conclusions based on likenesses and comparisons.

Catharsis Purging or discharge of unacceptable or unpleasant emotions.

Condensation The representation of two or more ideas, memories, feelings, or impulses by one construct or image as in a person's humor, accidental slips, and dreams.

Deductive reasoning Making inferences or conclusions based on predetermined premises.

Dialectical reasoning Practice of weighing and reconciling juxtaposed or contradictory arguments for the purpose of arriving at the truth.

Gestalt Term used for an organizational whole, therefore the perceptual organization of a whole visual space into foreground and background features. The term is used for a psychological theory and movement based on principles of the whole in mental processes.

Inductive reasoning The process of drawing out or making inferences or conclusions based on facts and observations.

Kent–Rosanoff word association test Psychological test usually composed of 100 stimulus words requiring a response, usually timed, of the first word that comes to mind on exposure to each stimulus word. Developed by psychologists Kent and Rosanoff in the early 1900s and standardized on over 1000 subjects.

Oxymoron A figure of speech in which incongruous or contradictory terms are brought together.

Semistructured research interviews Use of prepared questions and categories for eliciting interview information relevant to specific preconstructed hypotheses. These questions and categories are not presented in a set sequence but according to the flow and logic of the interview interaction.

Statistical significance Method for assessing the operation of nonchance factors in an event or series of events.

Unconscious Mental aspect containing psychic material that is not accessible to awareness but has a pronounced effect on conscious thought and behavior.

Creativity consists of the capacity or state of bringing into being entities that are both new and valuable. Three cognitive functions responsible for creative constructions and effects are the Janusian, homospatial, and sepconic articulation processes. During the course of creative activity, these processes operate both independently and in conjunction with each other. Dynamic interactions within and among the three processes produce emergent creative integration.

Empirical Studies

The creative cognitive processes were discovered through long-term empirical investigations consisting of extensive semi-structured research interview procedures (*Int=verbatim* quotations used) with consensually recognized highly creative achievers in the arts and sciences. Subjects have been: in literature – Nobel laureates (IntNL), Pulitzer (IntP) and other notable literary prizewinners; in science – Nobel laureates in physics, chemistry, and medicine or physiology (IntNLS)

in both the United States and Europe. Interview procedures were carried out over the course of the subjects' both long- and short-term creative projects and consisted of detailed objective examination of psychological processes in ongoing work and, where appropriate, past creative breakthroughs. Experimental assessments, as reported below, were also done with these and other creative subjects and noncreative controls. Additionally, comparison control research interviews, carried out in the same semistructured manner as with the creative subjects, were performed with less creative matching cohorts.

Documented accounts of breakthroughs and other creative productions of outstanding art and science creators of the past were also systematically analyzed. The large body of evidence collected indicates that the three conscious and intentional processes, Janusian, homospatial, and sepconic articulation, are used for creative work and thought in literature, art and science and, by extension, in various degrees in fields such as business, education, politics as well as general creative problem solving and everyday creative activities.

Janusian Process

The Janusian process, most commonly operative in the early or inspiration phase of creative production, consists of actively conceiving multiple opposites or antitheses simultaneously. The term, based on the multifaced (variously possessing two, four, or six faces) Roman god Janus looking always in diametrically opposed directions, denotes conscious conceptualization during the creative process of simultaneously coexisting and operative opposite or antithetical ideas, propositions, or actions. Although seemingly illogical and self-contradictory, creators construct these conceptualizations in rational states of mind in order to produce creative effects. In art and literature they are responsible for early conceptions of plot, character, metaphor, organization, and design; in music for compositional construction; in science for creative breakthroughs, theorizing, and experiments. Depending on the level of development of a creative product, the Janusian process also operates at later critical junctures and with practical solutions in a wide variety of fields.

Simultaneity of the multiple opposites or antitheses is a cardinal feature of the Janusian process. Creators conceive firmly held propositions about the laws of nature, the functioning of individuals and groups, or the aesthetic properties of visual and sound patterns as simultaneously true and not-true; harmonious and non-harmonious or, both opposite and antithetical propositions are entertained as concurrently operative. A person running is both in motion and not in motion at the same time, a chemical is both boiling and freezing, or kindness and sadism operate simultaneously. Previously held beliefs or laws are still considered valid but opposite or antithetical beliefs and laws are formulated as equally operative or valid as well.

These formulations within the janusian process are waystations to creative effects and outcomes. They interact and join with other cognitive and affective developments to produce new and valuable products. Homospacial and sepconic articulation particularly operate as later unifying processes. Analogical, dialectic, inductive, and deductive reasoning are applied also in the development of theories, inventions, and artworks.

The Janusian process initially disrupts preexisting contexts and conceptions. Highly surprising, even incredible and inconceivable, are propositions that the contradiction or opposite of well-grounded fact, theory, or actuality is simultaneously valid. Previously held ideas and systems of ideas are split apart and broken, even essentially destroyed. This disruption engenders the development of something new.

Janusian Process in Science

While working on an essay for the *Yearbook of Radioactivity and Electronics* in 1907, Albert Einstein had what he called "the happiest thought of my life." This happy thought was the key to one of the most far-reaching scientific breakthroughs of the twentieth century: the general theory of relativity. The circumstances producing it were revealed in a document by Einstein himself which was unpublished during his lifetime, titled, "Fundamental Ideas and Methods of Relativity Theory, Presented in Their Development."

Einstein had already developed the special theory of relativity, which holds that since the speed of light is constant for all frames of reference, perceptions of time and motion depend upon the relative position of the observer. He had been forced to postulate the theory, he said, to explain the seeming contradictions in electromagnetic phenomena:

[that] one is dealing here with two fundamentally different cases was, for me, unbearable. (Translations, Gerald Holton)

He felt strongly that he had to come up with a new and meaningful solution. For many years, he struggled to modify Newton's classical theory of gravitation so that it could be encompassed within a broad relativity principle, but he lacked a specific physical basis for bringing together the seemingly different or antithetical choices of Newton's theory and his own special theory.

All at once, Albert Einstein conceived his happiest thought. It was:

For an observer in free fall from the roof of a house, there exists, during his fall, no gravitational field . . . in his immediate vicinity. If the observer releases any objects, they will remain, relative to him, in a state of rest. The [falling] observer is therefore justified in considering his state as one of 'rest.'

Development of the general theory itself was highly complex, but the specific structure of the key step is clear. Einstein had consciously formulated the simultaneously antithetical construct that a person falling from the roof of a house was both in motion and at rest at the same time.

(IntNL) Physicist Edwin McMillan's formulation of critical phase stability leading to his development of the synchrocyclotron (later called the synchrotron) was derived from a sudden formulation involving simultaneous opposition of too high and too low energy. The synchrotron is a high energy particle accelerator that has allowed for the discovery of a number of new particles and other nuclear effects.

'I was lying awake in bed and thinking of a way of getting high energy,' he said, and I was thinking of the cyclotron and the particle going around and encountering the accelerator field. . . . It's going to oscillate back and forth, be going at too high and too low energy. Once I realized that, then the rest was easy. . . . Once you have an oscillation, you have the element of stability. The things will stay put. They will wiggle around but they won't get away from you. Then all you have to do is to vary your frequency, or vary the magnetic field, either one or both, slowly, and you can push this thing anywhere you want. That all happened one night and the next day I started to write down the equations for that and proved that it would work.

In physicist Niels Bohr's (1927) first formulation of his theory of complementarity, the theory that has been a foundation for modern quantum physics, he stated that wave or else particle states of light and electrons, widely believed at the time to be completely conflicting alternatives, involved:

no question of a choice between two different concepts but rather of the description of two complementary sides of the same phenomenon.

He then went on to formulate the full blown complementarity theory stated as follows:

two descriptions or sets of concepts, though mutually exclusive, are both necessary for an exhaustive description of the physical situation.

His key initial formulation of the complementarity idea was a Janusian process construct that both light and electrons were phenomena with simultaneously antithetical wave and particle aspects.

Janusian Process in Literature, Art, and Music

(IntPP) Novelist William Styron reported that he developed the initial idea for his Pulitzer Prize winning novel *The Confessions of Nat Turner* as he sat in a lawn chair reading Erik Erikson's book on Martin Luther's rebellion. He thought, in a Janusian process construction of simultaneous opposition, of creating a novel about another rebel, a revolutionary hero who, he said:

was responsible for the deaths of hundreds of people, but he himself would kill only one person with his own hand – and this was the one person who had been very kind to him and the one person he loved.

(IntPP) Playwright Arthur Miller disclosed that he had come up with the specific idea for the play "Incident at Vichy" while traveling through Germany:

Driving on the autobahn, I suddenly felt amazed and overwhelmed at how beautiful Germany had become.

He conceived of writing a play that would simultaneously express the opposites of the beauty of modern Germany and Hitler's destructiveness.

And then, I remembered a story I'd been told about a sacrifice made by an Austrian nobleman for a Jew in a Nazi official's waiting room.

He developed the story of the political simultaneously antithetical sacrifice in his play.

(IntPP) Poet Richard Wilbur related that he had been walking on a beach and became interested in the quality of some rocks along the sand. As he touched the surface of the rocks, he noted that they seemed to feel like human skin. They were, however, also hard, heavy objects – violent weapons. The idea that the rocks were at once sensual objects and weapons led to a conception of the simultaneous operation of sex and violence in the world, and Wilbur elaborated those aspects separately into the final version of a poem.

(IntPP) Poet James Merrill (1972a) had been home thinking about a past incident in which a horse had appeared at a lonely desert site, when it occurred to him that horses are animals who "renounce their own kind in order to live our lives." The idea that horses live human lives, that they are antithetically both beast and not-beast and human and not-human simultaneously, generated the poem, "In Monument Valley," with the central image and theme of a happy and

intense relationship between a young person and a horse, followed by a sad, resigned separation.

(IntPP) Poet and novelist Robert Penn Warren recounted that he was doing his morning exercises when he thought of a series of poetic lines that, as he described them, would use the last word of each line as the first word of the next – a juxtaposition that sets one word to simultaneously opposite functions, both ending and beginning a poetic thought. In the end, his poem implicitly retained that structure.

Artist Jackson Pollock's early drawings and paintings were strongly based on the styles of Thomas Hart Benton, Diego Rivera, and Jose Clement Orosco. During the summer of 1939, when he was improving from alcoholism and mental illness, he created his first abstract expressionist paintings, becoming the so-called father of that style. These revolutionary artworks, he later explained, were based on his conception of both obscuring an image and expressing it at the same time, a Janusian process formulation.

In music, the writings of composers from early to more recent modern times have stipulated simultaneous oppositions regarding germinal aspects of their compositions. Renaissance composer Claudio Monteverdi (1956) described his method of producing slow and fast tempos simultaneously as a means of conveying the "contrary passions aroused by war, prayer, and death." Modern composer and conductor Leonard Bernstein (1976) wrote of the use of "contradictory forces, chromaticism and diatonicism, operating at the same time." Composer Arnold Schoenberg conceived the simultaneous use of the opposites of consonance and dissonance in his musical creations and compositional instructions to disciples.

Homospacial Process

Mental representation of space is potentially more far reaching, extreme, and diverse than any physical actuality. The homospacial process responsible for many types of creative results involves mental representations that defy or go beyond actual physical space. This process consists of actively conceiving two or more discrete entities occupying the same space or spatial location, a conception leading to the articulation of new identities and integrations. In conscious mental space, creators superimpose, interpose or otherwise bring together shapes, patterns, written words, dimensions, distances, and other concrete entities. Subjectively, eyes closed or open, other physical receptors attentive or inattentive, the resulting mental image totally fills the conceptualized perceptual space. Any sensory modality may be involved: visual, auditory, tactile, kinaesthetic, olfactory, and gustatory. The imaginary image location may be considered to be the 'mind's eye,' 'mind's ear,' 'mind's taste,' etc.

Once the discrete entities in the homospacial process are consciously brought together, the mental conception is a rapid, fleeting one. In the creator's mind, the superimposed and interposed elements begin immediately to interact and produce new identities, including new ideas. These ideas constitute solutions to scientific and other problems and in the arts, they consist of created metaphors, plots, visual themes and constructions, musical passages, and other integrations.

Not a matter of simple combination, unconscious condensation, or of the discrete entities considered in stepwise or

analytic fashion, the homospatal process involves unstably related entities that interact. Ordinarily used later than the Janusian process but, as in an oxymoronic metaphor such as Hart Crane's 'penniless rich palms' from his *Voyages II*, both processes may operate early and concurrently. Newness in the created results produced by the homospatal process begins with creators breaching the physical percept that two or more discrete entities cannot in actuality occupy the same space. The valuable aspect emerges from rapid or delayed interactions among the superimposed and interposed elements.

Homospatal Process in Science

Mathematician Jacques Hadamard (1949) described the conception leading to the important 1892 discovery of the valuation of a determinant as a schematic diagram consisting of:

a square whose sides only the verticals are drawn and, inside of it, four points being the vertices of a rectangle and joined by (hardly apparent) diagonals.

He visualized a rectangle occupying the inside of a square, two discrete entities within the same spatial location.

Mathematician Henri Poincaré (1952) described the mental conception of a coalescing spatial superimposition of mathematical formulations which led to the discovery of a crucial aspect of his famous Fuchsian functions:

One night, I took some black coffee, contrary to my custom, and was unable to sleep. A host of ideas kept surging in my head; I could almost feel them jostling one another, until two of them coalesced, so to speak, to form a stable combination. When morning came, I had established the existence of one class of Fuchsian geometric series. I had only to verify the results, which only took a few hours.

(IntNLS) Microbiologist Joshua Lederberg reported that he arrived at an important new idea regarding enzyme replication after consciously visualizing himself superimposed upon a living cell.

Similarly, (IntNLS) chemist William Lipscomb described one of his Nobel Prize discoveries in boron chemistry as arising from a superimposed image of a hydrogen atom and a three center chemical bonding:

What I mean by the superimposition ... this hydrogen comes over here [points to formula], and interchanges with this vacancy. I saw the previous three center bond there, and then it came loose and twisted around. I did that in my head and it became perfectly clear in the nuclear resonance study I published. I had the right structure.

Homospatal Process in Literature, Art, and Music

The homospatal process is a prime factor in the production of poetic metaphors. To produce what was to be a central metaphor in a lyrical poem, 'the branches were handles of stars,' an author had become attracted early to the words 'handle' and 'branch' because of their shared sound qualities – the assonance or shared 'an' sound in the center of each – as well as the

shared shapes of the wooden objects themselves. He then superimposed these words and their concrete images in his mind's eye; he brought them together because he felt they ought to be together. In the next fleeting moments, he asked himself when in reality they were the same, and also fleetingly experienced a vivid impression of the letter 'a' overlapping in the two words. At that point the idea of stars was generated. Associational or analogical ideas of the country (or park) at night did not generate the metaphor; it was derived directly from the homospatal process conception that provided both the real scene and sound qualities that unified the words and their meanings.

In the creation of another type of metaphor, 'the tarantula rays of the lamp spread across the conference room,' this author was thinking about writing a poem about a vacation in the tropics and, among the various thoughts and words that came to mind, he became interested in the sound similarity between the words 'tarantula' and 'lamp.' He then actively superimposed images of the spider and a light source together, along with images of the letters in the words, because he felt these ought to be together. After mentally visualizing spidery light radiating out from a central source in the superimposed images, he thought of the metaphor, 'tarantula rays of the lamp.' Deciding to elaborate that fragment with a suggestive context, he next conceived of 'conference room.' Once the entire creation was constructed, he thought of overtones such as wars in the tropics, the idea of the slow crawl of a tarantula in contrast with the dazzling speed of light, and experiencing an awesome type of beauty, he was pleased. With both poetic creations, the author visualized a vague scene as well as found the answer in words. Later, he visualized more fully developed and vivid scenes similar to the ones experienced by a reader or audience, and he (sepconically, see below) articulated the metaphors as well as descriptions of the scenes into poems. The fully visualized scenes did not, however, produce the metaphors, they mainly added to the poet's feeling of the aptness of his creation.

Sculptor Henry Moore (1937) indicated the crucial role of a homospatal process in the creation of sculptural works of art as follows:

This is what the sculptor must do. He must strive continually to think of, and use, form in its full spatial completeness. He gets the solid shape, as it were, inside his head – he thinks of it, whatever its size, as if he were holding it completely enclosed in the hollow of his hand. He mentally visualizes a complex form from all round itself; he knows while he looks at one side what the other side is like.

In music, auditory metaphors and new musical patterns and themes develop from homospatal process constructions. Ludwig van Beethoven (1952) described that:

the underlying idea [of a musical work] ... rises ... grows, I hear and see the image in front of me from every angle, as if it had been cast.

Robert Schumann (1922) said regarding his composing process:

certain outlines amid all the sounds and tones ... form and condense into clear shapes.

Interaction Between Janusian and Homospatial Processes

(IntPP) James Merrill's previously described Janusian formulation of a horse as both beast and human simultaneously for the poem, 'In Monument Valley,' was subsequently integrated into a particular central poetic metaphor by a homospatial process conception. A horse and human being were conceived as occupying the same space; that led to the construction of the following poetic image:

Stillnesses were swarming inward from the evening star/ Or outward from the buoyant sorrel mare/ Who moved as if not displeased by the weight upon her./ Meadows received us, heady with unseen lilac./ Brief, polyphonic lives abounded everywhere. With one accord we circled the small lake.

The resulting image was neither a centaur, a mythical entity that is part human and part horse, nor was it some other mixture or combination of horse and man.

Experimental Evidence for Janusian and Homospatial Processes

A tendency or capacity for the use of the Janusian process among proven and potentially creative persons, manifested by very rapid opposite responding on word association tasks, was experimentally identified. Standard Kent-Rosanoff word association tests were individually administered to 22 Nobel laureates in science (physics, chemistry, medicine or physiology) and to rated-as-creative Yale College students. Control groups consisted of matched but rated-less-creative students and high IQ psychiatric patients. Test instructions were to give the first word that came to mind in response to a standardized list of word stimuli and both speed and content of response were electronically recorded. Results signified, for the most creative subjects, formulation of simultaneous or virtually simultaneous opposite associations. The statistically significant highest number of extremely rapid opposite responses (averaging 1.1-1.2 seconds) were given by proven creative subjects, the Nobel laureate group, and the next highest by the rated-as-creative Yale students.

Experimental assessment of the creative effect of the homospatial process, using the stimulus effects of ten concrete representations of such mental conceptions consisting of a series of ten transilluminated superimposed component slide images, were carried out with artist and writer subjects. Controlled side-by-side slide presentations of each of the individual component images were shown to half of each group. Results were the statistically significant greater production of both creative literary metaphors by writer groups and creative pastel drawings by artist groups in response to the superimposed images in comparison with the side-by-side controls. An example of a test superimposed stimulus image, consisting of nuns in front of St Peter's and racing jockeys is shown in Figure 1. An experiment using shorter stimulus exposure times to facilitate more rapid mental superimposition and manipulation produced similar results.

With highly talented award winning artists, another experiment was carried out to assess whether the results of the

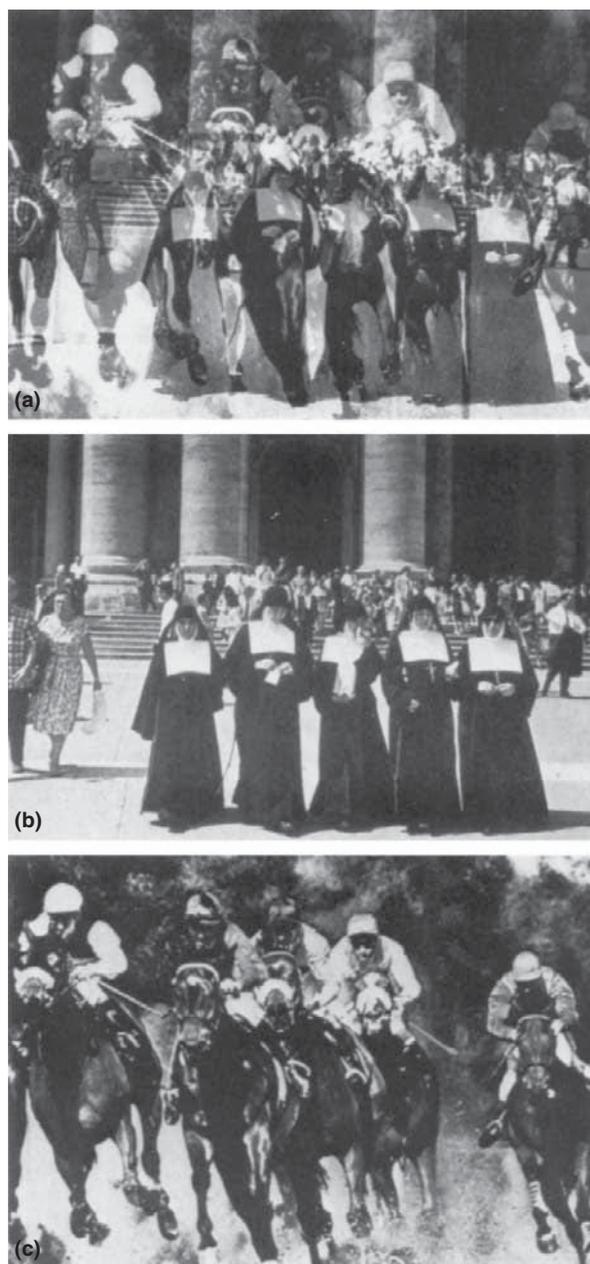

Figure 1 The first slide pair, superimposed and separate. (a) Photograph of colored slides as projected superimposed onto the viewing screen. (b) and (c) Photographs of individual color slides.

previous experiments could have been due to stimulus presentation effects. Results indicated that presentation of test superimposed images in controlled comparison with foreground-background (gestalt) displays of the same subject matter yielded significantly higher rated creative products.

Sepconic Articulation

The sepconic articulation process consists of conceiving or constructing separation and connection concomitantly. The term derives from the root meaning of articulation as joining,

joint, to join, and the commonly applied phrases, 'being articulate' or 'an articulate speaker.' Speaking smoothly and continuously, the articulate speaker joins words and ideas together and keeps them clearly separate at once. In creative work and activity, the creator uses such concomitant separation (SEP) and connection (CON), the process of sepconic articulation, in many different dimensions – conceptual, perceptual, affective, and physical. It differs from blending, fusion, combining, connecting or connectivism alone, in that the creator brings together separate component elements that retain their individual characteristics.

Integration characterizes created works and is a crucial factor in their positive value. The process of sepconic articulation, because of discordance of concomitant separation and connection, leads, as with conflicting elements of the Janusian and homospacial processes, to dynamic interaction and the emergence of integration. Separate individual elements retaining their identities contribute to the functioning of a large or small whole connected system. This integrated whole has qualities not present in any individual element or factor; it is greater than the sum of its parts.

When creators produce new ideas, procedures, experiments, neologisms, plot themes, artistic or musical patterns, they integrate them into a created result by means of the process of sepconic articulation. Integration, contingent organicity, and usefulness produce the value aspect of creations in all fields, science and art as well as the products of everyday ingenuity. Newness or originality alone does not guarantee successful application or appreciation. New elements, forms, or mechanisms must have articulating concomitance with previously existing elements, forms, or mechanisms in order to become creations. New factors must have connections with comparable past ones. Creative new theories and experiments, for example, are always connected to some degree with existing canons of scientific knowledge, creative new postmodern sculptural or painting styles are in some part connected with realism, op and pop art, action painting and many other previous approaches. Joyce's and Shakespeare's literary creations are connected both in subject matter and form with previous works of literature and life events. New factors, therefore, which are clearly distinct and separate are at the same time connected in some measure with the past. Creations are articulating concomitants of new ideas, objects, and structures with aspects, sometimes totalities, of the past.

Sepconic Articulation in Science

(IntNLS) Physicist Norman Ramsey conceived the 'Separated Oscillatory Field Method' which provided critically important high resolution in atomic and molecular spectroscopy for the production of the most precise atomic clocks. He disclosed that he had been working on making a connection between a short and longer magnetic field apparatus and had first conceived that the nature of the field was crucial and also that it would have to be uniform. Then, deciding later all at once that the uniformity of the field itself was less important than the separated beginning and ending, he conceived a solution in which the distinctly separated 'bits,' were concomitantly connected through oscillations. The interactions between the

concomitant separations and connections produced mutual modifications and a creative outcome. He said:

[the connecting oscillations produce] a short, much stronger field at the beginning and a short, much stronger field at the end, and then the middle part averages out.

(IntNLS) Chemist Jean-Marie Lehn is responsible for the creation of the field of supramolecular chemistry, developments in which have made important contributions to nanotechnology, work with catalysts and catalysis, pharmaceutical therapies, and drug delivery. 'Supramolecular chemistry,' he said:

has to do with the designed manipulation and use of weaker interactions, weaker forces, compared to intramolecular ones, which glue molecules together and allow you to construct large architectures.

He developed supramolecule structures from conceiving concomitant separation and connection:

What one wanted was building a three dimensional negative image in space. ... This is a cavity, a "crypt"; so there are "cryptands," "cryptates," and so on. ... The hidden aspect is important because the interactions of the outside species with what is hidden determines both the properties of what is inside ... and also what's outside.

Sepconic Articulation in Art, Literature, and Music

In literature, the development of characters results from the process of the author's sepconic articulation of self. Created literary characters are neither simply representations of the writer's personality or life history nor combinations of these factors with those of other persons, real or imaginary. Throughout the course of writing a novel, play, or poem, the author concomitantly connects and separates his own emotions, personality characteristics, and experiences with the fictional characters being created. There is continual interaction of features of the author's self and the developing portrayal.

The sepconic articulation process also operates in the creation of poetic form. (IntPP) James Merrill (1972b) created a central metaphor, 'a mastermind kept track above the mantel' of the poem entitled, '18 West 11th Street' through concomitant separation and connection of words pertaining to his self and the destruction of the eponymic house. It was the street address of a brownstone house in Greenwich Village that Merrill lived in as a child. The house much later was actually accidentally blown up by a revolutionary group called 'The Weather Underground' during a project of making bombs in the basement.

The 'mastermind' mirror in the poem allows a passing through in imagination of both the poet's childhood images and the world of the Weather Underground. During the process of creation, he wrote more than twenty-five different versions of these lines. Before the final step, he focused on an off-rhymed word-pair, 'mental' and 'mantel.' Then, in the process of sepconic articulation, he conceived the metaphoric word 'mastermind' by separating out from 'mental' the idea of mind and connecting it concomitantly with the idea of plotting

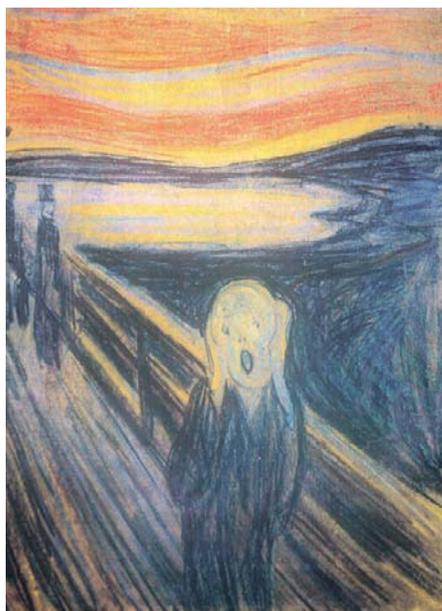

Figure 2 Edvard Munch, *The Scream* 1893. Oil, pastel and casein on cardboard. Oslo National Gallery, Oslo.

'saboteurs' from another portion of the poem. He was aware at the same time of continuing to separate out the initial consonants and vowels of the word pair 'mental' and 'mantel' and connecting them into an effective alliterative sound similarity: both alliteration (m) and assonance (en/an). The mastermind metaphor, effective in both structure and meaning, became an aesthetic integration in the poem.

In his diary, in 1892, expressionist artist Edvard Munch described a visual hallucination of a bloody red sky that provided the inspiration of emotionally charged elements that he integrated by means of the sepconic articulation process and, to a lesser extent, the homospacial process, into the famous artwork, 'The Screech' or 'The Scream' (Figure 2). Over a period of more than a year, he several times progressively connected and separated himself and his hallucination, as represented by a human subject viewing the sky, with nature.

He first did a drawing showing a solitary man far at the back leaning in profile over a bridge and looking at the sky and a boat on a small lake, then later a painting depicting the leaning still-profiled man located right at the front of the scene. In the next two charcoal drawing versions, he put a round bowler hat on this profiled spectator. After that, in an ink sketch much later in that year, he depicted the then bowler-hatted man facing fully forward and matched the rounded shape of the hat with the curved lines of both the sky and the contours of the man's body, a probable result of conceived superimpositions of the homospacial process. In the final version, first done as a lithograph and later as a painting, he developed critical aspects of the image by presenting the man concomitantly separated and connected with the nature scene. The forward-facing man was portrayed with no hat but with an oval screaming mouth. Both the red sky and man's body contained differently oriented ovoid types of curves. Mouth, sky, and body all were in this way separated and connected concomitantly. He thereby

produced a universal pictorial metaphor, a metaphor verbally described as 'the scream of nature,' that provides much of the integrated aesthetic power of this painting.

The process of sepconic articulation operates throughout musical creation. Just as the articulate and creative speaker brings phrases and ideas together smoothly and in continuous flow while concomitantly separating these phrases and ideas clearly, created music brings rhythms, themes, instrumental effects, and other sonorities together smoothly while clearly separating these elements. It produces the organic integration of created music. Classical composer Paul Hindemith (1961), using the analogy of seeing a heavy flash of lightning in the night, described the musical operation of both the homospacial and sepconic articulation processes together as follows:

Within a second's time we see a broad landscape, not only in its general outlines but with every detail. . . . We feel that not even the smallest leaf of grass escapes our attention. We examine a view, immensely comprehensive and at the same time immensely detailed. . . . Compositions must be conceived the same way. If we cannot in the flash of a single moment, see a composition in its absolute [connected] entirety, with every pertinent detail in its proper place, we are not genuine creators.

Phases of Janusian, Homospacial and Sepconic Articulation Processes

All three processes function in creation individually as well as in conjunction with each other. There are four phases in the creative process that occur over extended periods of time or else condensed into a very short span such as sometimes occurs with sudden breakthroughs and insights. Ordinarily, the creative thinker uses the Janusian process earlier than both homospacial and sepconic articulation processes. All three begin with a first phase consisting of the deliberate motivation to create; nothing new and valuable is created without the intention to do so. Both the intentional goal and the area chosen for creation have emotional (including aesthetic) importance for creators themselves. Combined emotional and ideational motivation provides the drive to conceive the inconceivable and use other daring and unusual cognitive modes in the next phases.

In the second phase for each of the three processes there is a deviation from the customary. The creator using the Janusian process focuses on seemingly unreconcilable poles of opposition or antithesis. Scientific creators, highly knowledgeable about their fields, at this time begin to break away from widely held precepts of approach and content. In art, literature, and music, knowledgeable creators' choices of particular opposing elements of form or content in their works differ in some fashion from those of previous writers, artists, or composers. This is the beginning of a small or large departure from the known and accepted that ultimately produces newness in the created product. Creators' gradual and continuing development of specific thematic poles and aspects serves to separate and isolate critical factors in the area of investigation, technology, or aesthetic production.

In both the homospacial and sepconic articulation processes, in the second phase, creative thinkers choose entities that, while they differ both singly or in multiples from the

usual, have functional or structural similarities with each other. For the visual artist it may be repetitions, juxtapositions, contraries, or oppositions in shape and color, for the writer (especially the poet) and musician it may be sound and physical relationships, and for the scientist it is functional, conceptual, or physical relationships within the problem being worked on.

In the third phase of the Janusian process, creative thinkers conceive multiple opposites or antitheses as operating simultaneously. It is here that ideas constructed sometimes seem surprising to the creators themselves. At first unthinkable, even disjunctive, are postulates that antithetical factors co-exist or operate together, or that something that has existed or was known previously continues to operate together with its diametric opposite. Also, one pole or portion of an opposite or set of opposites may up to then have been in conscious focus while others have been dimly held at the periphery. Conscious positing of the simultaneous validity of these opposites may become a sudden and enthralling experience, producing a sense that is sometimes described as 'something coming out of the blue.' With respect to newness, the simultaneity of opposition is a phenomenon experienced as being out of time. As it is out of time, or out of temporal succession, it appears as discontinuous with previous factors and therefore new.

Distinct cognitive abilities and proclivities are involved in the Janusian process and emotional underpinnings interlock with these. When emotional involvement involves meaningful conflict, it especially jibes with the cognitive tendency in the Janusian process to focus on opposites and antitheses and bring these together simultaneously. The simultaneous opposition and antithesis with its retained conflict among composing elements is isomorphic with emotional conflicts in all types of creators.

In the third phase of the homospacial and sepconic articulation processes, creators bring together the functionally or structurally similar elements. In the homospacial process, they are superimposed or interposed in the same mental space; in the sepconic articulation process they continue to be separate identities while they are connected. Creators bring together these entities because they conceive that they ought to be together. The conception deviates from previously known composite structures in similar fashion to the types of deviations of the Janusian process. There are several reasons for this conscious act of volition, many of which are emotionally driven and may be unique to the particular thinker.

In the fourth phase, both the homospacial and sepconic articulation processes lead individually to partial or complete integrations. Also, they operate together with the Janusian process, modifying it and integrating the simultaneous opposites into the full dimensions of the artwork, theory or discovery. Stepwise logical and synthesizing mental processes operate in this phase as well. Not to be minimized in any way, specific skills are critically important, such as, in science, high intellect and intelligence, observational and deductive capacities, and knowledgeable attention to canons of empirical validation. In art, music, and literature, high level skills with language, sound and pictorial relationships are necessary to produce the fully developed aesthetic product. Other specific skills are necessary for creativity in various other fields.

Aspects of both Janusian and homospacial processes have features in common with sepconic articulation. Opposites and antitheses in the Janusian process are both separated and connected when simultaneously posited. In the homospacial process, discrete separate entities become connected within the same space. Sepconic articulation is used conjunctively throughout all phases of the creative process, interacting and interlocking with the various phases of both Janusian and homospacial operations. Creators use it independently primarily in the fourth phase construction of the completed work. Overall, the sepconic articulation process has a biphasic configuration. In the early aspect, the person who is motivated or 'inspired' to create takes in emotionally laden stimuli, experiences, and concepts. Analogous with the literal meaning of the term inspiration in breathing or respiration, the taken-in contents are, like elements in inspired air, modified and mentally interact both consciously and unconsciously. Not simply expelled or expired, through such postulated mechanisms as unconscious breakthrough or as catharsis, the elements are sepconically and consciously articulated. Similar to the everyday creation of human utterance in which inspired air is articulated by the voice apparatus and the brain to construct words and language, the sepconic articulation process modifies initially taken-in inspirations in an extended final phase.

James Joyce 1882–1941

R B Faux, Duquesne University, Pittsburgh, PA, USA

Background

Dublin: 1882–1904

James Augustine Aloysius Joyce was born on 2 February 1882 in Rathgar, a suburb of Dublin, Ireland and died on 13 January 1941 in Zurich, Switzerland from a perforated duodenum. He was the oldest of ten children (six sisters and four brothers). His father was John Stanislaus Joyce, his mother was Mary Jane Murray. Joyce's father was able to support the family quite well for a number of years before losing his job as a tax collector, at which point the family went into financial decline that forced them to move from apartment to apartment, often doing so in the middle of the night to avoid landlords demanding back rent.

From 1888 until 1891 Joyce attended Clongowes Wood College (a Jesuit-run school); he dropped out when his family could no longer pay tuition. While at Clongowes Wood College he excelled in academics and often found himself the head of his class. Joyce briefly studied at a school run by the Christian Brothers before taking up studies in 1893 at Belvedere College, another Jesuit institution. At Belvedere Joyce studied French, Italian, and Latin. Also he began writing poetry and honed his writing skills with a series of essays. Joyce's poetry is often overlooked when compared to his later prose work. However, he did publish two collections: *Chamber Music* (1907) and *Poems Penyeach* (1927). Joyce was uncertain whether he had the talent to write poetry but continued to write it for many years. During his last year at Belvedere Joyce discovered the work of Henrik Ibsen (the Norwegian dramatist). Ibsen figured prominently in Joyce's artistic development. It was Ibsen's questioning of middle class values, his individualism, and his ability to represent the events of everyday realistically that attracted Joyce to him. Joyce's only play, *Exiles*, was heavily influenced by Ibsen's dramas. Joyce was to look to other European writers for inspiration rather than Irish writers.

After leaving Belvedere College, Joyce enrolled at University College, Dublin. In 1902 he obtained a degree in modern languages. While at university Joyce was more interested in acquiring life experiences than academics. It was at this time the he began to question more deeply the Catholic Church and the role it played in restricting intellectual freedom in Ireland. From 1900 to 1902, Joyce gave a series of controversial lectures in which he presented the view that art and drama need not be related to morality or ethics but should reflect the real life of characters. Drama, for Joyce, was the highest form of art. In addition to all of these activities, Joyce made the acquaintance of William Butler Yeats, George Russell, and Lady Gregory, all of whom were to support him artistically as well as financially.

In December of 1902 Joyce left Dublin for Paris where he planned to attend medical school with the intention of combining a career in medicine with one in writing. Yeats and Lady Gregory provided him with valuable contacts. However, this endeavor was short-lived as Joyce recognized that he could not

afford the school's fees. He did not return to Dublin but remained in Paris living on what he could make from book reviews, English lessons, and money from his family.

Joyce did finally return to Ireland upon learning that his mother was dying. She died on 13 August 1903. Her death broke the family apart and left it poor and desolated. Joyce would never forget this. It reinforced his increasingly negative feelings for Ireland and significantly shaped his emotional life, influencing his artistic development. It was during this time that Joyce began to drink. Prior to this he refrained from drinking partly in response to his father's intemperance. His drinking was encouraged by his friend Oliver St. John Gogarty. Joyce would continue to drink heavily for the rest of his life, even at the risk of damaging his already impaired vision and breaking up his family.

Out for a walk on 10 June 1904 Joyce spotted the person who would change his personal and artistic life forever, Nora Barnacle, walking along Nassau Street. He was immediately smitten with her. They met on 16 June and walked from Dublin to Ringsend. It should be noted that this is the same date on which the events of Joyce's *Ulysses* take place. Nora was to be Joyce's companion, wife, and muse for 36 years. In Nora Joyce found someone who could fill the void left by the death of his mother and someone who understood him but was not intimidated by him. Nora attended school only until the age of 12 and had little interest in literature, so she would seem an unlikely mate for someone such as Joyce, but she was self-possessed, courageous, and witty. She determinedly looked after Joyce, constantly berating him for his almost nightly drinking bouts. He was impervious to her concerns about his drinking, even when she threatened to leave him. Joyce viewed his nightly drinking as a way to relax and as a way to mingle with people and observe their behavior and habits of speech as a source of material for his writing. He did not drink during the day.

Joyce was in awe of Nora and she would be the wellspring of his inspiration. Their letters to one another are voluminous and range from being obscene to outpourings of love and admiration. He would spend hours listening to her talk, eventually using this material in his work. Nora's ways of thinking and speaking was the model for Molly Bloom.

Trieste: 1904–1915

Joyce rejected the institution of marriage, and since they could not live together unmarried in Ireland Nora and Joyce moved to Zurich, Switzerland where Joyce had been promised a job at the Berlitz School. Upon arriving they were informed that the position had been filled. Next they traveled to Pola and to another Berlitz School. After five months they relocated to Trieste, Italy, where they would live for the next ten years. Nora gave birth to two children: Giorgio and Lucia. While in Trieste, Joyce returned to Ireland three times. After each visit he became more and more aware that if he were to develop as an artist he would have to remain an exile.

Life at this time was difficult because Joyce had to find ways to support his family. He worked at a bank for a while then gave English lessons at a Berlitz School. His roles as provider, husband, and father intruded upon Joyce's artistic development. In 1905 Joyce convinced his brother, Stanislaus, to move to Trieste. While there he took on many of the problems besetting the family, leaving James the time to write.

During the Trieste years Joyce began or continued work on a number of writing projects. Shortly after arriving in Trieste Joyce commenced writing stories for the book that would be called *Dubliners*. It would not be published until 1914. He also continued to write an autobiographical novel entitled *Stephen Hero*. This work would be reworked and given the title *A Portrait of the Artist as a Young Man*. This was published in 1916. Joyce also began writing *Ulysses*. It would be published in 1922.

In 1913, at the recommendation of Yeats, the American poet Ezra Pound contacted Joyce and offered him the opportunity to publish in American and British journals. Pound played a significant role in getting Joyce the exposure he needed. He published several of Joyce's stories from *Dubliners* and encouraged his contacts to promote Joyce. The ten years spent in Trieste were among the most productive years of Joyce's writing life. However, in July of 1914 Austria–Hungary declared war on Serbia, thus bringing on World War I. This made life in Trieste difficult and even dangerous, compelling Joyce and family to move to Zurich, Switzerland, leaving their books and furniture behind.

Zurich: 1915–1919

After arriving in Zurich the Joyces discovered that it was an expensive city and that they needed assistance. That assistance came from Yeats and Pound and two other benefactors, Harriet Shaw Weaver and Edith McCormick Rockefeller. Weaver would prove to be a great supporter to Joyce; she helped him both financially and intellectually for many years. Because of this financial help Joyce was able to devote most of his time to writing *Ulysses*, and was able to write a great deal of it during this time. The final installments of *A Portrait of the Artist as a Young Man* were published and Joyce attempted to have his play *Exiles* produced. This proved to be extremely difficult as there were legal and artistic battles at every turn. The play was performed only sporadically throughout Joyce's lifetime.

After the war the Joyces returned to Trieste for a year. The city had changed for the worse in Joyce's eyes. They moved in with James' brother Stanislaus and sister Eileen, along with her husband, two daughters, a babysitter, and a cook. In these less than ideal conditions Joyce continued to work on *Ulysses* and helped translate *Exiles* into Italian. After seven years of corresponding Joyce and Pound finally met face-to-face in June of 1920. During this meeting Joyce was persuaded by Pound to move to Paris where he would be able to get *Ulysses* published. The Joyces left for France in 1920.

Paris: 1920–1940

Joyce and family lived in Paris until 1939. Unlike their life in Trieste, Paris confronted the Joyces with numerous cultural experiences and the attention of the literati. Because of Pound's efforts Joyce was now seen as a celebrity of sorts.

Joyce was nearly finished writing *Ulysses* and began looking for a publisher. This proved to be very difficult as four chapters of the book that had been serialized in America were confiscated and deemed to be obscene by the US Post Office. A court case ensued bringing with it negative publicity. Potential publishers were scared off by this and Joyce doubted if the novel would ever be published. One of the most important contacts Joyce made in Paris was with Sylvia Beach, an American expatriate who owned the bookstore Shakespeare and Company. She agreed to publish *Ulysses*. Once Beach agreed to publish Joyce had to write the final three episodes and revise earlier ones. Joyce viewed the revision process as a part of the creative process. With earlier drafts and his notes, Joyce began to link themes, phrases, and words to give *Ulysses* an overall sense of coherence. Because of the speed with which Joyce had to make revisions the first edition of the book was filled with errors. *Ulysses* was published in February of 1922.

Ulysses received critical praise. However, British customs officials confiscated the book on charges that it was obscene so it was not allowed to be published in England. The first American edition of *Ulysses* was published in 1934 and the first British edition in 1937.

After the publication of *Ulysses* Joyce began to contemplate his next writing project. He began studying his unused notes for *Ulysses*. This is notable, as Joyce's novels seemed to develop or emerge from one another. In March of 1923 Joyce declared to Harriet Shaw Weaver that he had written two pages. These two pages represent the beginning of Joyce's last work: *Finnegans Wake*. It would take Joyce 16 years to complete the book. Two reasons it took such a long time to write were Joyce's worsening eye problems due to glaucoma, and his daughter Lucia's increasing mental instability. Three other very personal events occurred in 1931 and 1932. Joyce and Nora were officially married on 4 July 1931. The marriage took place so that in the event of Joyce's death his estate would be transferred to Nora and their children. On 29 December 1931 Joyce's father died. He did not attend the funeral and considered abandoning *Finnegans Wake*. On 15 February 1932 Joyce and Nora became grandparents to Giorgio's son, Stephen. Through all of this Joyce continued to work on his next project and would write and revise in outbursts of creativity. Joyce and his family moved from Paris and lived in Saint-Gérard-le-Puy in the south of France for a year. During this time, the stomach pains that had plagued Joyce became more severe. Doctors discovered that he had a duodenal ulcer. With the arrival of the Nazis, Joyce and family, except for Lucia, his daughter, left France and returned to Zurich. Joyce would never see Lucia again.

Zurich: 1940–1941

Once in Zurich Joyce's stomach condition worsened and it was decided that he should be operated on. He was conscious after the surgery but fell into a coma soon after. Joyce died of a perforated duodenum on 13 January 1941.

The Work

Joyce is best known for his four novels: *Dubliners*, *A Portrait of the Artist as a Young Man*, *Ulysses*, and *Finnegans Wake*. At the

time they were published these works stirred controversy and were deemed to be obscene by authorities. However, many others saw them as revolutionary and changing the form of the novel and ushering in modernism. *Ulysses* and *Finnegans Wake* are considered to be among the greatest novels ever written. Throughout his writing life Joyce encountered editors who insisted that some word or phrase be changed or deleted because they were confounded by what they had read or feared retribution for publishing obscenity. In each case Joyce refused; it was essential for him to keep his works as he wrote them, and he battled editors throughout his life.

Joyce as a modernist writer overturned traditional ways of writing and experimented with different narrative techniques and focused on the psychological lives of his characters. Joyce, along with other modernist writers, was able to reflect in their work the ever-changing realities of everyday life. The only way to do this effectively was to write very complicated works that reflected the complexities of real life; this is especially true of *Ulysses* and *Finnegans Wake*.

As one reads Joyce's works it is clear that although he lived in exile from Ireland for most of his life, he maintained intellectual ties with it, as all of his novels take place there, especially in Dublin. Another striking characteristic of Joyce's work is its increasing complexity. The early novels, *Dubliners* and *A Portrait of the Artist as a Young Man*, are accessible and are the most widely read works Joyce produced. The late novels, *Ulysses* and *Finnegans Wake*, are challenging to read as Joyce does his most daring experiments with language in these later works. Despite their differences from the longer works, Joyce's earlier, shorter works resemble the longer ones in their structures and themes. Joyce would reinterpret, revise, and reuse much of the material from his earlier writing in his later work. The transformation and increasing complexity of the themes and issues of the early novels in the later ones illustrates Joyce's incessant reading, writing, revising, and experiencing. This accumulation of material from different sources is called accretion. Joyce used all of the knowledge and material he had at his disposal in the writing of his novels.

Dubliners

With this collection of short-stories Joyce first experienced what would be a common reaction to his work, namely, that it was obscene. It took Joyce nearly ten years to get the book published. It was published on 15 June 1914. It is organized around four themes: childhood, adolescence, maturity, and public life.

Joyce did not originally intend for *Dubliners* to be a short-story collection. He had been asked by George Russell to write something about rural Irish life for the *Irish Homestead*. For this Joyce wrote *The Sisters*. Joyce wrote two more stories for the *Irish Homestead* before being told by Russell to stop. This was due to countless complaints of obscenity. When Joyce submitted the 15 stories of *Dubliners* for publication he doubled the length of *The Sisters* and made it a more complex story. The last story of the collection, *The Dead*, could be a novella on its own. In it Joyce repeats and recombines themes from the other stories in the collection. Many consider *The Dead* with its complexity the beginning of Joyce's transformation into a novelist.

This early work has features that will characterize all of Joyce's later novels: the allusive method and gnomons. The allusive method refers to the indirect presentation of an idea or fact through concrete symbols. Gnomons are missing pieces of information in a story that make it difficult to come to an interpretation of the action. The gaps produced by gnomons force readers to speculate about what might be happening or what some action might mean. Another characteristic found in *Dubliners* and reflects Joyce's realism is the technique of presenting multiple and overlapping conversations and points of view without a narrator to sort them out. This technique is used again in *Ulysses*. This may give the reader the very real sense of eavesdropping. Characters often use idiomatic words and utter incomplete sentences and it is up to the reader to render an interpretation.

A Portrait of the Artist as a Young Man

This second of Joyce's novels began as his autobiographical novel *Stephen Hero*. After much revision Joyce produced *Portrait*. It was serialized in *The Egoist* from 1914 to 1915; it was published as a book 29 December 1916.

The central character of this novel is Stephen Dedalus. In many ways Stephen is Joyce. This novel can be seen as an expression, through Stephen, of Joyce's views on Ireland, religion, aesthetics, and love. It also represents a move from an entirely realistic novel, such as *Dubliners*, to a focus on Stephen's psychological life. That is we see the world from Stephen's perspective and are privy to his artistic and personal struggles. *Portrait*, thus, falls into the categories of Bildungsroman (a novel of education that describes the psychological and spiritual development of the main character) and Künstlerroman (a novel in which a character seeks life experiences and artistic expression).

Ulysses

Joyce originally conceived *Ulysses* as a short story to appear in *Dubliners*; abandoning the idea of a short story, he considered it as a sequel to *Portrait*. Only after seven years had passed did Joyce commence writing it as a novel. It was published on 2 February 1922; Joyce's fortieth birthday. It is based and structured on Homer's *Odyssey* and represents one of the first examples of a modernist text. The action of the novel takes place on one day, 16 June 1904. This is perhaps the book most associated with Joyce and the one not likely to have been read by most people. It runs to 700 pages and displays a vast amount of knowledge and rhetorical styles. It is divided into 18 episodes; each episode representing a particular style of narrative and theme. The three main characters are Stephen Dedalus, from *Portrait*, Leopold Bloom, and Molly Bloom.

One of the most important narrative techniques Joyce used in *Ulysses* was the use of interior narration. This is unspoken material that is revealed in the thoughts or internal dialogue taking place in a character's head. Joyce presents interior narration in a realist way, meaning that the thoughts a character may be having are fragmented, incomplete, or random. Joyce does not explain them; it is up to the reader to figure out what a character's thoughts might mean. A related technique is

stream-of-consciousness. This is a form of narrative that reveals the conscious experiences of character. It is a way to lay open their inner lives. The use of these two techniques represents the beginnings of the modern novel. The novelist invites readers to explore the psychological worlds of characters, leaving it up to readers to figure out what a character is thinking and experiencing. Thus, the modernist novel is a work filled with a great deal of ambiguity.

Finnegans Wake

Joyce began writing *Finnegans Wake* in 1923. Until it was published in 1939 it was referred to as 'Work in Progress.' The actual title was known only to Joyce and Nora. This work represents Joyce's most radical exploration of narrative form and language. As with many of his other works how Joyce actually wrote this is still a mystery. There are those who view Joyce's method as being random; explaining that Joyce had a keen ear and would pick up an odd word overheard on the street or in a restaurant and jot it down in a notebook. He would even rely on his own conversations for material. This approach to writing is somewhat random. Others see Joyce's method of composition as being logical and mechanical. Joyce would consult and study a vast array of literary material. His knowledge of languages is best displayed by his use of portmanteau words. This is the blending of two or more words to form a new word; for example breakfast plus lunch is brunch. Given the length of time it took Joyce to write and the complexity and length of the book, there are others who argue that Joyce's method of composition was a mixture of these two. It is clear that Joyce did not work from beginning to end; rather, he composed and revised various sections at a time going back and forth between sections. This is referred to as a diachronic method of composition.

'Work in Progress' appeared in serial form as it was being written. It was not well received by many of Joyce's supporters who found it incomprehensible. Discouraged by the reception Joyce thought about handing the work over to Paul Stephens, another Irish writer. However, Joyce continued writing and produced a novel that revolutionized Western literature.

Influence

James Joyce is one of the greatest and most controversial writers of the twentieth century. His work still amazes and confounds many a reader. Joyce's feat transformed literature

from a clear and logical description of reality to an exploration of human consciousness and unconsciousness, of waking and sleeping. He redefined the relationship of both writers and readers to literary texts. Joyce's texts *Ulysses* and *Finnegans Wake* have less to do with representing reality than they have with the experience of language itself.

As we read Joyce's works from his earliest works to his last, we see a transition from a description of a reality to which most of us can relate to a reality disconnected from the world and tied to the unique consciousness experiences of Leopold and Molly Bloom in *Ulysses* and Humphrey Chimpden Earwicker and Anna Livia Plurabelle in *Finnegans Wake*. The inner lives of the characters become the focus. This shift from objective experience to subjective experience and focus on form and language would transform literature and influence writers to this day.

Glossary

Analytical psychology A psychological science, developed by Carl Gustav Jung, that grew out of psychoanalysis and includes theory, research, and practice.

Archetypal image A representation, or motif, of an archetype that has infinite manifestations. The produced archetypal image gives a voice to the archetype itself and is commonly found in fairy tales, legends, religion, mythology, dreams, and art. Also referred to as a primordial image.

Archetypes Limitless instinctual forms, not yet ideas or representations, within the collective unconscious thought to be passed down through the ages and found in all cultures. Archetypes are not visible until an image is created.

Autonomous complex An emotionally charged part of the psyche that usually includes material from consciousness as well as the unconscious. Forms the connection between the personal and archetypal parts of a person. Autonomous complexes, which are many, include the creative complex.

Collective unconscious The second layer of the unconscious, preceding the personal unconscious, which

houses the archetypes (often used interchangeably with the concept of archetypes, defined above). Considered the reservoir of great art.

Individuation The cornerstone of Jung's theory of personality development. The process is life long and the goal, which is attainable only in stages and not in total, is to become whole, complete, and truly individual. Making great art is linked to this process.

Personal unconscious The first layer of the unconscious that stores traumatic memories, experiences, and ideas that are unique to the individual's past. This layer of the unconscious precedes the collective unconscious.

Symbol The greatest conceivable expression for an idea; the idea cannot be produced in a better way. Symbols can be recognizable connections to archetypes, but their actual meaning is unknown. Great art is truly symbolic.

Wholeness The ultimate form of expression of all parts of the personality to one's self, others, and nature. Being psychologically whole equates with health, and health equals creativity – the goal of individuation.

Carl Gustav Jung – The Man

Carl Gustav Jung was born on July 26, 1875, in Kesswil, Thurgovie, Switzerland (also spelled as Kesswil, Thurgau in other biographies). His family was economically poor. Jung's father, a doctor of philosophy, worked as a pastor in the Swiss Reform Church and was also an Oriental and classical scholar. His father was described as quite conventional in his religious beliefs, from which Jung later strayed. Kind, tolerant, reliable, and otherwise liberal were also reflective of his father. By some accounts, Jung believed his father was weak and unpowerful. On the other hand, Jung's mother was thought to be inconsistent and divided in her thoughts. She often contradicted herself. He seemed to identify with her in many ways, especially regarding his intensely complex inner world and that she seemed to have two strong parts of her personality that opposed one another. This opposition was part of Jung's experience of himself (and later a central part of his theory of personality.) When Jung was three years old, his mother was hospitalized for several months, probably due to problems in her marriage that continued throughout his youth. Over time, Jung developed mixed feelings for his mother. Jung was a highly sensitive, curious, and bright child who had several bouts of physical illness. He was acutely aware of his thoughts, feelings, and surroundings. Growing up in the country afforded him a great deal of pleasure and a place for exploration. He enjoyed the beauty of his homeland and was in a frequent state of discovery about the world around him.

The beauty and brightness he experienced was contrasted by several dark experiences that followed him for much of his life. The dark experiences included themes of death, religious activity, dreams, and fears. This duality serves as the cornerstone for much of his theoretical frame. Jung took playing quite seriously, and playing alone became a constant for Jung as he was an only child until the birth of his sister when Jung was nine years old (he had a brother who died two days after his birth, two years preceding the birth of Jung). He was quite interested in Eastern religion, mythology, and nature as a young boy. Being alone allowed him the space to ponder the many questions he had about life, especially religion. Some believe that the materialization of analytical psychology was his way of finding a replacement for religion. He did not have any companions that he trusted enough to share his meaningful ideas or questions, and thus he felt even further isolated.

School for Jung was wrought with ups and downs. At times he was strongly engaged and at other times he was disengaged. His interest varied depending on experiences he had with other students and his teachers, as well as their perception of him.

After much deliberation, Jung decided to attend medical school. He struggled with this decision because he originally wanted to study natural science or the humanities. His decision was largely based on practical matters of expenses and obtaining a reasonable income after college. Within the field of medicine he was inclined to choose surgery or internal medicine. Psychiatry, which became known to him late in his academic career, was his final choice. He found his university

experience exciting and challenging. In addition to medicine he was able to continue his study and exploration of theology, philosophy, and Eastern theories. After finishing school in 1900, Jung moved to Zurich, Switzerland, where he lived for the duration of his life. He began training at a psychiatric hospital in the city. For the first six months he lived in the hospital, immersing himself with psychiatric literature and learning firsthand what the experience was like. Here he became fascinated with the minds of patients with many disorders, including schizophrenia. Many of his theories originated from his work in the hospital. He became rather disillusioned by the way patients were treated and began to experiment with alternative therapies. This disillusionment led him to the work of Sigmund Freud. Jung published his first paper in 1902 and began lecturing at the university in 1905, meanwhile building a private practice in Zurich. In 1907 Jung met Freud. From the beginning, Jung was reluctant to embrace many of Freud's theories, yet conversely he was intrigued with Freud and his work. At times Freud and Jung worked closely. Jung was beginning to formulate more of his own theories and had trouble accepting key ideas in Freud's theories. Yet he found himself unable to disagree overtly with Freud as Freud saw him as a loyal protégé. The final break between the two men occurred with the publication of Jung's book on libido (psychic energy) in 1913. Jung's work was met with a great deal of judgment, and he was rejected by many of his friends and colleagues leaving him isolated once again. The next four years were wrought with a great deal of distress, mystery, and growth. Some reports indicate that Jung had a psychotic break, primarily because he was experiencing visions and emotional turmoil. Through these experiences he began to further understand the workings of his unconscious, which led him further along the path to the idea of the collective unconscious. He studied his dreams and fantasies, drew pictures of his visions, and began to create mandalas (circular drawings that become central to his theory of individuation). This creative and very dark period gave him the material to sort through and define for the rest of his life. He did not understand all that was occurring, only that it was significant, and later the meaning would be revealed. From 1918 to 1919 Jung came out of his so-called darkness. He attributed the change to ending a relationship with a woman who continued to believe his fantasies were that of art. He adamantly opposed this assertion. Some writers point to the curious nature of his insistence on this matter. For when he was a young boy he derived great pleasure, and felt successful, making art. The second factor that released him from his darkness was his understanding of the mandalas he created. Mandalas will be discussed later, but for the sake of his story, Jung found them to be a way of journaling his internal growth. Jung continued on this journey of understanding the psyche, especially that of the collective unconscious. He traveled throughout the world, which gave him greater evidence for his belief in the collective unconscious and the role of archetypes. Everywhere he visited he was able to see connections to the archetypal and mythical world. The common images existed despite cultural, language, or age barriers. Jung spent the majority of his life writing about these experiences as well as maintaining an esteemed clinical practice. Regarding Jung's family (which he rarely wrote about), he was married in 1903 and had five children. Jung's wife, Emma, also an analyst,

contributed to the work of analytic psychology and wrote several works. At the time of his death in 1961 he had 19 grandchildren. Most of his life, he had a great number of students and people who worked with him. He was frequently sought after and deeply respected by most accounts. He received many awards throughout the world. He has contributed enormously to the field of psychology and continues to have a great number of followers with Jungian analytic institutes worldwide.

Model of the Mind

As mentioned earlier, Jung's theory of the mind rests on the concept of opposites and opposite forces, which is important to be mindful of as his theory unfolds. This section provides an overview of several key concepts of Jungian psychology, including the ego, consciousness, personal unconscious, collective unconscious, individuation, and wholeness. Whenever possible, the implication to the creative process associated with the corresponding structure of the psyche will be made. Psyche, or psychic material, refers to the entirety of both conscious and unconscious psychological processes. The psyche is very complex and works to keep itself in balance.

The Conscious Mind

The conscious part of the mind has the primary job of sustaining the relationship with the ego. The ego is a complex (see the definition of *autonomous complex* in the glossary at the beginning of this article and a further description following the archetypes) that contains a great deal of continuity and identity. For psychic material to be conscious, the ego must be aware of the material. Conversely, when psychic material is unknown to the ego, it remains unconscious. Awareness in this case is not merely intellectual but rather intuitive, emotional, and with meaning. Further, consciousness is thought of as the opposite of the unconscious.

The Unconscious Mind

The unconscious is the second psychic structure to which Jung referred. Consciousness is the unconscious' opposite and houses information that is not accessible to the ego but may later be accessible. The unconscious is vast in size and fluid in movement. The relationship, or link, between consciousness and the unconscious is referred to as compensation. Compensation means balancing or adjusting. In this case, compensation comes into play when consciousness is too one-sided, leading the unconscious to try and reach a balance. The personal and the collective are the two substructures of the unconscious. Both substructures serve as a source of art, although in very different ways (which will soon be illustrated). First we take a closer look at the personal and the collective unconscious.

Personal unconscious

The personal unconscious, the first layer, is that part of the unconscious specific to the individual. Included in the personal unconscious are repressed memories (memories that have been pushed down into the unconscious without one's

control), ideas that are painful, and information without the strength, or the timing, to reach consciousness. Material in the personal unconscious was once conscious and may later be conscious again.

Collective unconscious

The collective unconscious, the second and deeper layer, is that part of the psyche that is shared by all people, in all cultures, throughout the ages. Jung believed that the collective unconscious is much more important than the personal unconscious because it is the seat of power, wholeness, and internal transformation. The collective unconscious holds dreams, visions, religious experiences, and myths.

He arrived at the idea of the collective unconscious through his knowledge of mythology, anthropology, religion, and art. The collective unconscious concept was further materialized from Jung's work with patients who were diagnosed with schizophrenia (importantly, the collective unconscious is found in everyone, not just in psychotic patients.) Furthermore, in his work he realized that images in people's dreams were not from their own personal experience, or life, but rather reminiscent of archaic symbols and images. He began to recognize these images in ancient works and religions that the patient who dreamed the material was not aware of. In many of Jung's original writings he unknowingly referred to the collective unconscious and the archetypes interchangeably. This confusion has led subsequent authors to speak of the collective unconscious and the archetypes together, not as separate structures.

Archetypes are universal structures in the collective unconscious that allow for the *potentiality* of ideas, but they are not ideas themselves. This point is often a source of confusion and the distinction is important to understand. Archetypes are known because of the archetypal image they represent in consciousness – in other words, how the archetypal images appear. The image is what gives proof of the existence of the archetype. You cannot see an archetype; you can see an archetypal *image*. Archetypes, and archetypal images, have a strong creative force along with many other qualities. Among the qualities present are that of favorability, emotion, number, intensity, and type. Archetypes are neither all bad nor all good. Rather, they simply exist, and understanding the importance of the structure is what is key. Intense emotion exudes from archetypal images. Experiences may be within the likeness of all human behavior, but the experiences that manifest within the category of archetypal are extraordinarily human. Going beyond the ordinary into the realm of the extraordinary, emotional response to an archetypal imagery is enthralling, bigger than life.

Because of the emotional magnitude of the archetypal image it acts as a communication device from the unconscious mind of the individual who produced the work, to the unconscious mind of the individual seeing or reading the work, through the symbolism inherent in the image. The communication is further enhanced by the image relating to mythological figures, or motifs, from ancestry. The manifestations of archetypal images change based on the current culture but are always linked to the past. When an archetypal image is seen or heard or read it evokes a great deal of emotion, power, and release. It is as though we are connected to our past and the *past of all mankind*.

Examples of archetypes

There are infinite numbers of archetypes and archetypal images. Some of the key archetypes that will be discussed are the anima and the animus, the shadow, the persona, and the self. Other archetypes are the mother, father, warrior, and wise old man, to name a few.

Unconscious archetypes of the opposite sex are referred to as the anima and animus, in Latin these words mean "the soul." The anima refers to a man's image of a woman; and animus refers to a woman's image of a man (which Jung viewed in traditional roles of the 19th century). The anima and animus are thought of as guides, primarily throughout the terrain of the unconscious creating a richer level of understanding of one's internal world. Another way of thinking about the anima and the animus is in their role of moderating between the conscious ego and the unconscious mind.

The anima was intensely studied by Jung as well as his followers. Less was written by Jung, and his followers, on the concept of the animus. The anima and animus are important for many reasons; especially in relation to the creative process. They are both portrayed continuously in fairy tales, myths, literature, film, and other art forms.

The shadow is another archetypal figure or image. The essence of the shadow is that part of everyone's personality that is disliked and incongruent with how one would like to be perceived. The part that harbors unacceptable feelings, thoughts, or wishes, distasteful impulses, and negative assessments of oneself. The shadow is actually the part of ourselves that we can only sometimes see and in varying degrees. Just as the sun creates shadows on all that catches its light, the shadow can be further thought of as the darker, uglier, and evil side of life (for example, violence, wars, and tragedy, as well as that part of the person who commits such crimes). Further, the shadow is the side of the personality that most people would wish to disown or pretend did not exist. The opposite, or counterpart, to the shadow is the ego. The shadow is often portrayed in movies, books, and art of all kinds.

Persona is the archetype Jung referred to as the mask that we *all* wear at times. The persona is thought of as the mediator between the ego and the outside world. The concept of the mask suggests that we respond to the expectations of society by presenting ourselves in a certain light, even though the persona is not our true or complete self. In extreme instances, the mask, or persona, is represented in the person who cannot leave his or her professional identity aside. For example, the lawyer is always arguing a point; the preacher is always wearing his or her religious garb and reading from the Bible. The true personality, or person, of the lawyer or preacher is unknown to the people in their lives. A common example is that most of us have different roles in society, such as brother, sister, daughter, son, student, date, employee, and so on. We show different sides of our personality as we relate to others in those varying roles. The self archetype is that of wholeness and completion.

The self further refers to the ability of the conscious and unconscious to work together in order for an individual to be free to be her or his true self. The integration of all parts of the psyche allows the individual to live in a creative and symbolic fashion – to be truly an individual. The self archetype is the representation of individuation, which will soon be discussed. Another concept often compared and contrasted to

archetypes is that of the complexes (referred to in the section on consciousness). Jung suggested that there are many complexes in the psyche; unlike the archetypes that number is finite. However, like the archetypes they are neither all bad nor all good; rather they are a part of the psyche to be understood. The autonomy of the complex is such because the conscious mind does not regulate or control the information. In other words, information comes and goes on its own. The autonomous complex operates when there is enough energy to move information from the unconscious to consciousness. Even though the information is conscious it is only perceived, not known. The creative complex is one of the autonomous complexes. The autonomous complex is the *living* part of the creative process, the part that takes on a life of its own (which will be discussed in detail).

Individuation

The following section provides an overview of the concept of individuation including the concept of wholeness, the integration of mandalas, and the production of active imagination. The process of individuation is key to understanding Jung's theory of creativity. Individuation further includes the integration of the conscious mind, the personal unconscious, and the collective unconscious.

The cornerstone of Jungian, or analytic, psychology is individuation. The *process* of individuation, likened to his description of the creative process, is the road of integration between parts of the self that are conflicted – again, the notion of opposites. Bringing into harmony the parts of the psyche, both conscious and unconscious, that are at odds is the goal. In addition to the internal work required for individuation is the external work of increasing one's individuality. Thus, individuation includes both internal and external movement. Full individuation can never be reached, instead Jung believed that it was best to approach it as a lifelong process. Importantly, not everyone chooses or is able to travel down the road of individuation.

The *purpose* of individuation is to bring about wholeness in the individual. Wholeness suggests that one is able to fulfill one's destiny and vocation. Wholeness allows the individual to be authentic in the world, thereby avoiding using only the persona, or the mask. Being aware of one's own internal reality is at issue, *not* getting rid of a part of the self that is disliked. Coming to terms with the darkness and the painful images in the unconscious is a necessary part of individuation. Also included in the process is greater awareness of the collective unconscious and the collective world around each individual, thus avoiding isolation. A sense of wholeness further encompasses the spiritual aspect of life.

Through the process of individuation, with the hope of reaching wholeness, is the production of images, archetypal images. These images allow psychic material from the unconscious to become conscious, in varying degrees, thereby freeing difficult material in the collective unconscious. In the case of the artist, moving further along the path of individuation with the production of art subsequently provides the viewer or reader of the art with a similar experience – that of individuation. One form in which individuation may be expressed is through the making of mandalas, which are a symbol of the

psyche's center, or the self. The self, an archetype, is reflective of both conscious and unconscious parts of the psyche. The creation of mandalas was for Jung a tremendous experience of integration within himself, of unconscious and conscious experience. The mandala is a circular drawing usually divided into fourths, or derivations of four or eight. Mandalas are actually used in the East as a form of meditation, although at the time Jung began making them he was not aware of this historical element. He considered this work to be in the realm of religion as opposed to art.

Others have considered the mandala to reside equally within the realm of art. The argument is that a work of art is also an integration of the inner world of the artist and the external world in which the artist lives – again, a representation of the unconscious and the conscious parts of a person. Another route to individuation is through active imagination, a fantasy activity primarily used by Jung with his patients and with himself. Introspection or meditation is at the center of the activity. Active imagination allows the individual to have a dialogue between consciousness and the unconscious. Jung was not certain if the unconscious rules over consciousness or if consciousness rules over the unconscious during active imagination. The important note is the interaction between the two structures of the psyche, the conscious and unconscious, lead to a greater sense of wholeness and individuation.

The form of active imagination can take various shapes such as painting, drawing, writing, and so on. The end result is not what is of primary importance but rather the interplay in the psyche of the creator and the creative process. He found that during active imagination, people were able to tap into their unique creative potential. He did not regard this act as making art per se, but rather engaging in their own process of creation.

Artistic Creation

This section provides an overview of Jung's conceptualization of the source and process of creativity, as well as his perception of the artist who creates. Jung was very cautious in his understanding and interpretation of artistic creativity, and he was primarily interested in literature, although he made references to all of the arts. He did not offer a complete theory of art primarily because he wrote on so many other topics, and because of his desire to resist overanalyzing art. As such, he was careful to identify the limits of his psychological study of art activity. In fact, he probably would not have touched the topic if he did not consider making art to be in the realm of psychology, which he did. In general, Jung believed that the process of creation has a feminine quality and the creative work is that of the "mothers," an archetype, within the collective unconscious. As previously stated, much of Jung's theory emphasizes the role of obtaining balance regarding the opposite poles within the individual. The making of art follows through with this idea. When the artist is out of balance psychically, the archetypal image rises to the surface to restore harmony in the individual and, in turn, society, thus keeping in line with the concept of individuation.

Jung made a distinction between the artist and the actual work of art. Artwork may provide inklings to the artist's life but

not reveal the unique qualities of the person who created it. Just as the artist's life may provide clues to understanding the work but not shed light on the meaning entirely, Jung felt strongly that psychology can never fully understand the causality of any work of art, largely because the creative urge originates in the unconscious. A reductionist approach to understanding art was contrary to Jung's position. (A reductionist approach to art is attempting to trace all the elements of a work of art to the artist's past.) He was in favor of experiencing a work of art (poetry, paintings, literature, etc.) on its own terms instead of looking for the psychological reasons, or causes, of art. Even though the material of the work can be linked, or traced, to the artist's past, this does not allow others to then understand the actual meaning of the work. In this way, Jung saw the artist as quite separate from her or his creative work. In other words, a work of art in some cases transcends the person and is thus a separate entity. Jung was primarily interested in this type of work, later referred to as type two, or visionary, work.

Types of Artwork

Work that transcends the artist and work that does not was further described by Jung in the following typology. He identified two types of art: one derived from the conscious mind and the second from the unconscious mind. The first type of art is controlled, conscious, and made with a specific intention. Jung later referred to this type of literature as psychological in nature. Psychological, in this case, refers to work that is derived from consciousness such as stories of love, family, crime, and society. These works are easily understood. Artwork of this type, whether literature or painting, is deliberate in that the artist knows exactly what he or she is intending to create. The artist and the creation are one; there are *no surprises*.

In contrast, the second type of art is unconscious, uncontrolled, and amazes the artist. The work produced takes on its own form and structure. Whereas the first type of literature is thought of as psychological, the second type is thought of as visionary. (Visionary does not exclude the psychological quality; rather it goes beyond the personal psychology into the suprapersonal realm). Visionary works are those that are unfamiliar, strange, gigantic, and superhuman. These works speak to the depths of the human psyche and the beginnings of our existence, holding ideas that transcend the words or images set forth. They are symbols of something unknown. Darkness surrounds them. Visionary works are primordial, or archetypal, experiences and not personal experiences. The origins of the creative process are the primordial experiences, but the mythological figures give the work conformation. The primordial images, or archetypal images, are too dark (e.g., demons, spirits). The mythical figures bring lightness to the dark by appearing less frightful or intense and thus bringing harmony to the imagery in a way that is digestible for the current times. These works are extremely important because they originate in the collective unconscious and bring a message for future generations. Positive or negative, the message is ultimately of value. The artist who produces the second type of work is astonished almost to the point of disbelief. In this experience the artist feels as if someone else has created the work. She or he must allow the process to

occur, but not at his or her control. The artist is the vehicle for which the creative process transcends. The artist and the creative process are separate; there are *always surprises*. A further distinction is made between the first and second type of artist. The distinction rests on the type of *activity* set forth by the artist. The first type of creative activity is thought to be introverted and sentimental.

Here, Jung borrowed from the work of Johann Schiller in his conceptualization of sentimental and naive. Intraverted refers to Jung's idea that the artist consciously shapes and controls the art work. On the other hand, the second type of creative activity is extraverted and naive. Extraverted refers to the idea that the artist allows the work to control him or her. In other words, the artist's unconscious takes over.

The action of the unconscious is thought to be the creative urge or impulse that may, in a sense, take over the person. The creative urge arises out of the psyche and is extremely powerful. At times, the urge is so strong that everyday life goes by the wayside in order to create. The creative urge is different for all people and varies depending on the type of work produced. The ability to *understand* both types of work is also different. The first type of work is intentional and comprehensible. The second type of work goes beyond our understanding to the same degree that occurred while the artist was in the process of creating it. The image, the poem, or the story can only be understood through intuition and always provides multiple meanings. However, within one piece of work there can be both types of expression. Further, the second type of art produces a symbol or symbols. A symbol is an expression of an idea that cannot yet be discussed or stated in another, clearer way.

The verbal expression is nonexistent. Works that are symbolic are difficult to understand and the meaning is not clear. They are challenging and stimulate the viewer or reader's thoughts and feelings. In contrast, the first type of creative work tends to be more appealing because it is complete, compared to the second type of work. Symbols are produced for the culture and the spirit, according to Jung. They are a product of the collective unconscious. They are based on intuition and are never planned. Symbols allow for society and the individual to move energy from the psyche into valuable accomplishments found in art and science, among other disciplines. Examples of symbolic, or visionary, art are found in the work of Paul Klee, Wassily Kandinsky, Carlo Carra, and Piet Mondrian. These artists were led by visionary images of their inner world that were indescribable.

The inner world is secretive, even to the artists themselves. These artists brought art making to a new level, that of the mystical and the spiritual, though not of a religious order. The manifestation of the spiritual and mystical visions were found in paintings, collages, and unusual figures made from stone, wood, metal, and glass. The tracing of these prominent artists reaches to the time of pagan religions. A very dark nature permeated and was pushed into the unconscious psyche of humankind. Pushing away the darkness created more ugliness and evilness manifested in the form of obsessions, addictions, and so on. Artwork of the beginning of the 20th century (e.g., Kandinsky, Klee, Carra, and Mondrian) brought about a positive resurgence of the primordial spirit in the form of archetypal images.

The *part* of the unconscious where art originates was important to Jung. He believed that art derived from one's personal unconscious was more a symptom of a problem or situation rather than a symbol manifested from one's collective unconscious. Conversely, art, great art, that is produced from the collective unconscious, or with archetypal images, has a tremendous effect on the viewer. Our own collective unconscious is stirred up through the form and shape of the artist's work. In this way, art continues to revitalize our connection to the past in a way that is understood by today's culture. Jung believed that this effect revealed the social significance of art and held the artist in high regard. Thus, the creative process is the artists' abilities to manifest archetypal images from the depths of their collective unconscious (which is essential for the process of individuation to take place).

In this way the creation of art is what Jung referred to as participation mystique, which is the mystique, or veil, of great art. This movement is in the realm of the collective unconscious. Asking an artist to explain his or her work is unnecessary (largely because great art is beyond explanation), and learning of her or his life is inconsequential and nonexplanatory to the creation. However, he did write the following brief summary about attributes of the artist.

The Artist

Jung saw the artist as an extraordinary human being, one that is granted the benefit and the tragedy of creative vision. Those who create only, or primarily, from their personal experiences are *not* of this lot. They are expressing a symptom of their experience, as referred to earlier. In contrast, artists who are producing great art must transcend the personal and move into the realm of the collective unconscious, thereby speaking to the mind and heart of humankind. Jung saw the artist as a medium for producing work that speaks for all. He or she does not have conscious control to create or not create but rather is propelled by the collective force to create. The artist does not have a choice.

Not only is the artist a creator but also a human being with wants and desires for everyday happiness and experiences. Jung saw the artist as wrought with conflict if these opposing forces – existence as a human being and as an artist – are not reconciled. Primarily the creator who does not acquiesce to the divine power of creativity that has been granted to him or her will be quite conflicted. The creative force is so strong that there is little energy to do much more in life, namely the simple pleasures of the average person. The artist is laced with a burdensome existence, often resulting in a selfish, helpless, infantile, egotistical way of being in the world.

The following analysis of Picasso serves as one, if not the only, analysis of visual art written by Jung.

Picasso

Jung reluctantly and briefly approached the subject of Picasso's artwork, and stayed close to the psychology of his art rather than critiquing his art from an aesthetic point of view. He did so looking chronologically at Picasso's work. Overall, Jung described Picasso's work as nonobjective art, originating from inside, or from his unconscious (earlier referred to as type two artwork). There were a few exceptions, as will be illustrated.

Again, work from consciousness, or outer experiences, produces images that are recognizable. The objects may be distorted but not to the degree that they are incomprehensible. Artwork created from the inside takes on a symbolic form, often producing works that are strange, unusual, and not understandable.

Jung viewed four periods of Picasso's work from the blue period to the post-Harlequin period. Picasso's blue period was described as objective, from consciousness. He then moved into a different period, which Jung described as moving into the unconscious, the inside. This period is very dark, characterizing the ugliness and evilness of life. Picasso's work then changed into another form and shape, that of the Harlequin, a tragic and ancient god – a very primitive image. The Harlequin image was disturbing to Jung. The period that followed was Picasso's unconscious attempt at conquering his internal conflict – that of opposing forces. The use of piercing, relentless color reflects the strength of the unconscious to handle conflicts of violence.

Summary

Carl Gustav Jung provided a wealth of information to the field of psychology and the process of creativity. From his early days he was ever present to the subtle nuances of the world in which he lived. He was keenly able to integrate his own experiences with those of people around him, from his biological family, to his clients, to his created family. From the beginning he was astonished, amazed, and excited by the duality of life – the secrets of a world of opposites. This dualism continued to plague and interest him for the duration of his life, and through his own experiences, both internal and external, he developed a complex theory of the human mind. Certainly his theory of the unconscious, with the division of the personal and the collective, was one of his greatest achievements. He has provided a legacy of imaginative, challenging, and intriguing ways of looking at oneself, especially in light of the creative process. In his work, Jung provided a theoretical structure of two types of art. The first type is conscious, controlled, and within the realm of the personal. The second type is without limits and truly the work of the collective unconscious, or the archetypes. The second type of art was the focus of Jung's interest because it is the work of the primordial. The images that arise from the collective unconscious are symbolic. Symbolic images are the magical images that the viewer relates to with great emotion although not really understanding why. It is through this process that Jung's theory of individuation comes into play, both for the artist and for the viewer or reader. Again, bringing into play archetypes in the collective unconscious, giving them a voice, and allowing others to experience the transcendence into their own collective unconscious is the stuff of great art.

Jung held great regard for the artist. He believed that the artist was chosen, that the artist did not choose to become a creative agent. The artist's life was wrought with conflict over the unbearable creative urge, on the one hand, and the desire to live an everyday life, on the other hand. Jung believed the artist was a true visionary.

In closing, Jung believed that the creative process was central to having a sense of wholeness within oneself. The sense of

wholeness provides the individual with an ability to be a true individual. The process of individuation is achieved through a number of different means with the end result, which is never wholly attainable, being that of an increased sense of self.

Frida's Early Years

Magdalena Carmen Frieda Kahlo y Calderon was born on 6 July 1907, in Coyoacan, a suburb of Mexico City, now part of Mexico City proper. According to Hayden Herrera, her first biographer, Frida changed her birth date to 1910 when she entered high school in 1922; she wanted to be associated with the Mexican Revolution. With this, her first political statement of a connection to the people (*la raza*), Frida began to make an indelible mark as an artistic, political, and cultural icon.

Her father was born Carl Wilhelm Kahlo in Pforzheim, Germany. Though the family maintained their ancestry as Hungarian-Jewish, records state he was Lutheran German. Frida's father sailed to Mexico in 1891 when he was nineteen years old and changed his first name to the Spanish equivalent, Guillermo. He was known as one of Mexico City's foremost photographers.

Matilde Calderon y Gonzales, Frida's mother, was of mixed Spanish and indigenous Mexican ancestry and a devout Catholic. Guillermo and Matilde were married shortly after his first wife died during the birth of their second child. Their marriage was quite unhappy, yet they did have four daughters. Frida was the third. Her father was surrounded by women and Frida was his favorite child.

Frida was born and lived most of her life in Casa Azul (The Blue House), in Coyoacan with her parents and four sisters and two step-sisters from her father's first marriage. Casa Azul is currently the home to the Frida Kahlo Museum. Her parent's marriage was marred by the death of Guillermo's first wife and Matilde's grief over her lost son. The family's legacy was shrouded by death, and created a family dynamic that strongly influenced her development and creative process.

Frida had vastly different relationships with her parents. Frida's mother was still in deep grief over the loss of her baby son when Frida was conceived. Matilde may have suffered from postpartum depression and she was unable to breast-feed baby Frida. Soon after Frida's birth, her mother became pregnant with her sister Christina. This may have deepened her mother's depression and overwhelmed her. Frida felt unloved and abandoned by her mother and became competitive with Christina.

Matilde could seem cold, self-involved, distracted and by many accounts depressed. When a mother is depressed, the child is often left unattended physically and emotionally: this inadequate mothering can leave a child unable to metabolize her experiences. Fortunately, from an early age, Frida had her

art. She also had childhood's natural connection to imagination through play and the arts. Her fantasy and imagination allowed her to create the images she needed to metabolize these painful experiences.

Her life was interlaced with tragedy. Frida contracted polio at the age of six and her left leg was less developed. During this period, Frida had an imaginary friend who lived in the interior of the earth and was always available to her when she was alone in bed. Her friend was her opposite, who could dance, and did not limp. She poetically describes her friend in her diary. As an adult, this imaginary friend was transformed into a series of unprecedented self-portraits, a form of empathic mirroring, the most famous of which was 'The Two Fridas' (1939).

Fortunately, she had a positive and close relationship to her father. Guillermo Kahlo suffered from epilepsy and was a distant father: intellectual and introverted and solitary within his family, with the exception of Frida. Guillermo adored Frida and she, in turn idealized him, identifying with his creativity, intellect, and physical vulnerabilities. During her period of confinement with polio, he encouraged her to be physically active, to pursue art and education and overcome her disability, a style that would remain with her throughout her life.

Many scholars, including Emily Tobeck, assert that Frida's paintings and journals reveal evidence of incest with her father, emotional and/or literal. This hypothesis could provide an understanding on her later behavior: sexual acting out in adolescence; her marriage to an older man, Diego Rivera; and her numerous bisexual affairs. The surreal painting of 'What the Water Gave Us' (1938) and her poetic journal entries are interpreted as evidence of this. Enacted incest, emotional or literal, seemed to create a paradox, one of possible suffering and the other as a creative source.

As an adolescent identifying with her father, she often dressed as a male, portraying a sense of androgyny. She was her father's daughter and this had a mixture of consequences. Frida adopted her father's attitude towards her mother – devaluing and considering her mother stupid. Her father turned his attention toward Frida, and away from his wife. Frida was resented by her sisters and she could have later re-enacted these triangulated relationships with her love affairs. Yet she also had the world of men opened to her, especially as she pursued her education with her sharp wit and superior intelligence.

In 1922, Frida entered the National Preparatory School, which offered the best education in Mexico. It was also the center of post-revolutionary ideological and political ferment,

and the center of the search for a Mexican identity. In an attempt to promote an identity founded on Mexican culture, the school hired painters like Diego Rivera (Frida's future husband), Jose Clemente, and David Alfaro Siqueiros to decorate the walls of the school with murals of Mexican history and culture. The faculty consisted of the best Mexican scholars of the time. In the middle of this milieu, as one of 35 girls in a student body of 2000, considered the most intelligent students in Mexico, Frida stood out. She was a brilliant student who rarely studied and chose a premed course of study. An avid reader and a gifted writer, she worked on the school newspaper. Frida was part of a primarily male high spirited rebellious group called the Cachuchas. She was often the ringleader of pranks, especially toward the fat, flamboyant muralist, Diego Rivera. She would challenge him, especially in front of his wife, Lupe Marin. Frida came to watch Diego work so much that she enraged Lupe. She reportedly said she wanted to have a baby by him someday.

Frida had a boyfriend at the time, Alejandro Gomez Arias, an outspoken student leader and orator. Frida seemed attracted to politically outspoken men. Over their three-year relationship, Frida's letters to him trace her development from child to passionate young girl, and then to a long-suffering woman. While involved with Arias in high school, she was also said to have bisexual affairs with both students and teachers according to another biographer, Martha Zamora.

The Accident

There are particular moments that can change the course of one's life. Frida had such an experience at the age of eighteen. In September, 1925, on her way home from school with Alejandro, the bus she was riding collided with a trolley car. Frida sustained grave injuries, including a broken spinal column, broken collarbone, broken ribs, broken pelvis, 11 fractures in her right leg, a crushed and dislocated right foot and a dislocated shoulder. Worst of all, a broken handrail entered her left hip and came out through her vagina. Frida often joked it was in this accident she lost her virginity. She suffered her entire life from the physical wounds of this accident, especially around her fertility. During the accident, her clothes were torn from her body, the handrail impaled her, and a sign painter on the bus had a container of gold-leaf paint that spilled during the crash and covered her bloody body. Many passersby called her 'la bailarina, la bailarina,' the dancer. With the truly Mexican sense of the macabre, her body, in a dancer-like pose, was golden and bloody, thus symbolizing the relationship she would have with her body for the rest of her life. Alejandro found the terribly wounded Frida, pulled the rod out of her, and pleaded with the doctors to operate and not give up on her.

Frida spent a month encased in a full-body plaster cast that made her look like a mummy. She spent a year in bed recovering from these injuries. Told she would never walk again, Frida remained determined, and did regain her ability to walk, but lived the rest of her life in constant pain, and eventually had 35 surgeries, mostly on her back and right leg and foot. Frida, a Catholic, identifying with Jesus' horribly bloody death, called this accident her Calvary. She lived in constant suffering for next 29 years.

The prior health issues of polio and a possibly undiagnosed congenital spina bifida, a malformation that occurs when the lower spine does not close during fetal development, can lead to progressive trophic ulcers on the legs and feet, eventually causing Frida additional suffering. In her later years, she would have her foot amputated due to the long-term effects of the accident and these ulcers.

The family experienced a decline in upper middle-class status due to a decrease in Guillermo's photographic business after the revolution, combined with the huge financial burden of Frida's medical expenses. Frida felt guilty and powerless to help her family. She first began to paint more out of boredom, and then in an effort to develop a home-based income. Frida's mother helped her by ordering a special easel that allowed her to paint while lying on her back. Her father allowed her to use his special brushes and paints. The loyal family offered themselves as models. Frida painted everything, even her plaster-cast corsets and herself.

For Frida, the near-death accident seemed to collapse life into a liminal space in which all is stripped away and she had to search anew for meaning, purpose, and rebirth. Frida wrote to Alejandro that she was reborn by this accident, "as a mature, sad woman who life had lost its color." In one of her metaphoric utterances, she told him "death danced around my hospital bed at night." Abandoning the goal of a medical career, she was reborn and her true essence emerged as a colorful Mexican painter. Symbolically, the accident birthed her as an icon of the wounded, triumphant feminine that her art and life holds for many women today.

Self Portraits

Having an essentially captive model, Frida drew and painted herself: 55 of her 143 paintings are self-portraits, which are among her best-known works. At first, her pieces were gifts to her boyfriend and friends so they would not forget her. This seemed to have been her way of ensuring their interest and love for her. In the early self-portraits, she represented her face in a serene and impassive way. Frida appeared to be denying the overwhelming feelings of helplessness and despair she felt. As she had done earlier, when she fell ill with polio by creating an imaginary double, she attempted to convey a sense of invulnerability, strength, and transcendence over her body's limitations. Through her early attempts at this artistic empathic mirroring, she begins to start metabolizing the horror she has experienced as well as expressing her inquisitive, irreverent, and intellectual spirit.

Self-taught, these first pieces were stylistically European, influenced by Botticelli from the Italian Renaissance and Modigliani's elongated figures. When Frida became involved with Diego Rivera, she turned to a deliberately naïve and flattened form of Mexican folk art that he loved, and she ceased painting in an aristocrat Renaissance style. Now, she wore pleasant blouses, Mayan beads and colonial earrings, representing herself as a Mexican girl full of self-possessed spunk. Following Rivera's style, she depicted herself and other subjects in a more Gauguin or Henri Rousseau raw, native style. She painted bold colors to honor the flowering of postrevolutionary Mexico. Her attention to detail

showed a tender interchange between artist and model, and between artist and self. In both her early and middle styles, there is none of the emotional tension found in her later self-portraits.

During her travels with her husband, Frida's work began to show the tension of dualities which she believed were the foundation of life. In her painting 'Self-Portrait on the Border Line between Mexico and the United States' (1932), she shows us the paradox of then-current reality, living in the United States while longing for Mexico. We also see her political leanings and her sense of power and androgyny. Here seems to be a painting in a more Cubist style. As her work matured, she starkly painted her pain, creating sometimes shocking images of her numerous operations, painful miscarriages, and her troubled marriage to Diego Rivera, symbolically depicting her physical as well psychological wounds.

As her individuation process deepened, her art changed. Her paintings became replete with bright colors and indigenous Mexican imagery and culture, and her self-portraits increasingly reveal her cultural embrace. The thorns, in 'Self-portrait with Thorns' (1940), pierce her neck as her face is surrounded by nature. She starkly paints her suffering while embraced by Mother Earth in this piece, as she does in many of her later self-portraits.

Frida provokes us with her metamorphosis on her canvases. In 'Roots' (1943), she gives fertility to the earth. In the transformative 'Broken Columns' (1944), Frida is no longer lying down as she was in life, but is upright and gazing into a reality that is beyond the personal, into the very nature of existence, an archetypal reality. During this later period near the close of her life, her self-portraits took on a surrealist bent, reflected as well by her poetry found in her journals. Accidents are made into art, a metaphor for Frida's life. Color and images are fragmented, distorted, and reassembled.

In the pieces created in the 3 years before her death, Frida's physical suffering increased dramatically. Her internal terrain changed as did her self-portraits. She related more to the archetype of life as depicted in nature. Her self-portraits, her empathic mirroring, and her imaginary friend were now fruit, foliage, and animals, the archetypal source of life. As we can witness in the piece, 'Sun and Life' (1954), her paintings fill with life. On the shadow side, her paintings were said to be 'over-exuberant,' due to her addiction to pain medications. It can be said, however, they also reflect the intensity one can feel about life with the approach of death.

Frida painted her painful inner experience through realism, symbolism, and surrealism always laced with her indigenous Mexican culture. She never liked these labels and often said she painted her own reality. She used art to reveal her internal experience and to heal and find meaning in her life.

Her Marriage to Diego Rivera

Frida Kahlo and Diego Rivera's lives intersected in many ways even before they fell in love. Frida was a budding artist and politically active before her accident. She had a high school crush on Diego, and taunted him while he was painting a mural at her high school. She would call him fat and then run and hide to see his reaction.

After the accident, her friend, Tina Modotti, an Italian photographer, actress, and leftist activist, introduced her to the inner circle of Mexico City's art and political leaders, of which Diego Rivera was a member. Their lives wove into each other's again. After meeting him at party at which Diego shot the phonograph, Frida became attracted to his untamed and unpredictable manner, perhaps one that matched her own. Though a tiny woman, Frida's personality was large, loud, vibrant and extroverted and could match his personality, if not his size. Her compensatory style of defiance became stronger after the accident. She would hide her vulnerability and pain with a strident, loud, and adventuresome persona.

At the age of 21, she fell fully in love with Diego Rivera, who was also affiliated with the Communist Party. As she sought his counsel on her paintings, their relationship flowered. He admired her work and began to spend time in her home, Casa Azul. Her parents had mixed feelings about Rivera. Her father understood her opportunities to marry were limited as she had massive current and future medical debts. Guillermo was more in favor of the marriage and realized Diego could help Frida as an aspiring artist. Matilde did not like Diego. According to her, he was too old, too fat, and a communist. Matilde thought it would be a marriage 'between a dove and an elephant' and said he looked like a frog. Many of these stories were recorded in a dual biography of Frida and Diego by Isabel Alcantara and Sandra Egnolff.

Nothing could deter Frida. They were married on 21 August 1929. She borrowed her maid's clothes and dressed like a regional Tehuana woman. Her appearance was unconventional; she declined to remove her facial hair and was known for her unibrow, small mustache, and for her flamboyant Mexicana-styled clothes: long, colorful skirts, peasant-style embroidered blouses, large beaded jewelry, all of which became her style of dress till her death.

At first, Frida tried to be a traditional Mexican wife, bringing Diego lunch and painting like him. She ignored his infidelities, and hid her own with men and women. Years later, she painted this aspect of their relationship in, 'Diego and Frida on their Wedding Day' (1941), depicting herself as small and child-like in contrast to the larger-than-life painter. His wife was his most trusted artistic critic. Soul mates and lovers, theirs was a turbulent relationship. Twenty years her senior, with a demanding and successful career, Diego was repeatedly unfaithful to Frida, with one of the most hurtful encounters occurring between Diego and her sister, Christina. Diego may have had this affair to retaliate for Frida persuading Diego to return to Mexico from the United States, where he had been commissioned to paint a number of now-famous murals.

Our relationship with our parents can influence our choice of spouse. Perhaps Frida and Christina enacted the family secret through their competition, triangulation, and betrayal by the affair with Diego. After she learned of the affair, she chopped off her long hair, which Diego loved, in an act of defiance. Reflecting her sardonic humor, at the top of this painting, 'Self Portrait with Chopped Hair' (1940), are the words of a popular song: "Look, I used to love you, it was because of your hair, now you're pelona (bald or shorn), I don't love you any more." She also used the cutting of her hair as a symbol of her rage, attempting to sever her attachment to Diego. Her fury is palpable in her ugly men's clothes,

mutilated hair, and angry expression. Frida's femininity had been sacrificed at Diego's altar of infidelity. Yet Frida never entirely severed her relationship with her husband.

After this betrayal, she became more blatant about her affairs. The most famous was with Leon Trotsky in 1937. Diego and Frida divorced in 1939 and were remarried in 1940 while both had affairs simultaneously. Their passionate, stormy relationship survived these infidelities, her seriously dangerous miscarriages, their divorce, remarriage, and her faltering health.

Frida suffered tremendously with her inability to birth a child due to the accident. In many of her pieces about miscarriages and abortions (e.g. 'Henry Ford Hospital' and 'Caesarian Section' both in 1932), she depicts her inner horror of being unable to bear a child. Through her art, Frida transforms pain into beauty and truth and then penetrates into our inner loneliness, universally bridging our experiences with hers.

Diego and Frida's relationship was very complex. On one level, he offered an arena for the enactment of her relationship with her father: the adored child, the triangulation and later betrayal as well as the positive artistic mentoring of her father. She had a sense of the enormity of his influence on her as she would say she had two grave accidents in her life: the street car accident and Diego. This paradox symbolically gave her life, death, and rebirth.

Diego indirectly influenced her to abandon her early European style and adopt a more Mexican, retablo style. Initially, she absorbed his cultural embrace along with his political idealism. As her journey of individuation matured however, her culture, politics and sense of style increasingly reflected the deeper sense of her true self.

Diego was her muse and supporter artistically. In his autobiography, Rivera said that Frida's canvases revealed an unusual energy of expression, precise delineation, character, and true severity. They showed none of the tricks in the name of originality that usually mark the work of ambitious beginners. They convey a fundamental honesty and an artistic personality of their own. They communicated a vital sensuality, complemented by a merciless yet sensitive power of observation. It was obvious to him that this girl was an authentic artist. He often said she was a better painter than he was.

Diego and Frida were comrades and bound by their commitment to Communism as well as art. In several self-portraits, she holds Diego in mind and heart, 'Diego in My Thoughts' (1943). They seem to complete each other, which is clearly evidenced in 'Painting of Diego and Frida' (1944). From a different perspective, they may have found in each other what they longed for in themselves, and hold the paradox of the masculine and feminine; anima and animus in the other.

The Psychological, Cultural Political, and Archetypal Symbols in Frida's Creative Process

Death and Death Masks

Symbols of death are replete in Frida's art. They reveal psychological, ancestral, and cultural roots from her life. In a number of paintings of family, she paints both the living and dead members. The death of Guillermo's first wife and her baby brother greatly influenced the family dynamics and she unflinchingly painted this reality.

The Mexican culture's Day of the Dead appears throughout her paintings. In this mythos, one has a close relationship with the spirit world. The spirits return to be fed when the veil is lifted between life and death on November 2nd of each year. Mexican author Octavio Paz said Mexicans have no qualms about getting close and personal with death. In 'The Four Inhabitants of Mexico' (1938), the Day of the Dead Skeleton is primary along with the worker, the indigenous child and Aztec goddess. In self portrait, 'Girl with Death Mask' (1938) she paints herself as a little girl with a death mask, while at her feet is a monster's mask, a paradox of how life and death exist simultaneously for everyone. Her piece, 'The Dream' (1940), she lies under her canopy with the Day of the Dead skeleton reclining on top of the canopy. Her life, her dreams, and her art are full of the acceptance of death.

Symbols of Mother: Dead and Archetypal

Frida painted how she imagined her birth in 'My Birth' (1932) created after her own mother's death, where she illuminates the suffering she endured in her relationship with her mother. In this painting, the baby is birthing herself from a dead mother, alone and unaided. On the wall is an image of the Virgin of Sorrows pierced by thorns, bleeding and weeping. This image seems to hold birth and death simultaneously. The mother wears a death's shroud and the baby emerges with a face of anguish.

The collective mother in 'My Nurse and I' (1937) gives Frida the nurturance she needed. Frida was not nursed by her own personal mother, but is nursed by the great mother of Mexico, forced to find the Great Mother by digging deep within her culture. Frida started to create the goddess and the mother she longed for. However, the nurse in this painting looks austere and has a pre-Hispanic death mask instead of a human face. Nurturance and life are laced with death and suffering while the baby Frida appears insecurely held.

In Frida's art, there are many Aztec and Mexican symbols of gods and goddesses. Frida's art seemed guided by the Aztec goddess, Coatlique/Coatlicue (pronounced kwat-lee-kweh), the Mother of the Gods, the goddess of life, death, and rebirth, the Lady of the Skirt of Snakes. She is the Aztec goddess of death, dismemberment, and destruction as well as life. She was created in the image of the 'unknown,' the mystery created by the decorations of skulls, snakes, and lacerated hands. Coatlique is the archetypal symbol of death like the Hindu goddess Kali. With skeletons and hearts in her paintings, Frida found a way not to fear Coatlique but to embrace her, thus finding meaning beyond suffering. With the help of this cultural icon, Frida came to understand symbolic death culturally as well as personally.

Paradox of Culture and Politics

This goddess's influence is best seen in the paradox of the 'Two Fridas' (1939): The European and the Mexican Frida. She becomes her imaginary friend and companion again as the two Fridas hold each other hands. Frida is painting her psychic pain, her exposed and wounded heart. She holds the duality of existence: the observer and the observed. This was also a death and rebirth in her art: the death of the European feminine, and a rebirth as a Mexican icon. Frida's eventual transformation

from a personal into an archetypal image stems from her rebirth as Mexican feminine icon.

Her painting of political paradox was first evidenced in 'On the Border between the United States and Mexico' (1932). In her 1945 piece, 'Moses,' her most mural-like piece, she attempts to depict the paradox of fear: the fear, of life and the fear of death. This piece is interlaced with spiritual and political imagery. Later, Frida even more poignantly declaims capitalism's superficial values and praises Marxism as the cure for the world's ills in 'Marxism Will Give Health to the Sick' (1954). In this piece, Frida no longer needs her crutches as they fall away. Marx is touched by the peace dove, and the United States eagle is surrounded by a red atomic explosion. Frida valued three things in life: Diego, her art, and communism. Frida used her culture and political beliefs as universal symbols, which C. G. Jung, founder of analytic psychology, called archetypes. They laid a foundation for her becoming an icon, an archetype herself in flamboyant Mexican attire, and her vivid use of color in her paintings

Her Later Years

Throughout their marriage, Frida and Diego traveled a great deal, mostly to the United States. Diego loved the United States while Frida always longed for Mexico. During their marriage they lived in small apartments and in two major houses, Casa Azul and the San Angel, joined homes designed by the famous Mexican designer, Juan O'Gorman. They separated many times and were divorced and remarried. When they remarried in 1940, her later years, Frida lived in Casa Azul and Diego would reside with her frequently while still maintaining his O'Gorman home. Frida became more accepting of Diego's ways and attended to him as if he were her baby, which is best reflected in her painting, 'The Love Embrace of the Universe, the Earth, Me, Diego and Xolotl' (1949). In this piece, Frida cuddles a baby Diego while she is held by the Aztec goddess Xolotl.

With a history of heavy drinking and smoking, which complicated her consistently poor health, Frida deteriorated even more throughout 1941. She was exhausted, losing weight, depressed after her father's death and in constant, extreme pain. Medical procedures and all kinds of corsets to support her back became a way of life. Frida now became manipulative with her true ailments in an attempt to secure Diego's attention, especially when another woman was on the scene. Many of her operations were said to be elective.

In 1943, Frida began teaching and developed a following of students who came to be called Los Fridos. She was an unorthodox and respectful instructor. Her instructions would be to go out in the street and get acquainted with life so they could better understand how to paint it. She held court with her students at Casa Azul.

In these later years, Casa Azul changed from a happy gathering place for artists and important people traveling through Mexico, to a home of intense suffering visited only by a small group of friends. In 1946, Frida painted two pictures, 'The Little Deer,' and the 'Tree of Hope Stand Fas,' symbolizing her hope that the pain would cease from a new operation to be done in New York. However, she did not improve. She suffered from mood swings, from euphoria to

depression, even paranoia. Periodically she became violent, was drinking heavily and was increasingly dependent on her pain medication. She became obsessed with her ailments and eventually entered psychoanalysis. Psychiatrist, Simon Grimberg explored her analysis in his books on Frida's life and noted she was the first in Mexico to do so. In 1950, a bone graft failed miserably, and she spent nine months in the hospital, yet continued to paint. Frida began a diary in 1944 that chronicles her physical and emotional suffering in poetic verse and drawings. When Frida was forced to have her right leg amputated below the knee, she grew more despondent, writing in her diary and capturing her gallows humor momentarily with "Feet, why do I want them if I have wings to fly?"

Diego sponsored her second solo show, though it was only her first solo show in her homeland, in 1953. This project lifted her spirits, but all were unsure if Frida would be able to attend. Following her doctor's orders, she did not leave her bed: instead she had her bed, with her in it, loaded into a truck and was escorted by motorcycles to the gallery. There is a very famous photo of Frida in her canopied bed greeting guests. It was macabre and theatrical, and entirely her style.

In that last year, Frida painted very little with the exception of still life of fruit, like 'Viva la vida,' (Long live life) (1954) her last self-portrait. Some of her hospitalizations were suspected suicide attempts. Her last public appearance was at a political rally on a rainy day, and she subsequently developed bronchial pneumonia. According the death certificate, Frida died of a pulmonary embolism. However, her death might have been by suicide or an accidental overdose of drugs and alcohol.

In her last piece in her diary is sketched a black angel with the words "I hope for a happy exit and I hope never to come back." Diego felt his soul was cut in two; he lost his best friend and the most wonderful part of his life. Frida was laid to rest, dressed and bejeweled with braided hair, at the Palace of Fine Arts in Mexico City. Five hundred mourners walked behind her hearse on the next day to pay respects before her requested cremation. The Internationale was played, and then Diego gathered her ashes in a silk scarf and took her home to Casa Azul.

Recognition Today

Diego Rivera was the first to preserve Frida Kahlo's artistic memory. One year after her death Diego bequeathed her home, Casa Azul, to the Mexican nation as a museum. It contained her Tehuana dresses, jewelry, her painting utensils, her letters, diary, books, and most importantly, her art, the most intimate aspects of her life. In July, 1958, four years to the month after death, her home was opened to the public as the Frida Kahlo Museum. In death's silence, her home illustrates a life of art, color, and passion.

For many years, she was only recognized as Diego Rivera's wife. She was not recognized widely as the singular artist as she is now for decades, till the 1980s when the Neomexicanismo movement began, where the values of contemporary Mexican culture were finally recognized and prized. In the 1980s, Frida Kahlo became a household name in Mexico. In 1983, a Mexican movie about her was a huge success. The next year, Mexican government decreed Frida's art a national treasure. Hayden Herrera published her seminal biography on Frida, which

became a worldwide seller. Many other books about Frida surfaced after this. She became recognized as Mexico's greatest woman artist, and by many, as Mexico's greatest artist.

In 2001, she became the first Hispanic woman to be honored with a US postage stamp. A year later, the American film *Frida* was released, based on the Herrera book. In 2006, her self-portrait 'Roots' (1943) set a Latin American record when it was auctioned at (US) \$5.6 million.

Her greatest recognition is among women as a symbol of the wounded but triumphant feminine. She persevered against all odds: physical injury, psychological wounds, and a culture that did not value small, intimate easel paintings or women's art. Frida is also seen as a political heroine as she demonstrated with the example of her life her love for *la raza*, the people. For the ill, oppressed and grieving, her art, with its open revelation of pain, sorrow and distress, ironically offers hope and life.

Two small excerpts from her diary may serve as coda:

I had smiled nothing more. But clarity was in me and in the depth of my silence.
He followed me. Like my shadow, irrefragable and light.
In the night he wept a song. . . .
He followed me.
I ended up crying, forgotten in the entrance of the Parish church
Produced by silk shawl, which soaked up my tears

And:

Mine is a strange world
Of criminal silences
Of strangers' watchful eyes
Misreading the evil.
Darkness in the daytime . . .
Was it my fault?
I admit, my great guilt
As great as pain
It was an enormous exit
Which my love went through

Glossary

Case-based/experiential knowledge structures A knowledge structure in which information is typically organized in terms of causes and goals.

Conceptual combination Combination or reorganization of unique and abstract features of concepts relevant to the problem.

Creative thought The generation of original, high-quality, and elegant solutions to novel, complex, and ill-defined problems.

Divergent thinking Generation of many different responses or perspectives to a problem, a process often used in creative problem solving.

Elegance An element of creativity that is indicated by flow, refinement, and focus in problem solutions.

Idea evaluation Evaluating and refining ideas relevant to problem solving.

Idea generation Developing and contextualizing ideas that may be valuable in problem solving.

Mental model A formal representation of a problem which influences thinking, actions one takes, and prediction of events.

Problem definition Establishing a clear perspective of what the exact problem is.

Schematic knowledge structures A knowledge structure in which information is organized in terms of underlying principles or key features that structure entities or events.

Introduction

The stereotypic view of creativity has held that knowledge, or expertise, typically inhibits creative thought. Underlying this view is an assumption that undue reliance on available knowledge would inhibit generation of the new ideas that have been found to be the hallmark of creativity. In recent years, however, it has become clear that creative thought is a form of performance involving the generation of original, high-quality, and elegant solutions to complex, novel, ill-defined problems. Although creative thinking, the generation of solutions to these problems, involves multiple processing operations, effective execution of all these processes, problem definition, information gathering, concept selection, conceptual combination, idea generation, idea evaluation, implementation planning, and monitoring, is held to depend on knowledge or expertise.

Accordingly, in the present effort we will examine the role of knowledge in creative thought. We will begin by examining what is meant by the terms knowledge and expertise. Subsequently, we will examine the available evidence pointing to the importance of knowledge and expertise in incidents of creative problem solving. We will then examine the critical operations involving knowledge in incidents of creative thought. Finally, we will examine how different types of knowledge influence creative problem solving and how people acquire the knowledge held to be required for creative problem solving.

Knowledge

Knowledge Structures

Knowledge may be defined as information bearing on an event stored in memory. Memory of information, and recall of this information from memory, has been shown to be related to many forms of problem solving including creative problem solving. The impact of information on problem solving arises

from the guidelines provided by this information for understanding the nature of the problem and generating viable problem solutions. Accordingly, mechanisms, such as accessibility of information in memory, working memory capacity, and salience of the information recalled *vis-à-vis* the problem at hand have all been shown to influence problem solving including the solutions provided to creative problems.

Knowledge, however, is not simply a matter of information retrieved from memory. Knowledge is typically held to involve a set of structures for organizing and storing the information contained in memory. Studies contrasting people who have more knowledge (experts), as opposed to less knowledge (novices), about a given domain indicate people typically store, and recall, knowledge based on relevant conceptual structures. Thus knowledge is held to be reflected not only in the amount of information available but also the structure applied to organize this information. Better organizing structures have been shown to facilitate the recall and application of information drawn from memory in incidents of problem solving including incidents of creative problem solving. Thus in problem solving people often recall concepts (e.g., birds) working with typical exemplars of this concept (e.g., robins) in generating problem solutions.

The importance of these organizing structures has two noteworthy implications for understanding the application of knowledge in incidents of creative problem solving. First, different types of information may be structured or organized in different ways. Schematic knowledge structures are typically organized in terms of underlying principle, or key features, that structure entities or events. Thus birds fly, have wings, and lay eggs. In contrast, experiential, or case-based, knowledge is typically organized in terms of causes and goals. For example, to get a raise on my job (a goal), I must work harder (a cause). These differences in organizing structures, in turn, imply that different types of knowledge being applied in creative problem solving may make different demands and may be applied in different ways.

Second, the organizing structures applied to different kinds of information are not necessarily constant across domains. Thus the key concepts involved in physics (e.g., forces, retention of energy) are not necessarily similar to the key concepts involved in psychology (e.g., rewards, affect). This point is of some importance because it implies that knowledge is a domain specific phenomenon. The principle of domain specificity, in turn, implies that knowledge acquired in one domain cannot be readily transferred to other domains.

Knowledge and Creativity

This thumbnail sketch of knowledge, and knowledge structures, in turn, broaches a fundamental question. More specifically, is there reason to suspect that knowledge contributes to creative thinking? Answers to this question are not necessarily straightforward. On the one hand, knowledge refers to known information. On the other hand, it has been found that in creative thinking people must work with and restructure this knowledge in such a way as to generate novel problem solutions. In fact, the available evidence points to the importance of knowledge as a basis for creative thought. Broadly speaking, four types of studies, (1) product, (2) experience, (3) group contrasts, and (4) psychometric, all point to the importance of knowledge in incidents of creative thought.

Creative thought involves the production of high value, original products. Accordingly, one way the influence of knowledge might be assessed is by examining the role of knowledge in the production of a creative product. In one study of creative products, the television comedy *All in the Family* was contrasted with a perspective British 'parent,' *Till Death Do Us Part*, and other American comedy series being aired at the same time. Content comparisons examined attributes such as controversy, idea refutation, and insults. The findings obtained indicated that in *Till Death Do Us Part*, extant knowledge provided a basis for development of the creative product, *All in the Family*, although *All in the Family* added new elements to extant knowledge such as a moral. Other work also indicates that transformations of extant knowledge are critical to the production of creative products in the arts such as Picasso's *Guernica*. Still other work indicates that knowledge transformations are also critical to creative achievement in the sciences.

Not only does the analysis of creative products stress the importance of knowledge, examination of how creative people develop over the course of their careers also points to the importance of knowledge. In a qualitative study of the Beatles as a creative enterprise, it was found that despite early mediocrity, the Beatles eventually produced creative products through continuous improvement and ongoing learning resulting in the acquisition of knowledge and expertise. Similarly, in a study of eminent achievers, people producing recognized creative products, it was found that extensive practice, practice contributing to the acquisition of knowledge, was critical to creative performance.

An alternative to examining creative products or gains in creativity with practice in a domain, is to contrast people who have more or less experience (experts versus novices) working in a domain under the assumption that greater experience will result in more knowledge. In one study along these lines,

professional knitwear designers (experts) were contrasted with student designers (novices). Think aloud observations were obtained as experts and novices worked on tapestry and rug designs. The findings obtained, following content coding, indicated that experts, as opposed to novices, were more likely to base designs on roles of the product. Notably, knowledge of product roles is typically acquired with experience working in a domain. Similarly, studies examining expert-novice differences in scientific reasoning have found that experts were more likely to produce creative products – often applying unique concepts, and approaches, in generating problem-solutions.

Still another way one might examine the influence of knowledge on creative thinking is by obtaining measures of knowledge. In one study along these lines, 110 army officers reviewed a list of 70 leadership tasks and then grouped these tasks into categories. These category sortings were then used to appraise knowledge structures bearing on leadership with knowledge structures being assessed for complexity, comprehensiveness, organization, use of principles, and theoretical accuracy. Additionally, study participants were asked to complete measures of intelligence and divergent thinking and they were asked to provide solutions to a military leadership problem calling for creative thought. It was found that knowledge structure attributes were related to production of creative problem solutions ($R=0.50$). More centrally, knowledge was found to contribute to divergent thinking ($\beta=0.27$) as well as both idea generation ($\beta=0.26$) and idea implementation ($\beta=0.14$) activities during creative problem solving. Thus expertise and knowledge appear to contribute to the execution of a number of critical activities involved in creative problem-solving – divergent as well as convergent thinking.

Taken as a whole, the studies examined above indicate that knowledge, or expertise, contributes to creative achievement and creative problem solving. The effects of knowledge, or expertise, on creativity, moreover, hold across methods. Thus stable effects are observed in studies examining product production, experience, expert versus novice comparisons, and direct measures of knowledge. Furthermore, the effects of knowledge on creative thought appear sizable. In the following section we will examine the mechanisms by which knowledge influences creative thinking.

Influences of Knowledge

Content

If it is granted that knowledge, or expertise, is critical to creative thinking a new question comes to fore, what aspects of the content of knowledge contribute to creative thought? Traditionally, it has been held that the availability of more diverse content will contribute to creative thinking. In recent years, however, it has become clear that the use of knowledge in creative thinking is more goal directed.

In a study along these lines 137 undergraduates produced solutions to two creative problems. One problem involved development of a new advertising campaign while the other involved a public policy management problem. Solutions to both these problems were scored for quality and originality. Participants were presented with a series of electronic cards presenting different types of information that might be used

in problem solving and the time spent encoding each type of information was recorded. It was found that people who produced creative problem solutions spent more time encoding information bearing on key facts and anomalies. Thus creative people appear to focus on critical factual information and incongruent information when generating problem-solutions.

Some support for the proposition has been provided in a more recent study in which participants generated solutions to a series of social innovation problems. It was assumed that the knowledge applied in solving social innovation problems was case-based or experiential knowledge. Prior to beginning work in solving these problems, participants were given training intended to help them identify critical causes (e.g., causes exerting large effects, causes exerting multiple effects). It was found that this training resulted in the production of higher quality and more original solutions to social innovation problems. Thus, again, it appears that a focus on key facts, in this study knowledge of critical causes, contributes to creative thinking.

In addition to critical facts, or critical causes, and anomalies, another aspect of knowledge content that appears critical to creative thinking are restrictions or constraints. It has been argued that multiple different types of constraints might be embedded in knowledge structures – goal constraints, source constraints, task constraints, and subject constraints. In a qualitative analysis of paintings produced by Max Beckman and Philip Guston, it was found that goal constraints which preclude routine solutions and promote novel solutions contributed to artistic creativity. Moreover, other constraints were embedded within these goal constraints. Thus creative people will rely on knowledge of constraints and restrictions in generating high quality and original problem solutions.

Another type of knowledge content that appears to be used by creative people are organizing concepts. In an analysis of how people solve insight problems, one type of creative problem, it was argued that a diverse and diffuse set of connections exist among various pieces of knowledge. Recognition of concepts that may be used to organize these diverse pieces of information gives rise to insight and thus the generation of creative problem solutions. Given the fact that knowledge structures are based on organization of discrete facts, it seems plausible to argue that creative people will expressly seek to identify and apply these organizing concepts in incidents of creative thought. These organizing concepts not only provide an efficient system for organizing the information embedded in knowledge structures, they may also provide an effective basis for adaptation and extension of extant knowledge.

Related to the concept of organizing structures, people may work with different types of information in relation to these organizing concepts. Information, or events, embedded under an organizing concept are referred to as exemplars. Exemplars of organizing concepts, however, differ in the degree to which they are typical or atypical of the concept at hand. Thus robins are typical birds while ostriches are atypical birds. In a study along these lines, undergraduates were presented with a series of conceptual combination problems where key concepts (e.g., birds, sporting equipment) were defined either by typical or atypical exemplars of the organizing concepts. Participants were asked to combine these concepts, label the concept, generate additional exemplars, and write a story involving this concept. Concept labels, exemplars produced, and stories

were scored for quality and originality. It was found that when people worked with atypical exemplars more creative products were obtained especially when relatively similar organizing concepts were presented. Thus creative people appear to use atypical exemplars or unusual bits of knowledge when generating problem solutions.

Our foregoing observations are noteworthy because they suggest that the knowledge employed by creative people is distinctly pragmatic, albeit openly pragmatic, in nature. This pragmatic origination is evident in the fact that creative people use key facts and causes, attend to restrictions, and apply organizing concepts. Their openness, albeit pragmatic openness, is evident in their use of anomalous observations and atypical exemplars. Thus creative people appear to rely on unusual knowledge elements applying these atypical elements to identify critical causes, restrictions, and organizing concepts. In fact, this patterning of knowledge content appears to underlie discovery of the Hepatitis B vaccine.

Operations

Of course, if one only had extant knowledge to work with it is difficult to see how creative people could generate novel problem solutions. Thus operations must be applied to knowledge to generate new knowledge and the production of novel problem solutions. Broadly speaking, three distinct operations appear to underlie people's use of knowledge in the generation of creative problem solutions. More specifically, these operations involve conceptual combination, elaboration and exploration, and contextualization.

Conceptual combination refers to the combination and reorganization of knowledge structures. With elaboration of these new concepts or conceptual relationships, new knowledge is created. This new knowledge, in turn, provides a basis for generation of the new ideas that are held to provide the basis for creative thinking.

In a study examining the operations involved in the combination and reorganization process, 155 undergraduates were presented with four examples of each of three conceptual categories. Participants were asked to combine these concepts to generate a new concept. They were then asked to generate exemplars of this new concept which were scored by judges for quality and originality. In the experimental conditions, participants were asked to search for typical features (e.g. birds have feathers) or atypical features (e.g. birds lay eggs), map typical or atypical features across categories, and then elaborate, or not elaborate, additional features of this new category. The findings obtained in this study indicated that feature search and mapping operations, along with elaboration, contributed to the production of higher quality, and more original, exemplars of the new concept.

A series of extensions of this study confirmed this basic set of operations and provided findings pointing to three critical extensions of this basic set of operations. In the first study, undergraduates were asked to solve a conceptual combination problem and list emergent features of this new concept. These new features were scored for emergence or originality. The findings indicated that new features emerged from conceptual combination with emergent features being observed more frequently when the material being worked with in conceptual

combination involved unique and anomalous elements. In the second study, individuals were asked to draw aliens. It was found that the alien drawings displayed more unique features when people were asked to think in an abstract fashion. In the third study, participants were asked to work on a conceptual combination problem where exemplar accessibility was manipulated through a pretask rating intervention. It was found that while primed exemplars were used more frequently, people, in conceptual combination, tended to rely on typical exemplars.

This series of studies is noteworthy for five reasons. First, it suggests that people rely on typical exemplars in conceptual combination. Second, use of abstract features leads to more effective conceptual combination efforts. In keeping with this proposition other studies have found that when people are asked to work with less closely related concepts in conceptual combination they often employ metaphors (e.g., birds fly and flight represents freedom). Third, more new concepts emerge when people work with atypical exemplars in conceptual combination. Fourth, the new features emerging from conceptual combination provide the new knowledge which promotes idea generation. Fifth, because emergent new features are ill-defined, creative thinking to generate new knowledge requires exploration or extensive elaboration of these emergent features.

What should be recognized in this regard, however, is that conceptual combination gives rise to the production of new knowledge, not necessarily new ideas. Thus people must explore the implications of new concepts emerging from conceptual combination. Put another way, idea generation requires knowledge about how to apply new concepts.

In a series of studies intended to test this proposition, people were presented with preinventive forms – for example, a triangle and a hooked stick. People were asked to combine these preinventive forms, or concepts, to construct a new form. Notably, when people were asked to think about the applications of these new forms more creative new tools were generated. This finding is important because it suggests that knowledge about applications may be important in incidents of creative thought especially when new knowledge arising from conceptual combination is to be used to generate new ideas. Thus creative thinking, at least in part, depends on real-world knowledge.

In addition to real-world knowledge, however, another form of knowledge may be involved in creative thought. People rarely generate a single idea. However, given the time and effort required for development and implementation of new ideas, it is clear that people must evaluate ideas. In keeping with this proposition, it has been found that idea evaluation skills are positively related to generation of creative problem solutions.

What should be recognized here, however, is that knowledge is also likely to play a role in idea evaluation. In a study examining the influence of knowledge in idea evaluation, 148 undergraduates were asked to assume the role of an advertising executive responsible for developing a new advertising campaign. The campaigns proposed were evaluated for quality, originality, and feasibility. Prior to starting work on these advertising campaigns, participants were presented with either high quality or high originality ideas. In appraising these ideas, and suggesting revision to these ideas, people were asked to apply either efficiency standards (e.g., short term gains) or innovation standards (e.g., business development). One set of

findings indicated that the use of compensatory approaches in idea evaluation, for example attempting to improve the quality of an original idea, contributed to the production of more creative advertising campaigns. By the same token, however, these findings also pointed to the importance of both knowledge of the idea and knowledge of the standards to be applied in idea appraisal and revision. Thus knowledge bearing on appraisal standards may prove critical to effective idea evaluation.

Types of Knowledge

Operations

Our foregoing observations bear on the role of knowledge as a general phenomenon in creative thought. However, it should also be recognized that multiple different types of knowledge structures exist which might be applied in creative thought. For example, creative thinking might be based on associational knowledge, conceptual or schematic knowledge, case-based or experiential knowledge, spatial knowledge, or mental models. These different types of knowledge structures contain different content and are organized on different bases. Thus case-based knowledge structures are highly complex with cases including information bearing on causes, goals, outcomes, actions, actors, and restrictions where cases are organized on the basis of typical cases plus commonly encountered exceptions. In contrast, conceptual or schematic knowledge structures are organized hierarchically with respect to basic principles where exemplars of these principles are graded in terms of typicality. Associational knowledge structures are organized in terms of network structures where relationships are established based on the frequency and salience of event pairings.

These differences in the content and organization of knowledge structures are noteworthy for two reasons. First, they suggest that different types of knowledge may be applied in addressing creative problems arising in different domains. Thus, it has been argued that case based knowledge is critical in solving social innovation problems. In contrast, it has been argued that mental models are critical in solving creative problems arising in science and engineering. Second, differences in the content and organizing structures applied to different types of knowledge structures imply that differences will be observed in how people work with knowledge in generating creative problem solutions.

In this regard a related study is noteworthy. In the study, 190 undergraduates were asked to assume the role of principal of a new experimental school and formulate a plan for directing this school. These plans were evaluated for quality, originality, and elegance by judges. Notably, a curriculum planning task was used because such problems can be solved using either schematic or case-based knowledge. Prior to developing these plans, participants were presented with either case summaries or key concepts, schema, drawn from the literature on cooperative learning techniques. Some participants were presented with schema, or principles, and were asked to apply conceptual combination operations – feature search, feature mapping, and elaboration. In contrast, other participants were presented with cases and were asked to apply a different set of operations in conceptual combination – analysis of critical case attributes, identification of case strengths and weaknesses, and forecasting.

The number of cases, or associated concepts, presented was also manipulated. It was found that application of both schematic and case-based operations in conceptual combination gave rise to production of higher quality, more original, and more elegant problem solutions. Notably, however, when more material was presented application of schematic knowledge resulted in production of more creative solutions. When, however, cases were presented, use of fewer cases, due to the complexity of case-based knowledge, resulted in the production of more creative solutions. Thus different types of knowledge structures imply different operations. And, the available knowledge is employed in different ways.

Content

These observations with regard to the effects of knowledge on the operations involved in creative thought broach another question. Is there reason to suspect that use of different types of knowledge would contribute to greater creativity? This issue has been addressed in a recent study.

In the study Hunter 247 undergraduates were asked to generate ideas for solving an educational creative problem-solving task and propose solutions to this problem. Problem solutions were appraised by judges for quality and originality while idea generation was appraised with respect to the number of ideas produced. Prior to generating ideas and problem solutions, participants were given a set of training interventions intended to encourage application of associational, schematic, or case-based knowledge along with various combinations of these knowledge structures. The obtained findings indicated that use of associational knowledge promoted idea generation. However, creative problem solutions were more likely to be observed when schematic or case-based knowledge was employed.

Thus it appears that different types of knowledge structures have different implications for the production of creative products – ideas versus problem solutions. Moreover, recent findings have indicated that use of associations, even when coupled with the use of schema or cases, tended to inhibit the production of creative problem solutions. Although these effects can be attributed to the diffuse, disorganized nature of associational knowledge, which inhibits production of problem solutions, they also suggest that a complex set of interactions may be observed when multiple different types of knowledge are applied in incidents of creative thought.

Acquiring Knowledge

Practice

Our foregoing observations indicate that creativity is strongly influenced by knowledge or expertise. However, the effects of knowledge on creative thought may be more complex than is commonly assumed. For example, the knowledge structures applied influence the operations involved in creative thought, and certain aspects of the content of a given knowledge structure appear particularly important to creative thought. Although further research is required to more fully delimit these relationships, these observations, nonetheless, broach a fundamental question. What actions can be taken to improve the application of knowledge in creative thinking?

Although different types of knowledge are acquired at different rates, associational knowledge is acquired quickly and automatically, while schematic knowledge is acquired slowly and with conscious analysis. One way knowledge is acquired is through practice on solving problems within a domain. Thus, recent studies have provided evidence indicating that creative thinking improves with practice in a domain. What should be recognized here, however, is that incidents of real-world creative achievement typically require substantial practice – 10 000 or more hours of practice on the kind of real-world problems where creative thinking is valued.

The need for extensive practice, however, appears to be linked to three key attributes of the nature of knowledge as it is applied in incidents of creative thought. First, as noted earlier creative thinking depends on the availability of well organized knowledge structures which are based on organizing concepts. However, the available evidence indicates that critical organizing concepts are acquired rather slowly, primarily as a function of contrasting successful and unsuccessful incidents of problem solving. This observation, in turn, implies that structured practice intended to provide critical organizing concepts is likely to prove especially useful in enhancing creative thinking.

Second, in most real-world incidents of creative problem-solving multiple knowledge structures will be involved. Thus people, in generating creative problem solutions, often apply associational knowledge, case-based, or experiential, knowledge, and mental models. Given the recent findings pointing to inhibitory interactions among certain knowledge structures, extensive practice may be required to offset these inhibitory interactions. In other words, extensive practice may allow for synchronous operation of multiple, potentially competing, knowledge structures.

Third, it is not only the content of knowledge structures that is of concern in creative thinking, the operations applied in working with this knowledge, procedural knowledge, are also important. In fact, a meta-analysis of creativity training programs found that training interventions intended to provide more effective procedures for working with knowledge in problem solving were particularly effective. By the same token when one considers the complex nature of creative thinking operations, and the complex nature of the relevant knowledge structures, it seems reasonable to expect that substantial practice will be required to promote creative thinking.

Of course, one way to minimize practice demands is through formal educational and training interventions. Education can provide core organizing concepts, it can provide schematic principles, and, through exercises, it can provide cases-based knowledge. Thus there is reason to suspect that education will contribute to knowledge acquisition and creative thought. In keeping with this proposition, one study administered creative thinking tests, measures of divergent thinking skills, to first, second, and third grade students. It was found that creative thinking improved with education, especially on verbal tasks. Thus education does appear to contribute to creativity in part by providing students with requisite knowledge structures.

In this regard, however, the nature and complexity of the knowledge structures involved in creative thought should be borne in mind. For example, while it is useful for educational systems to provide organizing concepts and key facts or critical causes, such interventions are only likely to prove of value in

enhancing creative thinking if anomalies are examined and atypical exemplars are provided. Moreover, educational interventions that provide students with experience in solving creative problems may also prove useful by providing students with case-based knowledge, procedural knowledge, and associational connections. Along similar lines, educational interventions that clearly articulate relevant mental models for understanding phenomena operating in a domain may prove useful.

Practice Conditions

In educational interventions, and practice, it is important to bear in mind a critical point. Passive practice is likely to prove of limited value in acquiring the knowledge structures required for creative thought. Thus in the analysis of the creative achievements of the Beatles, it was found that active practice induced by team work and competition was critical to the acquisition of requisite expertise. The importance of active practice suggests that identification of anomalies, constraints, organizing concepts, and typical *and* atypical exemplars is likely to be promoted through ongoing analysis of problems and the outcomes of problem solving efforts. This active analysis may be induced through a number of techniques – reflection on the strengths and weaknesses in performances, team competition exercises, or illustration of real-world consequences. Regardless of the specific techniques used to induce active practice, the value of these techniques will depend on whether the individual uses this experience as a basis for constructing viable knowledge structures.

In this regard, however, it is important to bear in mind a set of observations arising from a series of studies. In these studies a distinction is drawn between a deliberative and implementation mindset. In implementation, cognitive analysis does not occur as people simply focus on execution. In a deliberative mindset, however, analysis of strategies, approaches, and knowledge is more likely to occur. Because this deliberation is critical to the acquisition of stronger knowledge structures, it appears that active practice is likely to prove beneficial only if it is associated with deliberation. In fact, there is evidence indicating that deliberative mindsets do contribute to creative thinking at least when people are seeking to identify critical causes through the case-based knowledge applied on social innovation problems.

Conclusions

Taken as a whole, our foregoing observations lead to some straightforward conclusions. Perhaps the first, and most important, conclusion flowing from the present effort is that knowledge, or expertise, is critical to creative thought. However, the present effort makes another important point. The importance of knowledge in creative thought arises because it is through the combination and reorganization of extant knowledge that people become capable of generating the new knowledge structures that provide a basis for subsequent idea generation and idea evaluation. Thus knowledge provides the foundation for creative thinking.

Not only is knowledge important to creative thinking, but certain characteristics of these knowledge structures appear to promote creative thinking. Knowledge structures that stress key facts, or causes, anomalies, restrictions, and are based on both typical and atypical exemplars all appear to contribute to creative problem solving. More centrally, however, well organized knowledge structures appear critical to creativity.

Although certain key content of knowledge structures contribute to creative thought, the influence of knowledge on creativity appears far more complex than one might at first think. Knowledge is domain specific. Moreover, multiple alternative knowledge structures may be employed in creative thought within a domain, schematic, case-based, associational, spatial, and mental model knowledge structures, and these knowledge structures appear to interact in complex ways. To complicate matters further creative thinking in idea generation and idea evaluation also appears to depend on real-world knowledge bearing on potential applications of knowledge and the standards to be appraised in evaluating ideas. Finally, people must have skill in applying this knowledge through operations such as conceptual combination, if they are to generate creative problem solutions.

The complex, multi-faceted ways in which knowledge influences creative thinking has an important implication. Creativity in real-world settings will often require substantial practice. By the same token, understanding how knowledge influences creative thought makes it possible to formulate a viable set of educational interventions for enhancing creative thinking. For example, educational programs that stress organizing concepts, key facts, constraints, and anomalies will prove of value especially when they encourage active and deliberative practice. We hope that the present effort will lay the groundwork for future efforts intended to provide people with the kind of knowledge that provides the basis for creative thought.

Hans Adolf Krebs 1900–1981

Biochemist

Discoverer of the urea cycle and the citric acid cycle

F L Holmes, Yale University, New Haven, CT, USA

HANS ADOLF KREBS was a German-born biochemist who settled in England after the Nazi takeover of Germany in 1933. Trained in medicine, Krebs learned in the laboratory of Otto Warburg the methods and style of biochemical research that he later pursued with great success. Two years after beginning independent research, Krebs discovered in Freiburg in 1932 the ornithine cycle of urea synthesis that marked him as a rising star in his field. In England he spent 2 years in the biochemical laboratory at Cambridge, then moved to the University of Sheffield, where he discovered in 1937 the cyclic reaction sequence of oxidative carbohydrate metabolism, later known as the "Krebs cycle," for which he was awarded a Nobel Prize in 1953. Together with numerous other publications on metabolic reactions, these two major landmarks made him by the beginning of World War II one of the leading architects of the emerging subfield of intermediary metabolism. In 1945 he became director of a Unit for Research in Cell Metabolism, later transferred from Sheffield to Oxford University, which became an international center for research and training in this field. Maintaining a steady scientific productivity for the remainder of his long life, Krebs continued to be a leader in his field for nearly 50 years.

Hans Adolf Krebs, Nobel Laureate in Physiology or Medicine, 1953. Copyright © The Nobel Foundation.

The second of three children of Georg Krebs, a highly regarded otolaryngologist in the picturesque Hanoverian town of Hildesheim, and of Alma Davidson Krebs, whose family had been established there for many generations, Hans grew up in a comfortable, well-ordered, but strictly disciplined family. Hans deeply admired his father, a widely cultured, witty, but somewhat aloof figure in his life, who regarded Hans as less talented than his mathematically gifted younger brother, Wolf. Educated in the classical tradition of the humanistic gymnasium, Hans did well in all his subjects, but did not excel in any single area. Without close friends

outside his family, he industriously pursued crafts such as bookbinding, read widely (especially in history), and practiced the piano assiduously, even though he recognized early his limited musical ability. Both of his parents were Jewish, but because his father believed in assimilation as the best course for German Jews, Hans was raised without any formal religion. When he was about fifteen, Hans Krebs decided that he would enter medicine, assuming that he would eventually join his father's practice. Drafted into the army during the last months of World War I, he was released after receiving a few weeks of basic training, and immediately began his medical education at the nearby University of Göttingen. Following a longstanding German custom, he attended several other universities, including Freiburg, Munich, and Berlin, to hear the lectures of outstanding teachers in each of the basic science and clinical fields. Inspired by the discussions of their own scientific or medical discoveries that some of these teachers included in their lectures, Krebs became interested in the possibility that he too might go into research. At Freiburg he had an opportunity to carry out a project on the vital staining of cells, which led to a publication under his own name and reinforced his ambition to do further laboratory work. In emulation of some of his teachers, he envisioned that he might combine a clinical career in internal medicine with research in problems related to that field. After receiving his M.D. from the University of Berlin in 1923, Krebs performed his mandatory year of clinical service at the Third Medical Clinic in Berlin. There he was able to undertake, nominally in collaboration with his supervising clinician, an experimental study concerning the passage of various dyes from the circulation into the cerebral spinal fluid of dogs. Essentially unaided, he designed, carried out, and published the results of these relatively simple but soundly conceived experiments. Krebs then spent 1 year in a special course designed to teach chemistry to medically trained investigators.

Through chance personal connections, Krebs had an unexpected opportunity, at the beginning of 1926, to enter the laboratory of the eminent biochemist Otto Warburg as a paid research assistant. Spending 4 years there, Krebs learned the precise experimental techniques that Warburg had devised to study cellular metabolism quantitatively. Using an improved version of a micromanometer employed by physiologists since the beginning of the century to measure the rates of oxygen consumption and carbon dioxide formation in tissues, Warburg had found that thin slices of tissue placed in a fluid medium approximating that of their physiological environment could survive for several hours, maintaining their normal rates of gaseous exchange. Warburg applied these methods mainly to investigate the catalytic properties of what he called the *Atmungsferment*, or respiratory enzyme, and to compare the

respiratory properties of cancer cells with those of normal tissue. While working on problems that Warburg assigned him, Krebs had the idea that these methods could be readily applied to study also the intermediary steps in the metabolic reaction sequences that connect foodstuffs with the final excretory products of organisms. One of his teachers at Freiburg, Franz Knoop, had impressed on him several years earlier that a central goal of biochemistry was to establish unbroken connections between the starting and end points of these reaction chains. Warburg did not permit Krebs to carry out such an independent project, but Krebs kept the idea in mind until he was able to begin research on his own. Then it became the guiding force in his early career.

Because Warburg informed him late in 1929 that he must leave his laboratory by the end of the following March, and then gave him little assistance in finding another job, Krebs concluded that his mentor did not consider him capable of a research career. Whether this was the case or only a subjective impression, Krebs did a “great deal of heart-searching” about the kind of career he could manage. His own doubts about his scientific competence were counterbalanced by his strong interest in continuing what he had learned to do under Warburg. In a department of medicine in a hospital that encouraged research, he thought, he might be able to try for a research career, even while obtaining the clinical training that would enable him to fall back on medical practice if he did not succeed as an investigator. With the help of an older clinical friend in Berlin, he found a position at a municipal hospital near Hamburg. There he had time, despite heavy clinical duties, to begin his own research projects. One year later he moved to Freiburg, in a department of medicine headed by Siegfried Thannhauser. Here, too, he had clinical responsibilities, but entered a university environment conducive to basic research, where he had also the company of other able young scientists. In Freiburg Krebs took up an investigation of the synthesis of urea, using the methods he had learned from Warburg, that led him within 9 months to his first major discovery—the ornithine cycle (see Fig. 1).

This auspicious success gave him a self-confidence that never again faltered. His research career thrived in Freiburg,

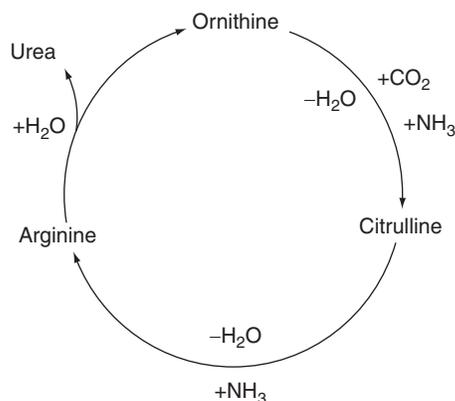

Figure 1 Ornithine cycle of urea synthesis. “The Discovery of the Ornithine Cycle of Urea Synthesis,” by H. A. Krebs, 1973, *Biochemical Education*, 1, p. 21. Copyright 1973, with permission from Elsevier Science.

where he soon began to attract a small group of young investigators, until it was abruptly interrupted by his dismissal, in April of 1933, under the terms of the Nazi Civil Service reform law that barred non-Aryans from university posts.

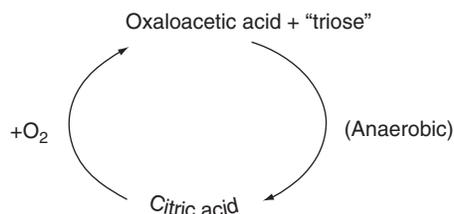

Invited by Frederick Gowland Hopkins to work in the biochemistry department at Cambridge, then one of the leading international centers of the field, Krebs was able to bring his manometers with him and quickly resumed his research where he had broken it off less than 3 months earlier. In England he did not reenter medicine. From then on he devoted himself tirelessly, 6 days a week, to his chosen science. After 2 years in Cambridge, he was offered a position as lecturer in the Department of Pharmacology at the University of Sheffield. Krebs left Cambridge for this much less prominent location largely because he anticipated that in Sheffield he would have sufficient laboratory space and other resources to begin to build a team of investigators. One year after settling there, he announced the discovery of the citric acid cycle (see Figs. 2 and 3). Many of the experiments were performed by his first graduate student, William Arthur Johnson. As Krebs’s reputation grew, students began to come also from other countries to learn the techniques and to benefit from the leadership that he was now exerting in the field of intermediary metabolism.

During the war, Krebs was able to maintain his metabolic research, but he participated also in war-related investigations of human nutritional requirements with conscientious objectors who volunteered to serve as subjects. At the end of the war the Medical Research Council selected Krebs as one of the promising scientists that it would support by establishing a research unit under his direction. The additional funding thus made available enabled him to expand his facilities to make accommodation for the increasing number of young scientists who gravitated to his laboratory.

Post-War Career

Much of the work that Krebs and his associates carried out in the postwar years involved further exploration of the scope and function of the citric acid, or Krebs cycle. It was now seen not only as the pathway of oxidative carbohydrate metabolism, but as the final common pathway for the degradation of all classes of foodstuffs, as well as the source of the carbon skeletons for many cell constituents. Beginning in the mid-1950s, Krebs turned his primary attention from the identification of metabolic reaction sequences to the regulation of their pathways.

In 1954 Krebs received an offer to become the professor of biochemistry at the University of Oxford. After negotiating to bring his Medical Research Council (MRC) unit with him, he accepted. At Oxford Krebs had responsibility, in addition, for the large existing department. Administrative duties and his efforts to introduce changes that would make it easier to attract and retain able scientists consumed much of his time, but he managed, with the support of his associates, to sustain his research productivity. Since the war, he had not personally performed experiments at the bench, but he kept in close daily contact with the students, technicians, and postdoctoral fellows who worked under his supervision. Unlike Warburg, Krebs also encouraged more experienced investigators to pursue relatively independent projects.

In this cycle "triose" reacts with oxaloacetic acid to form citric acid and in the further course of the cycle oxaloacetic acid is regenerated. The net effect of the cycle is the complete oxidation of "triose."

The conversion of citric into oxaloacetic acid passes through the following intermediate stages:

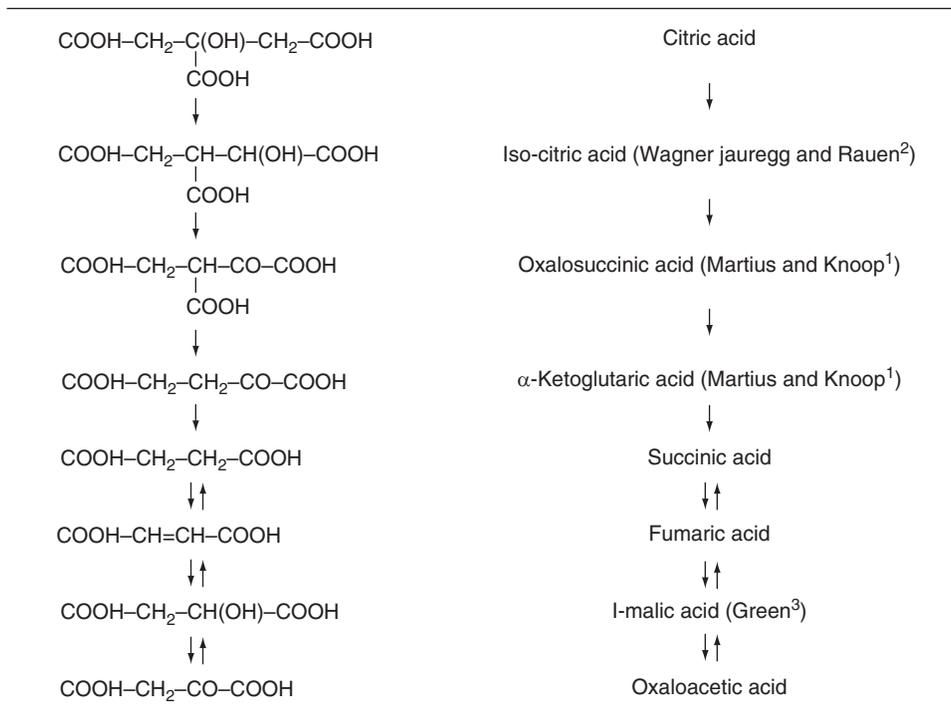

Figure 2 First schematic representations of Krebs cycle, redrawn from a sketch by Krebs in manuscript submitted to *Nature*, June 10, 1937. This paper was not published. A similar representation was published in 1937 in *Enzymologia*, vol. 4, pp. 153–154.

At the statutory retirement age of 67, it appeared that Krebs would be at last forced into research inactivity or else to leave England; but through the intercession of two prominent senior associates, he was able to obtain enough laboratory space at the Radcliffe Infirmary to continue, with the support of the MRC and a small core of his former research team. There he and his team followed the same lines of investigation that he had pursued for more than 30 years. Krebs stayed actively engaged in this work up until 2 weeks before his death, at the age of 81, in November 1981.

Patterns of Creative Activity

The general pattern of Hans Krebs's scientific activity displays characteristics that might appear at first sight disparate. Over the long trajectory of his career there were two peaks, attained during his first 7 years on his own, that tower over the field in

which he specialized. The first, the ornithine cycle, marked, in the opinion of the distinguished historian of biochemistry Joseph S. Fruton, the beginning of a new era in biochemistry. The second, the citric acid cycle was, according to the influential recent textbook of biochemistry of Alfred Lehninger, "the most important single discovery in the history of metabolic biochemistry." Together these two discoveries formed the basis for a more general conception of the metabolic cycle as a distinctive pattern of chemical reactions peculiar to life. To some observers, Krebs brought to the field a deep creative insight that has given shape to this area of biochemistry.

The research on which these contributions were immediately based took place within surprisingly short periods of time. From the beginning of his investigation of urea synthesis to the first publication announcing the outlines of the ornithine cycle, only 9 months elapsed. The broad problem of the oxidative metabolism of fats, carbohydrates, and several prominently identified intermediates occupied him

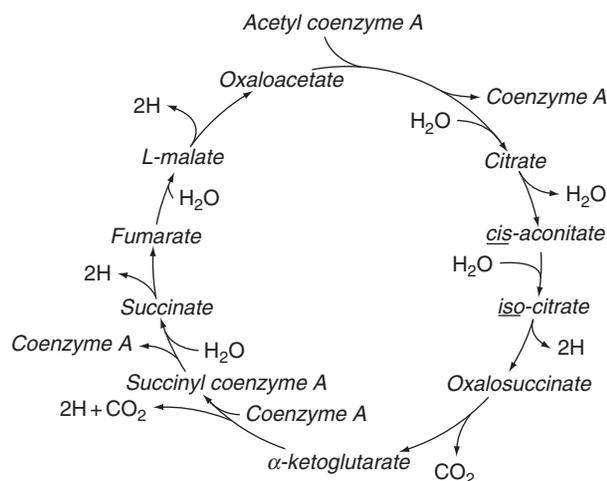

Figure 3 Krebs cycle as represented in *Energy Transformations in Living Matter* by H. A. Krebs and H. L. Kornberg, 1957, Berlin: Springer Verlag, p. 215. The cycle was at that time called the “tricarboxylic acid cycle,” rather than its original designation, “citric acid cycle,” because of doubts, later resolved, that citric acid itself lay on the main pathway.

intermittently for several years between 1933 and 1937. But after he obtained a crucial clue from a publication of Franz Knoop and Carl Martius in April 1937, it took Krebs less than 2 months to perform or direct the experiments and formulate the conclusions on which he based his proposal for the citric acid cycle.

These were not, however, isolated bursts of inspired activity. They were only highlights along a relentless course that Krebs pursued almost without interruption from the time he entered Warburg’s laboratory in 1926 until the end of his life. From Warburg he acquired the habit of performing two sets of manometric experiments daily, 6 days a week, 11 months of the year, year after year. In no year from 1925 onward did Krebs publish fewer than 15 papers on work he had either carried out or supervised. Along the way there were other significant discoveries, such as the synthesis of glutamine; some steps in the synthesis of uric acid; a modification of the citric acid cycle—the glyoxylic acid cycle—which replaces the former in certain microorganisms and plants; and in the later stages of his work, wide ranging explorations of the mechanisms that control metabolic pathways. There were also many papers that reported relatively minor refinements to the evidence for, or additional information on, the repertoire of problems with which he concerned himself.

An unbroken run of the laboratory notebooks in which Krebs kept the daily record of his experiments from the time of his entry into Warburg’s laboratory until beyond the publication of the Krebs cycle has survived. With these documents and from extensive interviews with Krebs during the last 5 years of his life, it has been possible to reconstruct his research pathway in fine detail through these years. The character of that pathway resolves the somewhat paradoxical contrast between the two summits of apparently extraordinarily creative activity that resulted in the two cycles that secured his fame, and the long stretches of strictly disciplined but

seemingly more ordinary activity that connect them and that followed them.

As with other great achievements in science, the powerful integrations provided by the ornithine and citric acid cycles obscured the earlier progress made in the areas in which these discoveries impinged. Later biochemists tended to equate the work of Krebs, along with a few other landmarks in the 1930s such as the Embden-Meyerhof pathway of glycolysis, with the origins of intermediary metabolism. Because previous knowledge seemed afterward rudimentary and fragmentary, the new discoveries appeared to have fewer precedents than they actually had. It is true that, except for the sequence of fatty acid decomposition reactions, known as β -oxidations, proposed by Knoop in 1904, no extended sequences of metabolic reactions were firmly established before 1930. There had, however, been extensive investigations of these problems beginning at the turn of the century. By the time Krebs entered the field, a series of organic compounds, such as pyruvic acid, acetic acid, and several dicarboxylic acids, had been identified as important intermediates; certain types of reactions, such as dehydrogenation, hydrolysis and decarboxylation had been supposed to occur repeatedly in metabolic reactions; and strong rules for the criteria that a potential intermediate must meet were accepted in the field. Although the pathways along which foodstuffs are degraded to end products had initially been assumed to be linear, by 1930 there was reason to expect that they would be interconnected and branching. There had even been a closed circuit of reactions proposed during the 1920s to account for the oxidation of carbohydrates and fatty acids that received prominent attention. Some of its constituent reactions had been shown to take place enzymatically, whereas one critical step eluded efforts to confirm it.

Krebs came to these problems armed with the methods of Warburg, which enabled him to subject such proposed reaction sequences to critical, quantitatively rigorous scrutiny. His own training in organic chemistry was, on the other hand, too limited to allow him to reason as deeply as some of his contemporaries about possible reaction mechanisms. Consequently, he developed a style of research in which he kept closely in touch with current and recent literature in the field, seeking ideas that he could test in his experimental system.

The characteristics of his system—that he could perform many experiments quickly, with precise results that either encouraged or ruled out a given hypothesis—proved admirably suited to this style. Not given to long-range planning, he decided each evening what experiments to carry out the next day. When he became bogged down in one problem he quickly shifted to another.

Such an approach can easily lead to nothing more than the verification of existing views or the closing down of one possible lead after another. One can find many stretches along Krebs’s investigative pathway that appear to be heading toward nothing very exciting or original. His style and methods were, however, well suited to notice something unexpected and to exploit with flexibility every hopeful lead. In the case of the ornithine cycle, it was his response to the unexpectedly large increase in the quantity of urea formed in a liver tissue slice when he added a combination of ornithine and ammonia to the medium that turned a routine investigation into a major discovery. In the case of the citric acid cycle, there was no single result so dramatically unforeseen, but there was a flexible

approach in which his ideas were fluid, and fluctuating, and he tested a large number of current ideas before hitting on the fruitful ones that brought him quickly to a historic resolution of one of the central problems in his field. Neither the ornithine cycle nor the citric acid cycle were revolutionary in the sense of breaking with existing norms, overthrowing current views, or introducing dramatically novel principles. They represented, in fact, the fulfillment of quests on which Krebs's predecessors and contemporaries were already engaged. He had not brought a new perspective or profound original insights to the field, but he had persevered, with a powerful method, great discipline, and commitment, further along the same general pathway that others had followed and were following. His creativity was not of the type that ranges far ahead of his times in lonely ventures. Rather, it resided in the quality of his responses to what turned up along his route. His optimistic temperament enabled him to keep going when nothing did seem to turn up, to try out many ideas without worrying about those that failed, and to exploit with great resourcefulness the breaks that came his way.

The peaks in Krebs's research career are, however, far less than a full measure of his creative achievement. Too often scientific progress is measured only in prominent discoveries, especially in those for which Nobel Prizes are bestowed. The most remarkable aspect of Krebs's scientific pathway is the persistence with which he pursued, for half a century, a set of problems largely delineated within the first decade of his independent research, and the fact that over so long a time these problems never ceased to yield for him and his associates fresh increments of knowledge and understanding. No one did more over this whole period to shape the complex picture that we can see summarized in the intricate metabolic maps that frequently adorn textbooks of biochemistry or walls of biochemical laboratories.

Lifetime Productivity

Dean Keith Simonton and others have recently focused attention on the lifetime contours of scientific creativity and productivity. Simonton has shown that there are characteristic curves of productivity as functions of creative potential and of the length of time in which one has pursued a particular field of creative activity. It is interesting to examine Krebs's life work within such a general analytical framework. Even without subjecting his output of publications to mathematical analysis, it is easy to see that Krebs's early productivity conforms in a general way with Simonton's curves. There is a rapidly rising output during the first 5 years and a further rise in the next decade. The "best work," the appearance of the Krebs cycle, comes at age 37, after 12 years of research activity, well within the ranges indicated by Simonton for the type of field within which Krebs worked. The most striking anomaly from the perspective of Simonton's analysis is that, whereas his curves predict a gradual decline in productivity from the point of best work to "last work," Krebs not only maintained but increased his productivity during that long phase of his career. Two dips in his output, between 1940 and 1945, and between 1955 and 1960, can be attributed, respectively, to wartime conditions and to the diversions

attendant on his move to Oxford. Between the age of 60 and 65 he produced, or closely supervised, 33 papers, compared to 30 during the 5-year period in which he produced the citric acid cycle. After his official retirement, he produced at an even higher rate: 55 papers between 1965 and 1970, and 46 papers during the next 5 years. As his former associates and biographers, Hans Kornberg and Derek Williamson, have pointed out, the 100 papers published between his retirement and his death represent "a significant contribution to the field of physiological biochemistry. ... Impressive is the range of subjects studied. ... Here was no eminent retired scientist ploughing a well-trodden path but an active brain seeking the answers to new questions."

How did Krebs evade the more standard trajectory of declining productivity? His own answer would be that he avoided the temptations that befall most eminent senior scientists to divert their energies in other directions. Although, like other Nobel laureates, Krebs too responded to some of the demands made on him by that accolade, he refused to allow himself to be drawn away from his laboratory. All the way until the final illness that preempted the last few days of his life, Krebs continued to show up at his laboratory every morning at the same early hour, just as he had been required to do in the laboratory of Otto Warburg as a young apprentice. Although he eventually allowed his associates to work a 5-day week, he himself was still at the time of his 80th birthday putting in an additional half day at his laboratory on Saturday. His mentor Otto Warburg had also worked regularly in his laboratory until the end of a long life, but Warburg had ended in isolation, pursuing old ideas and prejudices that were no longer acceptable to his younger colleagues.

How did Krebs keep himself in closer step with changing times? Unlike Warburg, Krebs tempered his selfassurance with sufficient humility to realize that his ideas required control by the criticism of others. Impatient as he was with criticism that he considered ill founded or superficial, he nevertheless recognized also that he could only remain competent to carry on scientific research by keeping in touch with the views and the advice of the many colleagues to whom his distinction gained him access.

Long after he had discovered the ornithine and citric acid cycles, Krebs pondered over their meaning and over the question why organisms utilized such complicated pathways when shorter, linear reaction chains might appear to yield chemically equivalent results. During his 80th year, a chemist, Jack Baldwin, suggested to him that one reason for the necessity of a cyclic pathway for the final stage of oxidative metabolism was that acetic acid cannot be dehydrogenated without first combining with another molecule. That idea started Krebs on a quest to understand not only the citric acid cycle but other metabolic pathways, on the assumption that they could survive in evolutionary competition only if they provided the most efficient means available to perform their particular metabolic functions. At two symposiums held that year in honor of his 80th birthday, Krebs invoked these ideas to illustrate why he felt the deep satisfaction that he derived "from creative work" still far outweighed the pleasures that he might receive from the leisure time that he would gain if he were to retire. Krebs enjoyed his preferred form of satisfaction to the end of his life.

Glossary

Group artistic creativity The efforts of many resulting in a single creative product.

Literary adaptation Literary adaptation is the adaption of a literary source (e.g., a novel, short story, poem) to another genre or medium, such as a film.

Rashomon effect The Rashomon effect is the effect of the subjectivity of perception on recollection, by which observers of an event are able to produce substantially different but equally plausible accounts of it.

World cinema Films and film industries of non-English-speaking countries.

Akira Kurosawa was born on 23 March 1910, in a suburb of Tokyo, the youngest of three older brothers and three sisters. His father, Isamu Kurosawa, had a moderate military career before Akira's birth, and in his later years worked as an athletic director at a junior high school affiliated with the Japanese military. Though his father was steeped in Japan's traditional family and military values of the day, he nevertheless believed in the benefits of Western culture. Indeed, he ensured Akira was exposed to American and European movies, even as the Japanese government gradually introduced restrictions on these imports. Kurosawa later credited his early interest in film to his father's influence.

Kurosawa identifies his first important creative influence as Seiji Tachikawa, an art teacher at the primary school he attended. Tachikawa taught Kurosawa that creativity stems from creating something new, not copying something that already exists. This broke with traditional forms of art education of the day that emphasized mastering and flawlessly duplicating the techniques of others. In 1927, about the time he completed middle school, Kurosawa enrolled in the Doshusha School of Western Painting and intending to embark on a career as a painter. He had early initial success, placing two paintings in exhibitions, but found it difficult to support himself through his art. Nonetheless, this early training in art brought a powerful sensibility to Kurosawa's films once he began directing, giving him a keen appreciation of the visual and emotional impact generous space can have around whatever objects are in the frame – a use of space deeply embedded in traditional Japanese art. During this period Kurosawa also started to explore Western literature. His main vehicle for this was as a member of the Japan Proletariat Artists' Group. His participation in the group was less about Marxist theory than about expressing personal resistance to the increasingly conservative and militarist Japan of that era. Though this group Kurosawa encountered the works of Tolstoy, Turgenev, and Dostoevsky, with Dostoevsky remaining an important influence, eventually resulting in his film adaptation of *The Idiot* (*Hakuchi*) in 1951.

Kurosawa was particularly close to his older brother Heigo, who was the brother closest to him in age. Heigo made his living as a *benshi* (narrator of silent films) whose speciality was foreign films. He would regularly bring Akira with him to the theater, to Japanese vaudeville, and to films, widening his younger brother's appreciation of performance and cinematic art. Heigo's relationship with their father was fraught with

tension and disapproval, with Akira often finding himself in the irresolvable middle. When sound came to movies in Japan, Heigo found it increasingly difficult to find work. He committed suicide in 1933, at the age of 27, for reasons that have never been entirely clear. But what is clear is that Kurosawa credited Heigo as a major influence in his life, and his death as a loss from which he never quite fully recovered.

In 1936, Kurosawa joined P.C.L. Studios (which evolved into Toho Studios) as an assistant director trainee. The successful applicant out of 500, he gradually advanced up the Toho production ladder, mentored and tutored by the director Kajirō Yamamoto. By 1941 Kurosawa had moved from support roles as a third assistant director and a first assistant director, to directing the second unit Yamamoto's 1941 film *Uma* (English title, *Horses*). Kurosawa's solo directorial debut was in 1943 with *Sugata Sanshirō*, based on a novel by judo master Tsuneo Tomita. The theme was the spiritual and athletic development of a student by the master, into a skilled martial artist. The film did well at the box office in wartime Japan, and while not explicitly political, fitted in well with the tenor of the times. Politics aside, it was the innovative balletic action sequences that caught the attention of other film makers and the public, and laid the early groundwork for martial arts action sequences by generations of subsequent film directors in the United States, Europe, and Asia, from 'Crouching Tiger, Hidden Dragon' to 'The Matrix.'

Concerning his work during the war, Kurosawa pointed out that, like most of his compatriots, he did not resist the currents of the times, but instead found ways to survive and continue working. This was a skill that continued to be applicable in the early post war years under the watchful eyes of the American occupation of Japan (1945–1952). Japanese films had to get past American censors, who dutifully suppressed any works it deemed sympathetic to Japan's militarist adventures or its feudal past. This was the fate of Kurosawa's first film, released just after Japan surrendered in 1945, and produced while the country was still at war. *Tora no o wo fumu otokotachi* (*The Men Who Tread on the Tiger's Tail*) was the tale of a servant and samurai who must switch roles in public in order for both to survive. It was reflexively banned by the American authorities – seemingly less out of ideological concern than a simple knee-jerk reaction to any Japanese film produced during wartime. It was finally released in Japan in 1952, and distributed in the United States in 1960, to a modest response.

The late 1940s through the 1950s saw a great explosion of commercial and artistic creativity in Japan, against a backdrop of postwar reconstruction for industry and disillusionment with Japan's government amongst artists and intellectuals. Those who had been mute during the war could now find their voice. This period was the golden age of Japanese cinema, and Kurosawa produced a string of artistic successes that brought him international recognition and paved the way for a commercial global cinema that extended beyond North America and Europe for the first time. For Kurosawa, his key creative moment came with *Yoidore tenshi* (Drunken Angel, 1948), which he considered the picture where he finally discovered himself as an artist. This was also the first Kurosawa film to feature the actor Toshiro Mifune. The Kurosawa–Mifune collaboration was an intense yet highly productive working relationship that survived into the mid-1960s and resulted in 16 films, many of which are now considered classics.

Lifetime creative output rarely yields an unbroken string of multiyear successes throughout a career. Rather, it is the constant engagement in the creative process that yields results spaced throughout time. Success may come as single works interspersed with less successful works or in temporal clusters, as in Kurosawa's case. His first cluster was *Rashômon* (1950), *Ikiru* (To Live, 1952), and *Shichinin no samurai* (Seven Samurai, 1954). The second cluster occurs in his sixties and seventies, a run of international cinematic achievement that included the Soviet coproduction and Oscar winner *Dersu Uzala* (1975), the period drama *Kagemusha* (1980), and the reworking of Shakespeare's *King Lear* into *Ran* (1985).

International recognition came first to Kurosawa through *Rashômon*, which won the Golden Lion for best film at the Venice Film Festival in 1951. It opened in Japan the previous year to unfavorable reviews and indifferent box office, and seemed destined to disappear without a trace. Serendipity intervened in the form of Giuliana Stramigioli, then the Japan representative for Italiafilm. Her interest in the film resulted in its official entry into the festival. The honors *Rashômon* won at Venice carried over to the United States in that same year, where it won the Academy of Motion Picture Arts and Sciences' Honorary Award for best foreign film.

It is useful to take a close look at *Rashômon* because it captures essential elements of many of Kurosawa's later successes. As with several of his other important films, it was part adaptation, part amalgamation, and part pure invention. It draws on two unrelated short stories by the early twentieth century Japanese writer Ryunosuke Akutagawa. Kurosawa uses Akutagawa's *Rashômon*, published in 1915 in *Teikoku bungaku* (Imperial Literature) to frame portions of the movie, particularly its interest in moral ambiguity. *Rashômon* (literal meaning, the Rashô Gate) was a gate that stood as an entrance to Japan's ancient capital Heian Kyo (modern day Kyoto), and was traditionally a place where unclaimed corpses were left – a setting whose moral power would have been instantly recognizable to his Japanese audience. For the film's narrative Kurosawa then draws heavily on Akutagawa's *Yabu no naka* (In a Thicket) to develop his overarching theme – that truth and morality are egotistical notions held by each individual, that the very notion of reality is a questionable concept we use to comfort ourselves, that images themselves are untrustworthy, with it all resulting in judgments and justice

that can by its very nature be little more than arbitrarily designed to fulfill our social, spiritual, and political conventions.

The movie explores four different accounts of a criminal event – the murder of an aristocrat and the rape of his wife. The accounts are those of the accused, the wife, the murdered noblemen told through the voice of a medium, and the story's narrator. All accounts, including that of the narrator, cannot free themselves from bias. The bias is made plain when an equal weight is given to each character's presentation. Though a quintessentially Japanese film, it fits rather well with Western notions of existentialism and post-modernism. This talent, to combine cultural elements in novel ways to produce intercultural major cinematic works with international appeal, defines Kurosawa's creativity throughout his career.

The influence of Kurosawa's *Rashômon* extends well beyond cinema. The *Rashômon* Effect has been written about in scientific research, and similar narrative devices have been introduced into Western films in the decades that followed its release. *Rashômon*-like is a term in itself, to suggest relativity of truth and evidence. Few films, especially foreign language films, have seen their titles converted into adjectives of common expression.

Though the film would have played to only limited art house audiences outside of Japan at the time, it introduced Kurosawa's work to western audiences and decisively launched his international career, which in return earned him renewed respect in Japan. It also created a dynamic that haunted and helped Kurosawa for the rest of his career – his work was often better received outside Japan than in it. This was partially a result of the way in which live action films were categorized in Japan throughout his career. They were either *jidaigeki* (period pieces) or *gendaimono* (contemporary). Kurosawa's films with period settings were sometimes seen by critics within Japan as pandering to Western audiences that wanted to experience Japan and Asia as odd and unusual. His films with contemporary settings were also criticized within Japan for their 'Western style' plotting and pacing. Yet outside of Japan, he was viewed as a uniquely Japanese director whose work crossed over to appeal to non-Japanese audiences. What is missed in all of this controversy is that his films always dealt with contemporary concerns and themes, regardless of their setting, and presented universalist themes that had the capacity to transcend the specifics of national culture.

Kurosawa's next great accomplishment was the 1952 *Ikiru* (To Live), one of his most humanistic works and considered his first fully realized masterpiece. At one level it is the story of Watanabe, a man with a terminal diagnosis of stomach cancer. He is a petty city bureaucrat in a Tokyo ward office in a ramshackle district who has done nothing with his life, and now faces death with the knowledge he has done nothing significant. With the little time left to him, he chooses to make a difference by pushing through permission and funds to build a park in a polluted, poor, and industrially chaotic part of town. This is not just about wresting personal meaning in the eleventh hour of life. It is also a tutorial on the meaning of democracy, as promoted by the American occupying forces of the time. In this model, bureaucrats are to become public officials who serve the public good, not isolated and unresponsive authority figures who specialize in nonaction in the face

of dire public need. The Watanabe character, diagnosed with an incurable illness that cannot but result in death, stands in as a metaphor for Japanese society, where prewar and wartime beliefs and norms must die, and in their place new democratic norms must be established. Yet, as Watanabe embodies, this must be done not by someone else, a new group of individuals, but by the very individuals who were responsible for the old system.

Shichinin no samurai (Seven Samurai, 1954), is the most well known of all Kurosawa films and is critically acknowledged as among the greatest action movies ever made. It is one of the four films Steven Spielberg tends to watch whenever starting a new project, the other three being 'Lawrence of Arabia' (1962), 'It's a Wonderful Life' (1946), and 'The Searchers' (1956). It had a direct influence on the American western when it was remade by John Sturges as 'The Magnificent Seven.' The highly kinetic nature of the action sequences helped to internationally revolutionize the action movie genre, while its nihilist tendencies, further developed in *Yojimbo* (The Bodyguard, 1961), laid the foundations for Clint Eastwood's 'Man with No Name' in Sergio Leone's spaghetti westerns. This highlights the fluid interchange between these genres – the American western and the Japanese samurai drama – where heroes exist on the fringes of a normal society they can never join, and align themselves with this very normalcy in a fight against villains. The thematic and cinematic achievements of the 'Seven Samurai' places Kurosawa on a plane with other great directors and their epics, such as David Lean and 'Lawrence of Arabia' (1962) and Sergei Eisenstein's 'Battleship Potemkin' (1925). It took a year to complete the 'Seven Samurai,' and when it was 'released, it was the most expensive picture ever made in Japan, all this at a time when Japan was still struggling to recover financially from its disastrous war effort and defeat.

In a move similar to most independently minded film directors, Kurosawa established his own production company in 1960 to gain greater creative and financial control over his output. However, this development never brought Kurosawa or his projects the financial stability he hoped for. His films in the immediate aftermath of founding his production company were mostly entertainment pieces, culminating in *Akahige* (Red Beard) in 1965. Parenthetically, 'Red Beard' was the last time Kurosawa and Toshiro Mifune worked together, Mifune no longer willing to withstand the exacting demands of Kurosawa. In the years that followed, Japanese studios fell into economic difficulties, making it increasingly difficult for Kurosawa to bankroll his projects, which in any case were always expensive by Japanese standards. His attempts to work with Hollywood producers were similarly unsuccessful. He reached a low point in 1968 when he began working with 20th Century Fox on 'Tora, Tora, Tora!,' a film about Japan's attack on Pearl Harbor. He was taken off the project by the American producers who feared increasing cost overruns and found Kurosawa difficult to work with.

Kurosawa's next completed project was *Dodesukaden* (1970), his first full color feature and an attempt to return to films with serious themes. It is a story about slum dwellers, with a mentally challenged boy at the center, and it was a financial failure that led to a serious period of personal and professional despondency, made worse by a painfully persistent undiagnosed ailment, later discovered to be gallstones. This culminated in a

suicide attempt on 22, December 1971, in which Kurosawa slashed his neck six times and his arms eight. Throughout his career there were rumors of other suicide attempts, perhaps as many as 13, but they have never been confirmed.

As Kurosawa recovered, he began working on 'Dersu Uzala' (1975), a production put together through the Soviet Union's Mosfilm and shot almost entirely on location in Siberia under extremely challenging weather conditions. It was based on the 1923 book of the same title, written by the Russian explorer Vladimi Arsenyev, about the friendship between a Russian explorer and a Manchurian hunter who lives in close rhythm with nature. As with *Rashômon*, we see Kurosawa returning to the literary adaptation as a formula for success. 'Dersu Uzala' garnered seven awards internationally, as a Soviet film, and was the beginning of another period of acclaimed work by the director.

Kurosawa's next project was the period drama *Kagemusha* (The Shadow Warrior, 1980), to be followed by the last of his great achievements, the reworking of Shakespeare's King Lear into *Ran* (1985). *Kagemusha* tells the tale of a petty thief chosen by the leaders of a clan as a look alike, to impersonate their feudal chief killed earlier in battle. *Kagemusha's* final scene, in which samurai from one clan, armed with bow and arrow and pike, are massacred by another clan's use of muskets, is one of the greatest and most poignant action sequences of Kurosawa's career. His next film, *Ran*, was set in sixteenth century Japan and adapted from Shakespeare's King Lear. This film, produced achieves a scale, intensity, and intelligence that Kurosawa had been aiming for throughout his career. 'Dreams' (1990), *Rhapsody in August* (1990), and *Madadayo* (1993) were the last three films he made and while 'Dreams' was visually stunning, none of these films captured the great energy of his earlier work.

In 1989, at the age of 72, Kurosawa was awarded an Oscar for Lifetime Achievement, "for accomplishments that have inspired, delighted, enriched, and entertained audiences and influenced filmmakers throughout the world." For his part, Kurosawa noted that, "To be an artist means never to avert one's eyes."

Combinatory Freedom, Predigital Sampling, and Creativity

Kurosawa's adaptations from the West – Shakespeare's Macbeth into *Throne of Blood*, King Lear into *Ran*, Dostoyevsky's *The Idiot* into *Hakuchi* and Gorky's *The Lower Depths*, demonstrates the creativity that can result when cultural material is absorbed and altered by individuals working from outside the cultural context of those materials. As Henry Seaton has noted:

"Ran is the embodiment of the 'otherness' in the playing of Shakespeare. Not only was this film directed by a Japanese director, Akira Kurosawa, not only was the film produced in a country on the other side of the world, not only is the language of the text 'foreign', not only is the setting for the action alien to the world of Shakespearian England, not only is the costume historically and geographically 'other' than English, not only are many of the characters different in gender to those in Shakespeare's text, and not only is the medium in which the text is encoded a twentieth century phenomenon, specifically bearing an oriental signature, but also . . .

the Fool-figure is played by a Japanese transvestite pop singer.” (Seaton H. (2000). ‘All licensed fool’: all licensed film: Akira Kurosawa’s *Ran*. Solihull College, Solihull, UK)

Kurosawa’s use of combinatory freedom in the analog age is a precursor to the digital age where sampling infuses, guides, and enriches so much of the creative process today. The characteristics of digital sampling – where works are taken out of context, trimmed, and transposed to suit the needs of the creative individual and the creative project, then combined in ways the original artist or culture never envisioned – are all found in Kurosawa’s way of working with the material on which he based some of his most famous and powerful works. He performed the same function when adapting material and techniques from Japanese culture, freely drawing on the texts, stylings, and actors training in the areas of *noh* and *kabuki*

Kurosawa is a complex figure whose body of work is both rooted in its Japanese and Asian cultural, economic, spiritual, institutional, and historical context, and transcends it. His work is notable for its capacity to thoroughly embody Western forms of representation, while using essential Japanese elements and extending them in new directions. Kurosawa is bound to neither Japanese or Western forms of imagery and film making, and used this freedom to create novel forms of expression that moved back into the world of film outside of Japan, and drove innovation on an international scale. It is a multidirectional phenomenon. Kurosawa’s admiration for the work of John Ford and his westerns combines with his knowledge of Japanese history and the Seven Samurai results. This, in turn, creates new story elements and styles and is taken up by the director John Sturges as *The Magnificent Seven*, which becomes a staple of American popular culture.

This open sampling, borrowing, and rewriting of cultural ideas raises issues about the nature of creativity itself, blurring the lines between creativity’s authorship and creativity’s production. It also challenges the implicit idea that true creativity is somehow a Western phenomena, which can be emulated or copied by others, but not exceeded. The twentieth century Japanese model of creativity – one where sampling, unconstrained borrowing, and a lifting of cultural artifacts from their cultural context and reintroduction in completely new and novel contexts – itself constitutes creativity, and a creativity that took root in the Western world several decades later. In short, combinatory freedom allows for artistic innovation and renewal, and a fresh merging of process and inspiration, in ways now supported by twenty-first century digital sampling, but it was a cultural and artistic form in Japan in preceding decades.

Indeed, as Lubart and Sternberg suggest, one of the significant limitations of the literature on creativity is its tendency to focus on Western cultural models. While creative models can be seen as traditionally different in the Asian and Western models, it is a position which conflates broad notions of cultural similarity across an Asia that is, in fact, highly diverse in its approach to creativity. Moreover, anecdotally, it is clear that individual creativity is not a Western phenomenon, any more than group creativity is an exclusively Eastern phenomenon. In addition to directors such as Kurosawa there are, and have always, significant and genre-breaking creatives

working in all areas of the arts and industry throughout Asia. In Japan alone, creativity has captured a global audience, from its industrial design, advanced robotics, management and manufacturing innovation, to modern art, and fashion. South Korea, Taiwan, and China also have their own energetic innovations and creative output. The literature on creativity is poised to capture these broader examples of international and non-Western achievement in the years ahead. One example of how this is already taking place is through the notion of group artistic creativity.

Group Artistic Creativity and Lifespan Productivity

Kurosawa conceived of, and made his films, in a highly individualistic yet collaborative manner. He initiated most of his own films, rather than having them handed to him by the studio. As his nickname, *Tenno* (The Emperor) suggests, he attempted to exercise an exacting control over his productions. Kurosawa’s ground-up experience with the process of film making allowed him to gain greater control over his final product than generally possible for other Japanese directors. While filming, his technical skill as an editor allowed him to edit together the rushes of each day’s scenes, so by the last day of shooting he already had a first draft of his entire film. He was also well known for his perfectionism. When a scene in ‘*Throne of Blood*’ (1957) called for Toshiro Mifune’s character to be pierced by arrows, Kurosawa insisted Mifune wear a protective vest and be filmed while shot at with real arrows. Evidence of his control over his creative process is also found in the fact that he was the primary editor on 19 of the 31 films he directed between 1943 and 1993. He also sustained an active dedication to writing, with 69 writer’s credits to his name, writing or cowriting the majority of scripts he used to make his films. He was deeply involved with the set up of his cinematographer’s cameras, with costume and prop design, and though no composer, known for conceiving of the music that would accompany his scenes as he wrote them. He did all of this while working energetically to maintain artistic autonomy from the studios that allowed him to work in the first place.

Yet, a hallmark of film making is its inherently collaborative nature. The theory of the auteur, where a film is the product of a single creative mind working through others, certainly has value when considering Kurosawa’s career, but even he was careful to point out the group nature of his filmic endeavors.

You know how I work? Talk, talk, talk – that’s all I do. Get the writers together and talk about the script. Get the actors together and talk acting. Get the camera crew together and talk production. I spend my life talking.

This is consistent with Dean Keith Simonton’s point, that the making of commercial films is inherently an example of group artistic creativity – or collaborative aesthetics – in which the efforts of many result in a single creative product. Simonton also suggests the basic variables that contribute to a film’s success: direction, male and female leads, male and female supporting roles, screenplay, art direction, costume design, make-up, cinematography, film editing, score, song, visual effects, sound effects editing, and sound. Moreover, given that film production is inherently a temporary work system, in

which crews of actors, technical specialists, managers, financiers, and workers come together for intense yet brief periods to produce a cinematic product, the need for collaboration and reliance on the skills and dedication of others increases, particularly in the production phase, where large crews are needed and divided into subgroups with distinct yet interdependent responsibilities.

An additional aspect of Kurosawa's career that bears special mention is his lifespan production and creativity. Lifespan creativity in terms of critical praise for film directors generally follows an inverted U, where success increases after their first film, followed by a decline in ratings in later films. Yet Kurosawa's career followed a multiple wave pattern, with international success in the 1950s – generally considered Japan's golden age of film – followed by disappointing results until the mid-1970s, and a surge of creative accomplishment in the 1980s, followed by smaller, less praised productions toward the end of his life. It is noteworthy that throughout his life, Kurosawa's films were realized with relatively modest budgets by Hollywood standards. This lends weight to the observation that creativity, critical and commercial, and success are not directly correlated with large budgets. Creativity in popular film is especially problematic, since it is a creative field that is intrinsically bound with commerce. The need for commercial success can be paramount for a director since this factor, more than any other single factor, can determine whether he or she get to make another movie in the future. In the case of Kurosawa, his distinctive yet evolving style, and his capacity to move between period dramas (*jidaigeki*) and modern works (*gendai mono*), likely aided the longevity of his career, suggesting that both creativity and adaptability were crucial elements in his lifetime productivity. Indeed, the more closely a director can link creativity with commercial success, the more likely they are to continue working and developing their creative style and voice.

Kurosawa's reputation as a film maker has increased since his death in 1998, and the globalization of film and film talent has increased exponentially since *Rashômon* was first screened at the Venice Film Festival in 1951. He worked within the specifics of his Japanese context, but with a thorough command of the international language of drama, literature, and action that gives his work a powerful universalistic appeal.

Filmography of Akira Kurosawa (Japanese Release Dates)

Madadayo (1993), English title: 'Not Yet.'
Hachi-gatsu no kyôshikyoku (1991), English title: 'Rhapsody in August.'
 'Dreams' (1990).
Ran (1985).
Kagemusha (1980), English title: 'The Shadow Warrior.'
Dersu Uzala (1975).
Dodesukaden (1970), English title: 'Dodes'ka-den.'
Akahige (1965), English title: 'Red Beard.'
Tengoku to jigoku (1963), English title: 'High and Low,' also as 'Heaven and Hell.'

Tsubaki Sanjûrô (1962), English title: 'Sanjuro.'
Yojimbo (1961), English title: 'The Bodyguard,' also as 'Yojimbo the Bodyguard.'
Warui yatsu hodo yoku nemuru (1960), English title: 'The Bad Sleep Well.'
Kakushi-toride no san-akunin (1958), English title: 'The Hidden Fortress.'
Donzoko (1957), English title: 'The Lower Depths.'
Kumonosu-jô (1957), English title: 'Throne of Blood.'
Ikimono no kiroku (1955), English title: 'I Live in Fear,' also as 'Record of a Living Being.'
Shichinin no samurai (1954), English title: 'Seven Samurai.'
Ikiru (1952), English title: 'To Live.'
Hakuchi (1951), English title: 'The Idiot.'
Rashômon (1950).
Shôbun (1950), English title: 'Scandal.'
Nora inu (1949), English title: 'Stray Dog.'
Shizukanaru ketto (1949), English title: 'The Quiet Duel.'
Yoidore tenshi (1948), English title: 'Drunken Angel.'
Subarashiki nichiyôbi (1947), English title: 'One Wonderful Sunday.'
Waga seishun no kuinashi (1946), English title: 'No Regrets for Our Youth.'
Asu o tsukuru hitobito (1946), English title: 'Those Who Make Tomorrow.'
Zoku Sugata Sanshiro (1945).
Tora no o wo fumu otokotachi (1945), English title: 'The Men Who Tread on the Tiger's Tail.'
Ichiban utsukushiku (1944), English title, 'The Most Beautiful.'
Sugata Sanshiro (1943), English title: 'Sanshiro Sugata.'

Awards Received by Akira Kurosawa

- 2001 Japanese Academy, Best Screenplay for *Ame Agaru* (1999), *posthumous*.
- 1999 Japanese Academy, Lifetime Achievement Award, *posthumous*.
- 1999 Association of Tokyo Film Journalists (Blue Ribbon Awards), Special Award for his body of work, *posthumous*.
Mainichi Film Concours, Special Award, *posthumous*.
- 1998 Nikkan Sports Film Awards (Japan). Special Award, for Lifetime Achievement.
- 1992 Directors Guild of America, Lifetime Achievement Award.
- 1990 Academy Award, Oscar for Lifetime Achievement.
- 1987 British Academy (BAFTA), Best Foreign Language Film, *Ran* (1985).
London Critics Circle Film Awards, ALFS Award, *Ran* (1985).
- 1986 Academy Award, Oscar for Best Director, *Ran* (1985).
Amanda Award (Norway), Best Foreign Feature Film, *Ran* (1985).
Association of Tokyo Film Journalists (Blue Ribbon Awards), Best Film, *Ran* (1985).
David di Donatello Awards (Italy), David Award, Best Director, Foreign Film, *Ran* (1985).

- Directors Guild of America, Golden Jubilee Special Award.
Mainichi Film Concours, Best Director and Best Film, *Ran* (1985).
National Association of Film Critics (Denmark), Bodil Award, Best European Film, *Ran* (1985).
San Francisco International Film Festival, Akira Kurosawa Award.
- 1985 Los Angeles Film Critics Association Awards, LAFAA Award, Best Foreign Film, *Ran* (1985).
National Board of Review (USA), NBR Award, Best Director, *Ran* (1985).
San Sebastian International Film Festival (Spain), OCIC Award, *Ran* (1985).
- 1981 British Academy (BAFTA), Best Foreign Language Film, *Kagemusha* (1980).
Association of Tokyo Film Journalists (Blue Ribbon Awards), Best Film, *Kagemusha* (1980).
Cesar Awards (France), Best Foreign Film, *Ran* (1985).
David di Donatello Awards (Italy), David Awards (2) for Best Director and for Best Foreign Film, *Kagemusha* (1985).
Italian National Syndicate of Film Journalists, Silver Ribbon, Best Director for Foreign Film, *Kagemusha* (1980).
Mainichi Film Concours (3), for Best Director, Best Film, and Readers' Choice Award, *Kagemusha* (1980).
- 1980 Cannes Film Festival (France), Gold Palm, *Kagemusha* (1980).
Hochi Film Awards, Japan, Best Film, *Kagemusha* (1980).
- 1979 Moscow International Film Festival, Honorary Prize, For Contributions to Cinema.
- 1978 French Syndicate of Cinema Critics, Critics Award, Best Foreign Film, *Dersu Uzala* (1975).
- 1977 David di Donatello Awards (Italy), David Award, Best Director, Foreign Film, *Dersu Uzala* (1975).
Italian National Syndicate of Film Journalists, Silver Ribbon, Best Director, Foreign Film, *Dersu Uzala* (1975).
- 1976 Academy Award, Oscar for Best Foreign Language Film, *Derzu Uzala* (1975).
- 1975 Moscow International Film Festival, FIPRESCI Prize and Golden Prize, *Derzu Uzala* (1975).
- 1966 Association of Tokyo Film Journalists (Blue Ribbon Awards), Best Film, *Akahige* (1965).
Kinema Junpo Awards (Japan), Best Director and Best Film, *Akahige* (1965).
Mainichi Film Concours, Best Film, *Akahige* (1985), English title: 'Red Beard.'
- 1965 Venice Film Festival, OCIC Award, *Akahige* (1965), English title: 'Red Beard.'

Glossary

Concept selection Choosing relevant or critical concepts to focus on.

Conceptual combination Combination or reorganization of unique and abstract features of concepts relevant to the problem.

Creative thought The production of solutions to novel, complex, and ill-defined problems.

Idea evaluation Evaluating and refining ideas relevant to problem solving.

Idea generation Developing and contextualizing ideas that may be valuable in problem solving.

Implementation planning The extensive use of forecasting and development of backup plans.

Information gathering Seeking information that is relevant to solving the problem.

Problem definition Establishing a clear perspective of what the exact problem is.

Solution monitoring Monitoring progress of solution implementation and changes resulting from implementation.

Leadership

The stereotypical image of the creative person is of an individual working alone to develop and gain acceptance for a new idea. Although this image appears appropriate in some cases, for example, Albert Einstein, in most cases new ideas, and new products, are rarely the result of an individual working alone. Illustrations of this point may be found in DuPont's development of polymer chemistry and the development of nuclear power systems. Both of these efforts involved hundreds, if not thousands, of people. If one grants that creative work often occurs in teams, then a series of new questions comes to the fore. How do teams influence the character and success of creative work? How do organizations influence creativity? And, how do leaders influence the nature and success of creative efforts?

In the present effort we will attempt to provide an answer to this latter question – How do leaders influence the nature and success of creative efforts? To answer this question we will address two key issues. First, we all consider how leaders influence others involved in creative work. Second, we will examine how leaders think about the problems posed by creative work. We believe the evidence bearing on these issues suggests not only that leaders are a powerful influence on the success of creative efforts, but also that leaders necessarily think about the problems posed by creative efforts in unique ways.

Leading Creative Efforts

Context

Leadership, ultimately, involves the effective exercise of influence. The effective exercise of influence, however, does not refer to the social outcomes of influence attempts – both Roosevelt and Hitler were leaders. Rather, this effective exercise of influence involves others reactions, reactions for good or ill, to the leaders influence attempts. In this sense, leadership can be viewed as a form of performance albeit an unusually complex form of performance.

As a complex form of performance, a number of variables have been found to affect the success of these influence attempts. These variables include leader traits, such as intelligence, extraversion, and achievement motivation, as well as the behaviors evidenced by leaders in the exercise of influence such as consideration, initiating structure, participation, and change management. Leaders, moreover, may exercise influence through the relationships formed with followers, the followers' identification with the leader, and the induction of affect by the leader. Although multiple mechanisms exist by which leaders can exercise influence, the mechanisms that prove most effective depend on the context in which the leader operates.

Despite the many mechanisms through which leaders can exercise influence, the influence attempts made by leaders do not always affect the performance of teams. Instead, leaders' exercise of influence makes a difference with respect to team

performance only under certain conditions. More specifically, leaders' exercise of influence makes a difference when teams, or followers, are confronting crisis conditions – conditions where risk/rewards are imbalanced, the issue at hand is in conflict, approaches for addressing this issue are not clear, and this problem at hand is novel. Recognition of the point that complex, novel, ill-defined problems with high risk/high rewards typically characterize most creative problems led Mumford, and colleagues to argue that leadership would be critical whenever people working on creative tasks.

Influencing Others

The observations, in turn, bring to the fore a new question. How should leaders exercise influence attempts to enhance creativity and innovation? Mumford and his colleagues have identified several ways influence can be exerted by leaders in such a way as to enhance creative and innovative efforts: (1) technical skills; (2) evaluation and direction; (3) mission definition; (4) planning and structuring; (5) motivation; (6) support climate; and (7) team formation.

In one study on leadership in research and development teams, specifically Andrew and Farris' 1967 study, appraisals of scientists with regard to the behavior exhibited by the leaders of 21 teams were obtained. It was found that leader technical skills ($r=0.53$) were better predictors of creative production than other leader behaviors such as motivating others and autonomy granted. In another study along these lines, Barnowe in 1975, examined the production (e.g., publications, patent awards) of 963 chemists in 81 research and development teams. Leaders were assessed by team members with respect to support, participation, closeness of supervision, task emphasis, and technical skill. He found that technical skill ($r=0.40$) was the best predictor of innovation on the part of team members.

Clearly, the leaders of creative groups must possess expertise in the field, or domain, in which creative work is being pursued. One reason why expertise is critical for leaders pertains to how influence is exercised with respect to creative people. Creative people tend to be autonomous and draw identity from the work being done. As a result, appeals to authority or rewards are unlikely to prove effective. Rather, it is only through appeals to expertise and definition of work requirements that leaders can exercise effective influence. Indeed, the use of expertise as a key influence mechanism is consistent with the tendency of creative people to identify with the profession as opposed to the leader or the organization.

The importance of the exercise of influence *vis-à-vis* expertise is related to another key set of skills that must be possessed by the leaders of creative teams. In 1972, Farris examined the communication patterns of more and less creative people working in research and development teams. He found that creative people were likely to communicate with team leaders under two conditions: (1) when initially defining or structuring the problem to be approached in their work; and (2) when seeking evaluation of work conducted with regard to its implications. These findings, of course, suggest that people doing creative work rely on leaders to support problem definition and idea evaluation activities.

In 2000, other work by Mumford, and coworkers point to the importance of problem definition and idea evaluation by leaders. In this study, the creative problem-solving skills of army officers were assessed, using a modified think aloud protocol, to provide assessments of problem definition, information gathering, concept selection, conceptual combination, idea generation, idea evaluation, implementation planning, and solution monitoring – all key processing skills involved in creative thought. In comparing more junior to more senior leaders with respect to these skills, it was found that more senior leaders, as opposed to more junior leaders, evidenced particularly high scores on problem definition and idea evaluation skills.

What should be recognized here, however, is that problem definition and idea evaluation must be executed by leaders with respect to other people and their work. Thus in 2004, Loneragan and colleagues presented advertising ideas to people assuming the role of managers in a marketing firm. Ideas were appraised with respect to different standards and feedback provided. It was found that the most creative advertising campaigns resulted when leaders provided feedback intended to improve the quality of original ideas and feedback intended to improve the originality of high quality ideas. Hence leaders in evaluating ideas, and providing feedback with regard to work on these ideas, must provide feedback intended to compensate for deficiencies. Thus leaders of creative efforts must possess exceptional problem definition and idea evaluation skills.

Leader's appraisal of problems and ideas, however, must ultimately be referenced against a set of technical objectives. The technical objectives being pursued in a creative effort are commonly referred to as a mission. A mission is similar to a vision. It differs from the visions discussed in theories of transformational and charismatic leadership in that emotionally evocative personal identity is not invested in a mission. Indeed visionary leadership, while motivating, may undermine creativity. Missions, however, by defining a significant technical and professional problem capitalize on, and activates, the professional orientation of creative people serving as a framework for formation of the shared mental models that promote team creativity and participation in the production of new ideas. In keeping with these observations, qualitative studies of successful leaders of research and development teams have found that mission definition and ongoing articulation of the mission was critical to successful leadership of research and development teams. In another study along these lines, Dunham and Freeman in 2000, found that mission definition and articulation was critical to the success of play directors.

With regard to mission definition and the articulation of this mission, however, three variables appear critical to leader performance. First, the technical, or professional, importance of the mission must be defined and articulated. Second, the room for creative contributions in achieving this mission must be articulated. Third, this mission must be used to appraise ideas and address the various crises that arise in virtually all creative efforts.

Missions are noteworthy because they provide a background for another way in which leaders exercise influence on creative people. Creative efforts by virtue of their novelty and ill-definition are uncertain ventures. As a result, the mental

simulation of the outcomes of various efforts, planning, is critical for the success of creative efforts, in part, because it promotes recognition of emergent opportunities, and, in part, because it promotes adaptive responses.

In keeping with this observation Arvey and coworkers found, in 1976, that planning and goal clarity were the principle dimensions underlying scientists' evaluation of their supervisors. More recently, in 2005, Marta and colleagues obtained measures of leader planning skills on a team creative problem-solving task. They found that leaders planning skills were strongly, and positively, related to team members' creative production, in part because these plans provide a basis for group structuring activities. Thus leaders planning behavior *vis-à-vis* mission accomplishment is a critical mechanism by which leaders influence creative people.

Not only must leaders define a mission, formulate plans, and appraise ideas with respect to this mission, they must also motivate their followers. In fact, many theories of leadership view this motivational function of leaders as critical. In the case of creative people, however, motivation is typically high due to the influence of professional involvement and the personal dispositions of creative people. Thus the problem confronting leaders is not building motivation but rather directing motivation toward the creative mission at hand.

One way leaders may influence motivation for creative work is by building followers' feelings of self-efficacy with regard to the creative work at hand. Thus, in 2002, Tierney and Farmer developed a model of creative self-efficacy. They found that creative self-efficacy was positively related to subsequent creative achievement. In another study along these lines, Jaussi and coworkers, in 2007, obtained self-report, survey, measures of creativity. They found that measures examining the creative self-efficacy and creative identity were positively related to creativity. These findings are noteworthy because they suggest that actions taken by leaders to build creative self-efficacy and creative identity *vis-à-vis* the mission being pursued, for example, expressing appreciation for the creative achievements or noting the unique skills the person brings to the mission, will enhance follower creativity.

Although leaders may exert direct effects on creative motivation indirect effects on creative motivation may also be exerted through climate. The climate contributing to creativity has long been of interest to scholars interested in creativity. Recently, in 2007, Hunter and colleagues conducted a meta-analysis of the relationship between measures of climate perceptions (e.g., perceptions of autonomy granted, support for creative work, and challenge) and subsequent creative performance. They found that climate measures were strongly positively related to subsequent creativity.

What should be recognized here, however, is that leader behavior is one of the critical variables shaping climate perceptions. In 2004, Amabile et al. provided evidence bearing on this ability of leaders to shape these climate perceptions. In this study, 238 knowledge workers assigned to 26 project teams were asked to complete a work diary. Peer ratings were used to assess each worker's creativity. Subsequently, these diaries were content analyzed to identify leader behaviors associated with environmental appraisals and affective reactions that might contribute to creativity. The obtained findings indicated that leader behavior was a critical variable shaping appraisals of

creative climate and affective reactions. These environmental perceptions and emotional reactions were, in turn, found to influence subsequent creative performance.

Not only can leaders influence peoples' perception of the climate for creativity, but also leaders exert indirect effects on climate through the team they establish to work on various aspects of a mission and the procedures they use in managing these teams. For example, leaders emphasis on intellectual problem-solving by teams, effective communication among team members, and exploration of the implications of ideas have all been found to contribute to team creativity. Leaders, however, may have another, perhaps more basic, effect on team creativity. More specifically, leaders identify the skills needed to exercise a mission and recruit individuals possessing these skills. Given the various studies indicating that team composition is a critical influence on creativity, leaders, by selecting and recruiting team members displaying a certain set of skills, may exert a profound influence on team creativity.

Influencing Organizations

Our foregoing observations have focused on how leaders exercise influence on creative people. Leaders, however, work in a boundary role position where they must manage relationships with the broader organization. In this case of the leaders of creative efforts, management, really leadership, with respect to the broader organization is of particular concern because organizations, based on costs, risk, and potential disruption tend to have an ambiguous, perhaps somehow negative, view of creative work. This observation led Mumford and colleagues in 2008 to argue that the effective leadership of creative efforts requires both an inward focus, a focus on the group, and an outward focus, a focus on the organization and the field.

Creative work in organizations is expensive and, without requisite resources, creative efforts tend to die. Because resources in organizations are allocated by top management teams, it is not surprising that Dougherty and Hardy found, in 1996, sustained top management support was critical to the success of creative efforts in the information technology industry. More centrally, in 2003, Hong, and coworkers found that top management support for creative efforts depended on engagement and contact. Thus the leaders of creative efforts must establish and maintain contact with top management teams taking actions intended to insure their engagement in creative efforts.

One implication of these observations is that leaders must 'sell' creative efforts to top management teams. This top management support is often obtained through project championing. In 1988, Howell and Higgins found, that the recruitment of project champions, politically skilled senior managers who are vested in the success of a project, is often critical to success of creative efforts. Thus the leaders of creative efforts must be capable of recruiting project champions and often will need to act as project champions.

In 2004, Howell and Boies examined, the key capabilities characterizing project champions. They obtained in matched pairs of champions and nonchampions involved in one, or more, of 28 technological innovations. Interviews with these champions and nonchampions bearing on their activities in

the innovative effort were content analyzed. Subsequent analysis indicated that project champions must both package and sell ideas. The basis for idea packaging and selling, however, lay in contextual knowledge and normative knowledge of the organization.

The Howell and Boies study is noteworthy for three reasons. First, it suggests that leaders of creative efforts must be effective sales representatives for the creative effort. Second, effective sales are based on a broader knowledge of the organization, its strategy and competitors, as well as the key leaders in the organization and their concerns. Third, leaders of creative efforts will need not only technical expertise but also expertise with regard to the organization and its mode of operation.

Not only must leaders of creative efforts have an understanding of the strategic and operating environment of the organization, creative work must be integrated within the organizational environment. The integration of creative work into the environment of organizational operations implies that leaders of creative efforts must be able to think strategically about the implications of work in their field for the effectiveness and success of the organization. This observation, in turn, implies that the leaders of creative efforts must be able to engage in strategic planning.

In 2008, Mumford, Bedell-Avers, and Hunter examined the key requirements involved in the strategic planning called for in the leadership of creative efforts. Broadly speaking, their conclusions indicate that a key activity required of leaders is the identification of the fundamentals to be pursued in creative efforts. The term 'fundamentals' refers to basic issues applying in a technical field which provides a vehicle for guiding creative work. Ultimately, the leaders of creative efforts must identify the fundamentals to be pursued with these fundamentals being used to develop expertise and absorptive capacity on the part of the organization. Thus the leader of DuPont Chemical Research Unit identified seven to ten fundamentals to be pursued by DuPont. What should be recognized, however, is that this identification of viable fundamental requires an understanding of both the technical field at hand and the organization as it operates with respect to this field. Thus the identification of viable fundamentals on the part of leaders will require integrative thought.

The need for leaders of creative efforts to identify viable fundamentals points to another skill likely to be critical for leadership of creative efforts. In 2001, Souitaris examined how the use of different information sources has related to new product development and fielding in manufacturing firms. He found that firms seeking various sources of external information (e.g., customer feedback, supplier feedback, competition monitoring, and technology monitoring) were more likely to both adapt and introduce new products. Thus the leaders of creative efforts must be engaged in ongoing environmental scanning – scanning that takes into account both the 'business' of the organization and developments within the technical field.

The leaders of creative ventures must not only identify fundamentals, but they must also make decisions about which creative efforts are to proceed to further stages of development. What should be recognized here however is that evaluation criteria differ as projects progress through different stages of development. Thus initial exploratory efforts may be

evaluated *vis-à-vis* knowledge produced while late stage fielding efforts are often evaluated with respect to product success. This observation is noteworthy because it implies that the leaders of creative efforts must be able to apply different evaluation strategies in decision-making depending on stage of development and the direct and indirect costs associated with the creative effort. Thus the leaders of creative efforts must not only possess requisite decision-making skills, decision-making taking into account organizational considerations, but they must also be able to apply these skills in a flexible fashion.

Our foregoing observations bring us to a final skill that must be possessed by the leaders of creative efforts. As projects move through different stages of development different problems will be encountered. Often these problems will arise from organizational blockades or constraints placed on creative efforts. At times, however, these constraints may arise from technical considerations. What should be recognized here is that when encountering blockades or constraints, creative people will look to leaders in attempts to remove these blockades. Under these conditions, the leaders of creative efforts must be able to find ways of working around these externally imposed constraints. In other words, they must be 'fast on their feet' bringing to bear adaptive, 'work arounds,' to blockades encountered. Thus the leadership of creative efforts will require leaders evidencing substantial adaptive capacity as well as the ability to recognize restrictions which can, and cannot, be worked around.

Leadership Capability

Taken as a whole, our foregoing observations indicate that certain actions taken by the leader with respect to creative people, an inward focus, and certain actions taken by the leader with respect to the organization, an outward focus, influence the success of creative ventures. By the same token, the complex set of actions required of leaders, they must define missions and they must sell, they must make decisions and provide compensatory evaluative feedback, and they must create a supportive climate and they must apply technical skills, suggests that the leadership of creative efforts is an inherently difficult and demanding venture. These multiple, conflicting demands, in turn, broach a new question – must leaders be creative?

At one level it is clear that creativity and leadership represent distinct phenomena. For example, creative people are often introverts. Leaders, in contrast, are often extraverts. Creative people are motivated by professional achievement. Leaders, however, are motivated by organizational achievement. Despite these manifold differences leadership does seem to require one critical aspect of creativity – leaders must be able to think creatively. Accordingly, in this section we will examine what is known about leader creative cognition examining points of similarity, and points of departure, from the literature on leader cognition.

Creative Thinking

Perhaps the most traditional method for appraising creative thinking is a person's performance on divergent thinking tests.

In 1998, Mumford, et al. administered a consequences measure of divergent thinking (an example question asks individuals to list what might happen if gravity was cut in half) to 1818 army officers serving in leadership roles ranging from second lieutenant (responsible for 30 individuals) to colonels (responsible for 2000 individuals). Responses to these questions were scored on domain specific performance attributes and attributes relevant to leadership, such as long-term consequences, positive consequences, and negative consequences. It was found that these domain specific measures of divergent thinking produced correlations in the 0.40 range with measures of leader performance such as attained rank, critical incident performance, and awards received (e.g., medals). Thus divergent thinking, at least when scored with respect to the performance domain at hand, seems to be related to leader performance.

Divergent thinking of course represents a measure of one process involved in creative thought. In a second study in 2000, Connelly, et al. used a modified think aloud procedure to obtain measures of the other creative thinking processes: (1) problem definition; (2) information gathering; (3) concept selection; (4) conceptual combination; (5) idea generation; (6) idea evaluation; (7) implementation planning; and (8) monitoring. Again, these measures were administered to army officers. It was found that effective process execution was positively related ($r=0.40$) to attained rank, critical incident performance, and awards received. Moreover, these processing skills evidenced growth throughout leaders' careers. Thus the critical processing skills held to enhance creative thought all appear to contribute to leader performance.

In still another study, by Vincent and colleagues in 2002, the researchers used this sample of army officers to examine the effects of intelligence, divergent thinking, and expertise on effective execution of these processes. Process execution was found to influence leader performance. Intelligence, divergent thinking, and expertise, however, influenced effective process execution. These findings are noteworthy because they indicate creative thinking processes influence leader performance even when other capacities are taken into account.

Creative thinking processes, however, may be executed based on a number of different knowledge structures – associational, schematic, and case-based or experiential. In 2007, Mumford et al. argued that leader cognition is typically developed from case-based knowledge. Case-based knowledge is particularly useful for leaders because cases provide models that guide action. By the same token, case-based knowledge structures are highly complex including information bearing on goals, causes, outcomes, restrictions, and contingencies. The complexity of case-based knowledge is noteworthy because it implies that the strategies employed in working through leadership problems may be different than those applied in other fields. As a result, while creative thinking is required of leaders, the strategies used in creative thinking may be specific to this domain.

Creative Thinking Strategies

In 2002, Mumford examined the cognitive strategies that contribute to creative thinking by leaders. These initial studies, primarily qualitative in nature, examined the thinking strategies employed by leaders responsible for historically

noteworthy social innovations such as Benjamin Franklin (e.g., public libraries, nonsectarian universities) and Frederick W. Taylor (e.g., efficiency studies, business management). Broadly speaking, the findings obtained in these qualitative studies indicated that creative thinking by leaders is often founded in case-based knowledge. More centrally, however, the findings emerging in these studies indicate that at least four unique strategies are evident in the creative thinking of leaders: (1) causal analysis; (2) forecasting; (3) network exploration; and (4) opportunistic integration.

In complex social systems critical causal variables guiding action are uncertain. Thus, analysis of causes embedded in cases and identification of causes to be manipulated is likely to be critical to effective leadership and creative thought. In a 2007 study intended to examine the influence of causal analysis to the solution of leadership problems, Marcy and Mumford trained undergraduates in causal analysis strategies likely to improve leader performance. For example, undergraduates were trained to think about causes having large effects or causes influencing the attainment of multiple goals. They found that causal analysis training resulted in the production of high quality and more original solutions to six social leadership problems (e.g., a bank merger, change in marketing strategy, and reorganization of a research and development unit). It was found not only that causal analysis training contributes to the production of higher quality and more original solutions to these leadership problems, but also that the effects of training were moderated by task conditions, for example, a deliberative versus implementation mindset, held to moderate causal analysis.

In another study along these lines that is currently in press, Marcy and Mumford asked undergraduates to work on an online leadership simulation task – decisions made as a university president. Objective performance scores were obtained as they worked on this task along with other measures reflecting attributes commonly held to underlie leader performance. Again, study participants were given training in causal analysis. Not only was it found that causal analysis training contributed to performance on the simulation task, but also such training resulted in the acquisition of stronger mental models for understanding the demands imposed by the leadership task.

One reason causal analysis is important to the creative thinking of leaders is that it permits better forecasting of the outcomes of various actions taken as a leader. However, forecasting also provides a basis for revising action plans – thus proving particularly important to leaders. In an initial study examining the impact of forecasting on creative problem-solving, Byrne, Shipman, and Mumford (in press) asked undergraduates to assume the role of marketing director developing a plan for advertising a new product. Participants were asked to generate ideas, forecast the implications of these ideas, and provide a marketing plan. Responses to the forecasting question were content analyzed by judges with respect to 27 variables (e.g., specificity of outcomes, considering obstacles, anticipating changes in restrictions). It was found that the extensiveness of forecasting contributed to the production of higher quality and more original advertising plans.

In another study along these lines, also currently in press, Shipman, and coworkers asked undergraduates to assume the role of principal of a new experimental school. They were

asked to prepare a speech to be given to students, parents, and teachers describing their vision for this new school under the assumption that effective vision articulation is critical to leader performance. Forecasts were obtained from an exercise presented prior to vision formation. It was found that the extensiveness of forecasts was positively related to the production of higher quality, more original, and more evocative vision statements.

One way leaders appraise their analysis of causes and their forecasts is by obtaining feedback from others. The need for feedback, however, implies that effective leaders may capitalize on their network of social relationships. In other words, they know the right person to talk to at the right time. These findings have led scholars to argue that the strategies leaders use in thinking about and exploiting social networks will also influence the quality and originality of the solutions they produced to leadership problems.

A fourth, although certainly not the final strategy, that might contribute to leader's creative thinking is opportunistic integration. Leaders encounter a variety of rapidly unfolding problems in the course of their day-to-day work. Accordingly, it seems plausible to argue that an explicit search for shared elements of these problems in an ongoing, opportunistic, fashion may represent an important influence on creative thinking by leaders. Although direct experimental evidence bearing on the merits of opportunistic integration in leaders' creative thinking is not available, qualitative studies provide some support for the potential value of this strategy. For example, in 2002, Mumford conducted a qualitative study of Franklin's social innovations. In many of these cases, for example, the establishment of fire departments, one sees a careful delineation of key causes. These causes, however, were events that Franklin encountered in his role as a newspaper editor. Thus it appears that the idea of establishing volunteer fire departments arose from opportunistic integration of these prior life events.

Conclusions

When one considers our foregoing observations with regard to the nature of creative leadership and the leadership of creative efforts two clear conclusions emerge. First, to lead effectively people must possess creative thinking skills. What should be recognized here, however, is the knowledge structures leaders apply in their creative thinking may not be identical to those employed in other domains. More specifically, leaders rely on case-based, or experiential, knowledge in solving problems that call for creative thought. Leaders' use of case-based knowledge, in turn, gives rise to a unique set of strategies that contribute to leaders' creative thinking. Clearly, research is needed to produce a more thorough analysis of these, and other, strategies that might contribute to leaders' creative thinking. In part, such research is useful because it might provide needed guidelines for the development of leaders' creative thinking skills.

Second, leadership does appear to make a difference with regard to the success of creative efforts. Leaders exert influence on these efforts through two mechanisms. One set

of mechanisms, technical skills, evaluation and direction, mission definition, planning and structuring, motivation, climate definition, and team formation, reflect a focus on the group doing creative work. The other set of mechanisms, championing, strategic planning, scanning, decision-making, and conflict management, reflect an outward focus where leaders must manage relationships with the organization.

What should be recognized here, however, is that leaders cannot treat inward and outward foci as separate, distinct, tracks. Rather inward and outward leadership activities must be integrated for leaders to exert positive effects on others' creativity. The need to integrate these inward and outward foci imply that creative thought will be required of those who lead creative efforts. We hope that the present effort will provide an impetus for a more thorough analysis of creative thought by those who lead creative work – for these are the individuals who will shape the world we all live in, not just today, but tomorrow.

Glossary

Effective productivity A subset of the total number of things created by an individual that have, according to some selective criteria, been assigned important intellectual or other value.

Novice effect The phenomenon in which entering a new discipline by changing fields appears to provide an individual with a new burst of creativity.

Persister A continuously creative individual or one who continues to be creative within a discipline beyond the usual age of other people in that discipline.

Polymath An individual who displays creative ability in multiple disciplines.

Swan song The final and often benchmark work created by an individual.

Ten year rule The observation that it takes about ten years of training before an individual can contribute creatively to a discipline.

Total productivity The total number of things created by an individual over a given period of time.

Worldplay The invention in play of an imaginary world, which a child or adolescent may document in multidisciplinary manner, thereby developing a wide range of creative skills.

Introduction to Life Stages of Creativity

Mathematician Leonard Euler, one of the most important and prolific mathematicians who ever lived, discovered his gift for mathematics when he was just a few years old and spent the rest of his life exploiting his talent. Amadeus Mozart and Pablo Picasso also discovered and developed their artistic talents at very young ages and focused their abilities single-mindedly on their professions thereafter. Conversely, Hans von Euler-Chelpin went to college to become an artist, got captivated by the science of color theory, switched majors to physical chemistry and became a Nobel prize-winning chemist. Fellow Nobel laureate (in Physiology or Medicine) Harold Varmus completed college as an English major and editor of the university newspaper before a trip to a scientific conference with a scientist friend opened his eyes to the possibilities of biomedical research. Having succeeded as a scientist, he switched gears again to become a successful politician, heading the National Institutes of Health. Yet another Nobel laureate, Roger Guillemin, traversed the opposite path, training as a physician, switching to physiological research, becoming captivated by the artistic potentials of early computer visualization programs, and finally leaving science to become one of the founders of electronic art. The engineer John R. Pierce managed his multiple interests concurrently instead of serially. Pierce invented satellite communications at Bell Labs while establishing a simultaneous career as a successful science fiction writer under the pseudonym 'J. J. Coupling.' In addition, he produced the first computer-synthesized music and, when he retired from Bell Labs, moved to Stanford University as Professor of Electronic Music.

These exemplars suggest that creativity may be expressed exclusively or dominantly in one way throughout an individual's life or in many different ways at different stages of an individual's life. Surprisingly little is known about life stages of creativity other than the waxing and waning of productivity within a single profession with age. This essay reviews the creativity-and-aging literature but also attempts to outline

how creativity (both personal and professional) may wander productively and effectively among and between disciplines over the course of a lifetime.

Types of Creative Productivity

It is easiest to study how a person's creativity changes over time within a single discipline, so we begin with this aspect of creative life stages. Creativity productivity, at least within specific professions, tends to vary with age in reasonably predictable ways. Two different types of productivity are often measured, one being 'total productivity' and the other 'effective productivity.' Total productivity is defined as the total number of professional creations a person generates during any given period of time. These creations can be books or articles published, paintings painted or exhibited, musical pieces composed, sculptures completed, novel processes patented, or widgets manufactured. The assumption underlying the measurement of total productivity is that every creation is of roughly equal value or importance as an indicator of creative thinking and energy. Effective productivity, in contrast, employs selective criteria to rate the value of the products. Not every painting by an individual is as good or as important (to the individual or to the art community) as every other, and a similar statement can be made of individual creations in every field. Effective productivity is a measure of the most important contributions an individual makes, and thereby separates the metaphorical wheat from the chaff. Effective productivity can be measured by varied means including number of historical references to a creation, whether it is still exhibited, performed, or used (i.e., whether it has stood the test of time), its 'impact' (e.g., how many people cite the work over a given period of time), and so forth.

The kind of contribution, as well as its quality, is also important in considering creative productivity. The creative process has many facets and an individual may be active in

one facet at one time in her career and switch to another facet later on. A composer, for example, may invent a new musical form or a new tonal scale early in his career (the innovation) but produce the most developed piece using that innovation only late in his career (the exemplar). Thus, it can be important to distinguish between the age at which some types of creativity (such as problem-recognition and inventiveness) are manifested and the age at which other types (such as applications or the production of exemplars) come to the fore.

Various trends in total productivity and effective productivity characterize different disciplines. Those in mathematical fields such as physics and economics are often told, with some justification, that if they have not made an important contribution by the time they reach age thirty, they never will. The mathematical sciences are, it is said, a young person's game. The same is said to be true of music and poetry.

Experimental and experiential disciplines, however, often have a very different age profile. Among experimental biologists and empirical economists, for example, major contributions are most often made during a person's fifties. While the invention of new musical forms and new types of art are usually made by young artists, the greatest works of most composers, playwrights, and painters are usually among their last. These observations suggest that there is a difference between creativity that is highly rule-bound and involves mainly theoretical or conceptual insight and creativity that involves acquisition of experience and extensive integration of facts and ideas.

Age and Creativity

Nearly all of the literature that exists concerning creative productivity, whether total or effective, as a function of age agrees on several basic points. First of all, children are often personally creative, but very rarely professionally creative. Mozart, it is true, began composing before he was ten, but it has recently been demonstrated that his pre-teen compositions are mainly copies, sometimes with small modifications, of the compositions of other musicians. They have little or no originality. Picasso certainly produced many drawings and paintings as a child (as do many children), but none of these break with traditional subjects, materials, or forms. What set Picasso's artwork apart from that of the average child was the range and excellence of his technical mastery.

All creative individuals must acquire technique and achieve content mastery. Creativity, in this regard, tends to be discipline-specific. Chase and Simon suggested that content mastery requires, in general, about a ten-year apprenticeship before significant contributions can be made by an individual (a concept later termed the 'ten year rule' by Hayes, Weisberg, and others). Children and adolescents are usually, though certainly not always, exposed to many possible creative activities that range from arts and music to literature, poetry, acting, dancing, crafts, sciences, and mathematics. Depending on opportunity, temperament, and reinforcement, they may choose to explore some or all of these within formal and/or informal educational environments or as part of organized or self-choice play. Creative skill sets developed through education and play often influence the choice of one or more professions. Because

childhood and adolescence are periods of creative exploration, most people do not begin serious training for a creative career until they are young adults, with the result that disciplinary creativity is seldom demonstrated until maturity. The major exception are prodigies, children with developed talents at near-adult levels. The younger people begin formal training for a profession, the earlier they are likely to be able to contribute to a field. For this reason, prodigies such as Mozart and Picasso had a jump on other people who begin to learn their discipline at a later age. There is no evidence, however, that learning a discipline at a later age alters the probability that an individual will make a creative contribution. Indeed, most prodigies do not become creative contributors to their disciplines and numerous 'late bloomers' exist (see below).

Because there is an extended period of skill and knowledge acquisition in every field, creative productivity, in the sense of effectively novel innovations, begins in nearly all disciplines no earlier than the teens and twenties. Total creative productivity within individual professions rises to a statistical peak sometime between the thirties and fifties for most individuals in most disciplines. Productivity then declines with age. Overall, the form that creative productivity takes can best be described by what is often known as a 'normal' or 'Poisson' distribution (see Figure 1).

Women have, historically, been less productive than men in terms of professional activities – undoubtedly due to social and cultural factors – but the productivity of women as they age follows exactly the same trend as that observed in men. Indeed, choice of discipline has a greater influence on productive aging than gender. People in the arts and literature have longer effective careers than the typical person in the sciences, for example.

The most comprehensive study of these phenomena was undertaken by Harvey Lehman in his 1953 book *Age and Achievement*, which remains a classic. Lehman focused most of his attention on effective, rather than total, productivity. Most studies subsequent to Lehman's have validated his general findings.

Lehmann clearly demonstrated that although the effective productivity curve is similar for nearly all creative endeavors, it begins, peaks, and tails off at different ages by discipline. On the one hand, he found that both mathematics and poetry are young peoples' games, with significant contributions beginning in early teenage years and peaking in the mid-twenties. Novel writing, playwrighting, and psychology, on the other hand, are the domain of more mature individuals, with effective productivity peaking in the mid-forties. Bridging these two opposing patterns, the productive pursuit of chemistry, as measured by the overall number of papers published and the most significant papers published, begins to manifest in the scientists' late teens, peak in their thirties, and tail off toward nil at around age 70. Similarly, productivity in the biological and medical sciences tends to begin in the early twenties, peak in the late thirties or early forties and tail off more slowly thereafter. Peak total productivity is reached in art and architecture in the late thirties and early forties. In these fields a similar peak is seen in effective productivity, but because effective productivity tends to be spread out chronologically much more evenly than overall productivity, paintings by 45-year old artists and 80-year-old artists are about equally likely to be considered exemplary.

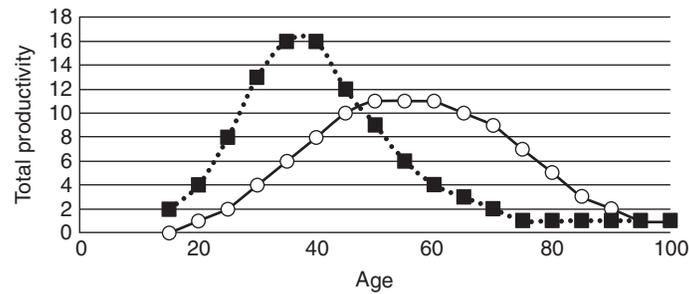

Figure 1 'Total productivity' is the number of things an individual creates (e.g., paintings, compositions, poems, mathematical proofs, scientific papers, etc.). Total productivity curves for all disciplines follow a general Poisson or normal distribution. In very few fields is it possible for an individual to make a creative contribution to the profession before the later teen years because it takes time to master content and skills. Some fields that are highly rule-bound with very clear criteria of excellence, such as mathematics, physics, dance, and poetry tend to have peaks at early ages, while other fields that rely more on experience and judgment, such as biology, playwrighting, history, and literature, tend to have peaks at middle age. For most people, total productivity declines with old age.

Lehmann looked at productivity measures in other disciplines such as business and politics as well, showing that peak incomes tend to be achieved at around age 60 and highest political office in a person's seventies. It is important, as Lehmann himself points out, to adjust all data concerning productivity at older ages for the increase in mortality that occurs with increased age. While mortality has little effect on productivity curves for disciplines in which the peak is reached very young, it has a very significant effect on disciplines in which the statistical peak is reached in later years. For example, the total number of 85-year-old millionaires is not much higher than the number of 25-year-old millionaires, but the probability that an 85 year old will be a millionaire is many times greater than that of the 25 year old simply because there are many 25 year olds in the population and few 85 year olds. Thus, an increasing number of studies have shown that *age-adjusted* productivity tends to remain reasonably constant in many fields. The phenomenon of apparently decreasing productivity with age can partially be accounted for by decreasing numbers of practitioners at older ages. Those who continue to create into old age tend to be very effectively productive. Those who are not effectively productive tend to leave the field altogether.

Indeed, Dean Keith Simonton, foremost expert on creativity and age, has noted what he calls the 'swan song' phenomenon among composers, which Lehman documented in other disciplines as well but without noting its importance. The swan song phenomenon consists of elderly individuals, often those facing death, who create their final gift to humanity. As with Mozart's *Requiem* or Beethoven's *Ninth Symphony*, this penultimate creative effort is more often than not remembered as the individual's most important. Lehman's and Simonton's effective productivity curves therefore show a significant upturn past the age of 70 in many disciplines. These works are rarely innovative, in the sense of introducing novel concepts or techniques, but often represent the best exemplars of a person's mature work.

Some loss of productivity with age appears, however, to be real. Studies of individual research careers in science and technology have clearly shown that total productivity peaks in the early decades and tends to diminish with age. Thomas Edison, for example, had his name on 1093 patents. He filed his first patent at the age of 20, reached the peak of his productivity at

the age of 35 when he filed some 50 patents in a single year, went through a period in which he filed no patents during his late forties, and then reached two plateaus at about 10 patents per year during his fifties and early sixties, with a handful of patents per year through his eightieth year. He filed his last patent at the age of 82. Edison's most important patents in terms of their long term impact on society fell mainly during the peak of his total productivity. Many studies have confirmed that Edison's career is typical of most scientists and inventors. Economists and policy makers are justifiably worried that as the general age of the scientific population increases over the next few decades, both real and effective productivity overall will drop.

Quantity of output is not directly related to quality, although limited evidence suggests that longer creative life-spans may result in a greater probability of producing important work. While Edison was the most prolific inventor in American history, and Picasso the most prolific artist in history, many prolific individuals are almost unknown. For example, the most published computer scientist in the world today has, according to citation analysis, never published a paper considered by his colleagues to be of any value. Georges Simenon published over a thousand novels, but only a handful are considered by critics to be worth reading. Similarly, the most prolific composer of symphonies – one Melchior Molitor (1696–1765) – left us 170 of these pieces (and hundreds of others), none of which are part of the modern orchestral repertoire. Franz Joseph Haydn, on the other hand, wrote 108 symphonies, many of which continue to be played today.

At the other end of the productivity scale, Joseph Heller, author of the classic *Catch 22*, experienced a 20-year period of writer's block following the extraordinary success of his novel. Borodin produced only a handful of orchestral and chamber works, yet all of these remain in the modern repertoire. Gregor Mendel's total output was a mere seven papers written in a ten-year period as a young man, yet these papers sufficed to create a revolution in genetics. Thus, effective productivity can almost be completely divorced from total productivity. In fact, one study of scientists demonstrated that most scientists have very little impact on their field as measured by citations to their papers; the impact of the remaining scientists was mainly limited to two or three papers published within a five year

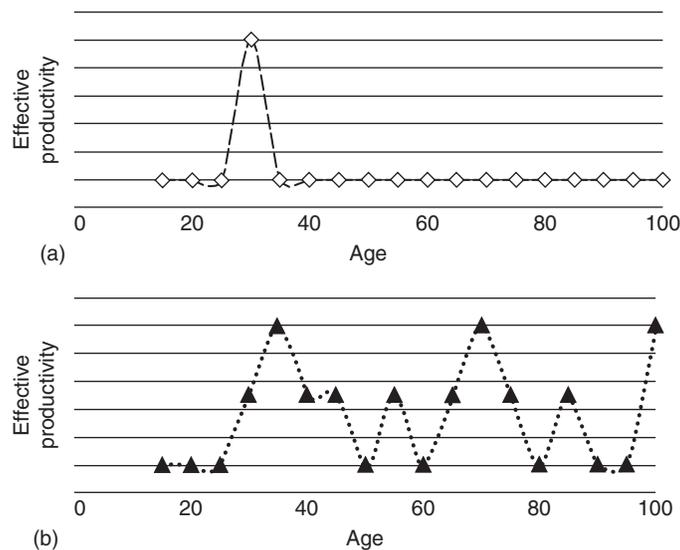

Figure 2 'Effective productivity' is the measure of the most important (measured socially or professionally) things an individual creates. Effective productivity is rarely correlated directly with total productivity (Figure 1). Most creative people have effective productivity profiles that look like A (the upper portion of the figure), in which there is a single spike of effective products appearing within a short space of time (a few years). 'Persisters,' polymaths, and field changers, in contrast, often have effective profiles more like B (the lower portion of the figure), in which effective products appear in short, repeated bursts as new styles, techniques, subjects, or fields are explored (see discussion of the 'novice effect').

period of time; while a very small minority of scientists, comparable to Haydn in music, maintained a very high output of very high impact papers throughout their careers (see Figure 2).

Not all creative people remain within a single discipline, however, which means that the stages they proceed through can differ significantly from those of people who do. Chemist-composer Aleksandr Borodin provides a good example. His total output in both fields was low, yet it was of uniformly high quality and impact. It is clear from reading his biographies that while each vocation interfered with the total productivity of the other, yet each activity in some ways also fed the other. This multidisciplinary interaction is particularly notable in the career of biologist Desmond Morris, who has successfully integrated three vocations: research ethologist, science popularizer, and Surrealist painter. Current approaches to measuring productivity would make Morris' career appear in any single vocation as a series of punctuated bursts of activity, whereas an examination of his total and effective productivity across all his activities shows it to be very high and continuous. The metamorphosis of the child-actress Shirley Temple into international ambassador Shirley Temple Black presents similar difficulties. Her productivity as an actress and as an ambassador are totally distinct in both nature and time, yet she was never uncreative. Further theoretical and empirical research will be needed to properly come to terms with such multifaceted people.

Exceptions to the General Trends

The examples of Borodin, Morris, and Temple Black lead to the conclusion that exceptions exist to the general lifetime productivity trends. As the Introduction suggests, such exceptions are fairly numerous and provide interesting insights into the trans-disciplinary factors at work in creative lives. The most notable

of these exceptions are prodigies, late-bloomers, 'persisters,' polymaths, and field-changers.

Prodigies are people who exhibit an unusually developed ability at an unusually young age. They are clearly recognized in fields characterized by very rigid rules or techniques such as musical performance and composition, chess, mathematics, logic, and sometimes poetry. Children excelling in these fields demonstrate technical mastery on a par with professional adults. Some prodigies also demonstrate productive mastery in the sense of creating new compositions or proofs even before reaching adolescence. The existence of prodigies in other fields such as art and literature is more controversial, especially where technical and/or productive mastery tends to be experience- rather than rule-based. Some consider Shirley Temple and Mickey Rooney to have been prodigious talents in the field of acting; they certainly performed with and for adults, as many musical and chess prodigies have done. It is less clear that early talents in the field of literature qualify as prodigies. Although more than a few people have written novels by the time they are sixteen, as both Jane Austen and Georges Simeon did, most of these remain unpublished juvenilia – without an adult audience and not competitive with adult creators. *Eragon* (2003), a fantasy novel written at age 15 by Christopher Paolini, is the rare exception. In general, literary writing, like great art, requires matured experience. For much the same reason, prodigies also seem to be absent from the experimental sciences, medicine, history, philosophy, psychology and other humanities in which the peak age for effective contributions is in middle age or later.

No matter the field of endeavor, status as a prodigy does not correlate with overall creative success. Lifetime productivity among prodigies ranges the gamut from extraordinary (e.g., Mozart, Herbert Spencer) to nearly nil. For example, in 1910 Harvard University was home to five undergraduates under the age of 16, all of whom had been recognized as infant prodigies

in music or mathematics: W. J. Sidis, A. A. Berle, Cerdric Wing Houghton, Roger Sessions, and Norbert Wiener. Sessions became an important and productive composer. Wiener, after many vicissitudes, moved from mathematics to writing and publishing and eventually founded the new science of cybernetics (feedback control systems) in middle age. Berle and Houghton went on to have unremarkable careers. And Sidis, a brilliant mathematician, became one of the youngest professors in the country – only to experience a total collapse shortly afterwards. He spent the vast majority of his life in penury, unable or unwilling to hold a job.

A more recent study of Science Talent Search winners, many of whom are extraordinary in publishing original scientific papers or obtaining patents as high school students, shows similarly diverse outcomes. Some of these young scientists go on (at unusually high rates) to become Nobel Prize winners, but over half leave science during college. Thus, in terms of their future *scientific* productivity, their early, near-prodigious work is actually of lower predictive value than is simply being a science major in college. Unfortunately, there have been no follow-up studies of Science Talent Search winners to determine whether those who move out of science end up being productively creative in other disciplines such as the arts, music, literature, etc., or whether these individuals opt for noncreative jobs.

Late-bloomers are at the opposite end of the age spectrum from prodigies. They are people who make a creative ‘splash’ during their middle or later years, not because they have struggled for decades to become successful, but because they do not begin a creative career until an unusually advanced age. Examples in the arts include Vincent Van Gogh and Paul Cezanne, who only took up art in their thirties and forties; Louise Nevelson, who came to sculpture in her forties after trying and abandoning half a dozen other arts; Grandma Moses, who did not take up painting until age 76 and continued to produce paintings till her death at 100; and Laurence Sterne and Edith Wharton, who began writing novels in their forties. Even in science a few late bloomers have risen to stardom, including two Nobel Prize winners, William Henry Bragg, who did his first original experiment at the age of 40, and Sir Francis Crick, who received his Ph.D. at the almost unheard of age (especially for a physicist) of 36! As would be expected in light of the ‘ten year rule’ – and given delayed start – the age at which late-bloomers begin to make substantial creative contributions to their discipline is usually significantly greater than colleagues who found their vocation at a younger age. Crick, uncharacteristically in this regard, was still a scientific novice working on his doctoral dissertation at the time he and Watson solved the structure of DNA.

Late-bloomer or not, Lehmann’s, Simonton’s, and Root-Bernstein’s research shows that most creative people tend to make their most important contributions in a single short burst of important work. ‘Persisters’ represent one of the most interesting exceptions to this general trend. Persisters make high-impact (effective) contributions to a discipline over an entire lifetime. Playwright George Bernard Shaw exemplifies the type. He died at age 94 having completed several well-known plays in his nineties. Stanley Kunitz, twice Poet Laureate of the United States, was also an enduring influence on his contemporaries, writing and publishing well-received work from the

1930s until 2005, the year before his death at nearly 101 years of age. Other examples include Pablo Picasso, who was still innovating in his eighties, and Guiseppe Verdi, who composed some of his best operas in his seventies and eighties. Dancer-choreographer Martha Graham, who came to dance at the relatively late age of 22, continued to perform her own dances up until the age of 76; over the next 20 years, she choreographed ten additional ballets, composing her last piece at the age of 95. Similarly, Felix Horowitz was still performing virtuoso piano pieces in his nineties, as was jazz pianist Eubie Blake. The Romanian pianist Cella Delavrancea (1887–1991) gave her last public recital at the age of 103. And Elliot Carter, mentioned in the Introduction, is still composing at 101.

Persisters also exist in mathematics, the sciences, and engineering, subjects in which most practitioners lose both total and effective productivity by middle age. Henri Poincaré and Paul Erdos are unique among twentieth-century mathematicians in having made a major contribution to every major area of mathematics, an achievement that, not surprisingly, took them each a lifetime. Mathematician Donald Coxeter produced some of his greatest insights into the geometries of infinite spaces during his eighties and nineties, continuing to present original papers at conferences until he was 97. Perhaps the most amazing example of a scientific persister is the eighteenth century mathematician Leonard Euler, a man so prolific that his novel contributions were still being put to press for the first time 50 years after his death. His total output consists of more than 75 volumes of original mathematics.

Analysis of persisters in mathematics and the sciences has yielded the unexpected observation that such people tend to be either polymaths or field-changers. Polymaths excel in more than one field, often simultaneously; field-changers commit themselves with great intensity to one discipline at a time, but only for a decade or so before moving on to another. Several studies have shown that the concurrent activities pursued by polymaths increase overall individual productivity as well as the probability of achieving a high degree of effective productivity. Thus, scientists who work on several research projects concurrently, have multiple consulting jobs, and are actively engaged in one or more creative hobbies far outstrip their more focused colleagues in measures of both total and effective productivity.

Field changers also tend to have greater overall and effective productivity compared with individuals who stay within their area of expertise. Many very successful scientists have stated that they change fields regularly and on purpose to stimulate new ideas. Similar strategies are apparent in the lives of continuous innovators in the arts. Picasso changed styles or moved into new media such as linoleum prints, sculpture, lithography, ceramics, and so forth about every five years. In the sciences, Nobel laureate Luis Alvarez took the unusual step, after an extended period during which he had no interesting research ideas, of apprenticing himself to two of his graduate students in order for *them* to teach *him* the intricacies of a newly emerging field about which he knew nothing. As he recounted in his autobiography, creative energy and creative ideas both returned. This phenomenon has been termed ‘the novice effect.’

The principle behind the novice effect is that a person is ‘allowed’ only one fundamental innovation or conceptual

insight per area of expertise or per artistic style and that this insight is most likely to occur within a decade of entering the field. The novice effect therefore helps explain why mathematicians must make a breakthrough by the time they are thirty or lose all hope of doing so. It also helps explain why major innovations in the arts, such as Arnold Schoenberg's 12 tone scale or Wassily Kandinsky's nonrepresentational art, are usually made by youngsters while exemplary works are the products of maturity.

The novice effect has its corollary: the fact that a person has made a creative breakthrough does not predict future creativity *within the same field of endeavor*. Past creativity demonstrates only that a person has the *ability* to discover or invent. Indeed, analysis of the careers of scientists who made a notable contribution in one area and stayed within that specialty for the rest of their careers showed that these individuals never made another significant breakthrough as measured by peer evaluation or citations to their work. This failure to be *continuously* effectively productive occurred even for scientists whose total productivity remained high and despite the receipt of awards such as Nobel Prizes that gave them high professional visibility. Only scientists who had multiple, concurrent research projects, or who regularly changed fields, showed continuous *effective* creativity (see Figure 2).

Toward a Typology of Creative Life Stages

One of the problems facing those who study the life stages of creativity is how to integrate the various types of data summarized above. Such an integration requires taking into account the 'ten year rule' for acquisition of skill and knowledge before creativity is likely to be manifested; the observation that both total and effective creative productivity obey Poisson distributions that peak at representative ages dependent on the profession and the conceptual or empirical nature of the work; and the various exceptions to these general rules that involve the

novice effect, persists, late bloomers, polymaths, and other unusual manifestations of creativity. We suggest a typology consisting of six more or less distinct trajectories through a creative lifetime: (1) early specialization, single mature focus; (2) early breadth, mature focus; (3) early breadth, mature breadth; (4) early specialization, mature breadth; (5) early specialization, serial mature foci; (6) early breadth, serial mature foci (see Figure 3).

1. *Early specialization, single mature focus.* Early specialization followed by a single mature focus is a common pattern for creative people. Euler, Mozart, and Picasso provide examples. Each was recognized as having a great deal of talent early in childhood, was given very focused education to develop that talent, and chose to remain throughout his creative career within the discipline for which he had been trained. This type of focused education and professionalism is very common among dancers, composers, musical performers, mathematicians, and other practitioners of disciplines with well-defined content, rules and techniques in which prodigies can be identified.
2. *Early breadth, mature focus.* Many creative people do not manifest early talent, finding their true calling only after exploring several possibilities. Composer Elliot Carter is a good example. Although he began playing an instrument as a child and displayed an active interest in composing, he went to university as an English major. Even after obtaining his Ph.D. in music and a job as a composer for an opera troop, he took a position as a professor at St. Johns College in Annapolis teaching math, physics, and Greek literature as well as music. Only in his early thirties did he devote himself fully and completely to musical composition. A similarly broad-to-narrow path characterized the life of Lejaren Hiller, Jr. as well. Hiller found himself torn between music composition and chemistry, taking courses in both during college. Even while obtaining his doctorate in chemistry, he took music composition classes with eminent

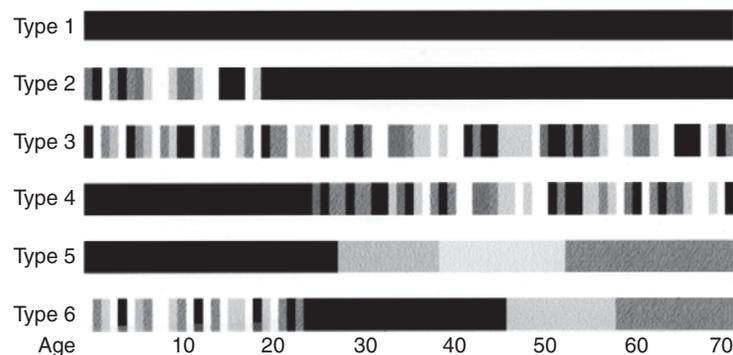

Figure 3 Six typologies of creative life stages. These typologies are generalized abstractions based on schematic representations of real creative production records first published by Root-Bernstein, Bernstein, and Garnier (1993). The different shades of black, white, and gray represent different types of creative activities that may be spread across a variety of arts, music, literature, sciences, etc. Type 1 represents people who specialize in developing one major talent early in life (e.g., prodigies) and successfully exploit that talent exclusively for the rest of their lives. Type 2 individuals explore a range of different creative activities (e.g., through worldplay or a variety of hobbies) and then settle on exploiting one of these for the rest of their lives. Type 3 people are polymathic from the outset and manage to juggle multiple careers simultaneously so that their creativity pattern is constantly varied. Type 4 creators are recognized early for one major talent (e.g., math or music) but go on to explore additional creative outlets, diversifying their productivity with age. Type 5 creators devote themselves serially to one creative field after another. Finally, Type 6 people develop diversified creative skills early and then, like Type 5 individuals, explore these serially, one at a time. Note that each of these patterns represents very successful types of people. No value judgment is intended by the ordering or numbering of these types or in the ways that they are represented.

composers such as Milton Babbitt and Roger Sessions. His first job as a dye chemist for Dupont involved modeling chemical processes with the first industrial computers; he soon began computer modeling of musical composition as well. Cultivating this unique combination of interests as a professor of chemistry at the University of Illinois, he also earned a masters degree in music. At the age of 34 he finally quit chemistry and, as founder of the Experimental Music Studio at the University of Illinois, committed himself fully and exclusively to music. He is now recognized as the inventor of computer-generated composition.

Many creative people have had to make the kinds of choices Elliot and Lejaren made. The Nobel prizewinning physicist Max Planck was torn in college between becoming a professional pianist, an economist, or a physicist. He gave up economics and kept music as his avocation. Similarly, the internationally prominent writer Vladimir Nabokov evinced an equal passion for literary art and for the study of butterflies. Early in his career he actually worked at the Harvard Natural History Museum classifying Lepidoptera; once he obtained a position as a professional writer, however, he relegated his butterflies to avocational status.

3. *Early breadth, mature breadth.* Sometimes the breadth exhibited by a young Carter, Hiller, Planck, or Nabokov does not resolve itself into devotion to a single profession, but rather leads to multiple simultaneous careers. An extraordinary example is Sofia Kovalevskaya, a late nineteenth-century Russian mathematical prodigy who became a world-renowned mathematician, and was also recognized by her early twenties as one of the most significant poets and playwrights of the period. Kovalevskaya produced mathematical papers and treatises along with poems and plays until she died prematurely of influenza at the age of 41.

Such dual careers are not uncommon historically. The inventor George Washington Carver learned as a child how to knit, crochet, make lace, weave, sew, draw, and carve – all of which served him well in his profession. He was also a painter throughout his life, winning a number of prizes at international art shows such as the Chicago World's Fair. This talent also held him in good stead as an inventor, for one set of inventions involved devising new materials for the making of oil paints and their pigments which he first used in his own paintings.

4. *Early specialization, mature breadth.* Sometimes creative individuals are recognized and groomed early for a particular talent, but find the time and inclination to branch out after they have established reputations in that primary field. A good example is the physicist Richard Feynman, who exhibited extraordinary mathematical ability as a child. Only after he had established an international reputation as a physicist did he begin to 'play' (his word) with a wider range of other activities, some within science and some outside of it. Within science, he constantly changed fields, explicitly employing the 'novice effect' to stimulate new creative ideas. During his late twenties, he took up bongo drumming, achieving near professional skill by his forties. During his forties, he took up painting, and acquired sufficient skill to sell his artwork under a pseudonym during his fifties and sixties. He told one interviewer that he would

consider becoming a professional artist if he ever ran out of scientific ideas. He never did.

Gordon Parks had a similarly diversifying career. He first came to prominence as an internationally recognized photographer. By his late thirties and forties, however, he began to branch out into multiple, concurrent careers as a musician, composer, poet, novelist, journalist, activist, film director, and painter. Many of these endeavors involved a synthesis of talents; in 1969, at age 57, he stormed the gates of Hollywood, writing the screenplay adaptation of his autobiographical novel, *The Learning Tree*, composing the film score and directing the film. He parlayed this success into a movie career as director of the 'Shaft' movies, yet also managed to perform and record original musical compositions, to choreograph a ballet, publish poetry and several novels, and at the end of his life exhibit oil paintings.

5. *Early specialization, serial mature foci.* It is probably more common for people to specialize serially than to attempt multiple careers simultaneously. Nevil Shute, the best-selling author of *On the Beach* and *The Far Country*, was actually trained as a mechanical engineer and spent the first 20 years of his professional life designing aircraft and other mechanical devices. He turned to writing professionally only in middle age. As noted above in the cases of Harold Varmus (literature to biomedical research) and Hans von Euler-Chelpin (art to physical chemistry via color theory), some people only discover by chance where their interests lie and make major changes in the nature of their professional training.
6. *Early breadth, serial mature foci.* Some people take creative career paths that mediate between the extremes of complete specialization and simultaneous multiple careers. These people often develop a broad range of talents as children and young adults but choose a single career path in order to obtain financial or personal security; achieving success they then set out to find new challenges. Roger Guillemin, who was mentioned in the Introduction, provides an example. Guillemin was raised in a well-to-do family in France and given every educational advantage, including a good foundation in drawing, painting, and music, as well as in literature and the sciences. He chose to train as a physician, but later became a biomedical researcher. Throughout his career, he continued to enjoy music and to paint in watercolors occasionally, but merely as pastimes. When he obtained a computer capable of performing drug design for his research, he recognized the potential of the programs to also design art and began toying with the possibilities. After an illustrious scientific career culminating in a Nobel Prize, he retired to become one of the founders of electronic art, which now consumes the greatest part of his creative passion.

How Common Are Different Typologies of Creative Life Stages?

How common are these different typologies of creative life stages and strategies? Unfortunately, no formal studies exist to answer this question. No reliable studies have been performed to estimate the number of prodigies that exist in any discipline. No reliable studies exist to describe the distributions

of creative *potential* (as opposed to IQ and other standardized test scores) during childhood and adolescence. We cannot, therefore, estimate with any degree of confidence how many precollege individuals actually exhibit or develop creative talent, whether singly- or multiply-focused.

Various studies, however, suggest some generalizations that may eventually prove to be useful. Prodigies are, by definition, rare. Some research has been put into identifying prodigies and studying their development and potential; Feldman, in particular, clearly demonstrated that prodigious talent requires a co-occurrence of talent, desire, and opportunity that is not always present. Gagne argued that as many as 30% of the student population displays evidence of at least 'mild' giftedness in some type of academic endeavor, but it is not known how many of these develop or train that talent, or do so to the relative exclusion of other pursuits. Almost nothing is known about children who are multiply-talented. It is therefore difficult to say with certainty how great this pool of polymathic children may be. A close look at worldplay, a very complex form of make-believe among children and adolescents, suggests, however, that this pool may be salient.

Worldplay, which involves the invention of an imaginary world sustained over months or years, may in fact serve as a surrogate marker for generalized creative ability. In their most elaborate forms, the imaginary worlds of childhood resemble the Middle Earth that J. R. R. Tolkien explored in *The Hobbit* and *The Lord of the Rings*, replete with imaginary peoples, languages, lands and landscapes, maps, histories, literatures and all the rest. Most childhood play worlds are obviously less developed than this, yet it is not uncommon for the young creator to explore one or even some of these elements in combination: invented languages and imagined people actualized in oral or written stories, perhaps; or make-believe ecologies and geographies visualized in drawings and maps; or whole invented countries with political histories painstakingly recorded in play newspapers and ersatz government documents. The Brontë siblings' amply documented play in Glass Town, Angria and Gondal is perhaps the best known example on record.

Four important points emerge from the study of worldplay. First, somewhere between 3 and as many as 12% of the population may have invented an imaginary world in childhood, so the creative nurture it provides affects a conspicuous proportion of people. Second, that invention provides sustained experience with creative behaviors and creative process. Third, this experience tends to be trans-disciplinary, involving skills and interests that cut across the arts, humanities, social sciences, sciences, and technologies. Fourth, and finally, the creative behaviors learned in childhood worldplay appear to transfer to mature professional endeavors. A population of creative adults invented imaginary worlds in childhood at a significantly higher rate than average college students. The Brontë sisters parlayed their worldplay experience into mature creative impact as novelists. Connections between childhood worldplay and mature creativity are also evident for other individuals mentioned above, viz. Morris, Tolkien, and Paolini. In sum, there may be at least as many young people building general creative capacity for mature endeavor through free choice forms of complex play as there are prodigies preparing more narrowly for particular creative vocations.

Studies of creative adults also confirm that early breadth of creative activities can be just as useful a form of training as narrow specialization. A study of Nobel Prize winners in literature, for example, found that about 35% had an adult avocation involving a visual art, most often drawing or painting, and most of these had begun this avocation as a child or adolescent. Some of these polymathic individuals, such as Hermann Hesse, Rabindranath Tagore, Derek Wolcott, and Gao Xingjian, have maintained second careers as visual artists. Another 24% of literary Nobel laureates had formal training in college or beyond as scientists, engineers, mathematicians, or physicians, and were actively engaged in both writing and another profession concurrently. Thus, at least half of all literary laureates have had a serious, often professional, interest in some discipline other than that in which they have been most creative, suggesting that breadth of interest may be beneficial to building creative capacity and certainly is not detrimental to it.

Studies of Nobel prizewinners in the sciences yielded similar results. There is a highly significant correlation between success as a scientist (as measured by election to the British Royal Society, the US National Academy of Sciences, or receiving a Nobel Prize) and actively maintaining one or more arts, crafts, musical, or literary avocations as an adult. On average, less than one-sixth of average scientists have such avocations, while on average almost every Nobel laureate does. As noted above, some of these eminent scientists, such as Guillemin, have second careers as artists, or, in the case of fellow Nobel laureate (chemistry) Roald Hoffmann, as poets and playwrights. Such data suggest that examining only the professional productivity of very creative individuals often misses a very significant fraction of their creative output. Quantifying total creative output across life stages, especially when it ranges across several disciplines, remains a challenging problem.

Summary and Conclusions

In sum, there are many productive ways to navigate the life stages of creativity, each of which requires different strategies and each of which poses a different set of obstacles and opportunities. Creativity need not be limited to a single discipline though it certainly can be. Understanding one's personal creative style, range of talents, and opportunities for development can help one to navigate the stages most productively and effectively.

Glossary

Categorical statement Statement of presumed fact.

Categorical syllogism Argument containing a major premise, a minor premise and a conclusion, each of which is a categorical statement.

Conditional statement Statement that is in, or can be put in, the form *If A then C*, where *A* and *C* represent *antecedent* and *consequent* respectively.

Conditional syllogism Argument containing a conditional statement as its major premise, and a minor

premise and conclusion, both of which are categorical statements.

Deduction Inference based on rules of logic.

Formal argument Argument expressed in a standard form, such as a categorical or conditional syllogism.

Induction Inference based on generalization from a sample to all members of a set.

Informal argument A set of claims, expressed informally, that are intended to establish the truth or plausibility of a conclusion.

Creative thinking is often contrasted with critical thinking. The former is generally seen to be relatively unfettered by logic or rules of any sort, while the latter is considered to be more logical, analytical and rule-based. In view of this distinction, which is widely endorsed among students of human cognition, why should there be a chapter on logic and reasoning in a book on creative thinking? The answer is that each kind of thinking needs the other to complement what it contributes to intellectual activity; either, by itself, is an incomplete story. Creative thinking is responsible for the generation of ideas and the invention of new processes; critical thinking is needed to evaluate those ideas and processes. The importance of each type, or aspect, of thinking is clear. Apart from the generation of new ideas, progress would not be possible; but not all ideas that are generated are of equal worth, and efforts to implement them all would produce only chaos, thus the need for critical evaluation. Individuals may differ with respect to the degree to which their thinking is characteristically more creative or more critical, but effectively intelligent living requires a modicum of both. The focus of this essay on logic and reasoning is intended to complement, to some degree, the emphasis of this encyclopedia on creative thought.

What Is Logic?

The item on *formal logic* in Runes's classic *Dictionary of Philosophy* goes on for more than ten double-column pages with very small print. It has nine major section headings: The propositional calculus; Hypothetical syllogism, disjunctive syllogism, dilemma; The functional calculus of first order; Opposition, immediate inference; Categorical syllogism; Theory of types; Algebra of classes; Algebra of relations; and Zermelo set theory. Logic, in short, is a very large topic, with many ramifications. The term can have numerous meanings depending on the context in which it is used. Moreover, several different systems of logic have been developed. Usually, however, the term, unless otherwise qualified, refers to a system of rules of inference and argumentation not greatly

different from those articulated by the early Greek philosophers, notably Aristotle.

Formal logic deals with the question of validity; it provides the rules for telling valid from invalid arguments. An argument is considered valid if its conclusion follows from (is implied by) its premises and invalid otherwise. A valid argument is guaranteed to produce an empirically true conclusion if, and only if, its premises are empirically true. An invalid argument, even with true premises, can produce either a true conclusion or a false one.

A distinction is generally made between deduction and induction – two basic types of inference that everyone uses. The difference is sometimes described by saying that deductive inferences go from the general to the particular, whereas inductive inferences go from the particular to the general. This characterization works fairly well, but not perfectly.

Deduction makes explicit in the conclusion of an argument only what is implicit in the argument's premises:

Any map can be colored with no more than four colors so that no abutting regions will have the same color.
Here is an outline map of the United States.
Conclusion: It is possible to color this map so that no two abutting states have the same color.

The conclusion of an inductive argument goes beyond what is in the argument's premises:

Many people have tried to construct a map that cannot be colored with only four colors so that no two abutting regions have the same color.
No one has succeeded in doing this.
Conclusion: It is not possible to construct such a map.

The examples just given illustrate the different degrees of certitude that the two forms of argument justify. The possibility that four colors suffice to color any map was stated as a conjecture in the middle of the nineteenth century, and it resisted all efforts to prove it either true or false until the latter part of the twentieth century. During that time, the second of the illustrative arguments could be made, but only with less than complete confidence that the conclusion was true. After the conjecture

was proved, and accepted by qualified mathematicians as a theorem, the deductive argument could be made and its conclusion accepted as definitely true (admittedly requiring faith in the opinions of the mathematicians who declared the proof to be sound).

With respect to the claim that what is explicit in the conclusion of a deductive argument is already contained implicitly in the argument's premises, one might ask if that is the case, what is the point of making it explicit? One compelling answer to this question is that what is implicit in the premises may not be obvious if it is not made explicit. Every mathematical theorem is implicit in the axioms of the mathematical system from which it is derived. It is, one might say, one of the conclusions that follow from those axioms. In most cases, however, the conclusion is far from obvious in the absence of the sequence of inferences that explicates the logical path to it from the axioms.

Deduction lends itself to formalization and there are many formal constructs and tools to facilitate construction and assessment of deductive arguments. These include syllogistic forms, calculi of classes and propositions, Boolean algebra, and a variety of diagrammatic aids to analysis such as truth tables, Euler diagrams, and Venn diagrams. Induction is not easily formalized; indeed *inductive reasoning* and *informal reasoning* are often used as synonyms. Inductive reasoning, which is also sometimes referred to as *plausible reasoning*, has to do with weighing evidence, judging plausibility, and arriving at uncertain conclusions or beliefs that one can hold with varying degrees of confidence.

Deduction and induction differ also in that there are generally agreed-upon rules of inference in terms of which deductive arguments can be evaluated, while generally agreed-upon rules do not exist for evaluating inductive arguments. Deductive arguments can be determined to be valid or invalid; the most one can say about an inductive argument is that it is more or less convincing. Consequently there is likely to be greater commonality of opinion with respect to the merits of specific deductive arguments than with respect to the merits of inductive ones. Different observers who are familiar with formal logic will usually make the same assessment of deductive arguments; in contrast, inductive arguments are often assessed differently by different knowledgeable observers.

Deductive arguments are often cast in the form of a *syllogism*. In Aristotelian logic a syllogism is an argument containing a major premise, a minor premise, and a conclusion. The deductive argument about map coloring above is in this form, and is an example of a *categorical* syllogism by virtue of having premises and a conclusion all of which are categorical assertions. In contrast, one of the premises of a *conditional* syllogism is a conditional assertion, as in the following example:

If he took the 2:30 bus, he will be here on time.
He did take the 2:30 bus.
Then, he will be here on time.

The many ways in which the rules of deductive logic can be violated, producing invalid forms of argument – forms in which the reputed conclusions are not implied by the premises – have been objects of study by philosophers for millennia.

Two frequently noted invalid forms of the conditional syllogism are the following:

If A then C
Not A
Therefore, not C

and:

If A then C
C
Therefore A.

The first of these forms illustrates the fallacy of drawing a conclusion from *denial of the antecedent*, and the second that of drawing a conclusion from *affirmation of the consequent*. (The first and second terms of the *if* premise of a conditional syllogism are referred to respectively as the *antecedent* and the *consequent*.) Inductive arguments can take a great variety of forms, and it is not possible to divide them neatly into those that are valid, or compelling, and those that are not.

What Is Reasoning?

Dictionaries give a variety of definitions of reasoning, some emphasizing the drawing of conclusions by means of inferential processes, some more or less equating reasoning with problem solving, some representing it as orderly methodical thought. Some, but by no means all, equate reasoning with thinking logically. For present purposes, reasoning is taken to be the mental activity involved when people attempt to assess the plausibility of a claim, work out a solution to a non-trivial problem, imagine the possible consequences of some contemplated action, ponder the relative merits of contrasting principles by which they might guide important choices, explicate tacit assumptions on which different positions regarding controversial issues appear to rest, weigh evidence for and against some tentative conclusion or hypothesis under consideration – for example, that a defendant in a criminal trial is guilty of the alleged crime – or engage in other cognitive activities of a similar nature.

This connotation of reasoning is relatively inclusive; notably it does not equate reasoning with thinking in accordance with principles of logic. From this perspective, whether people, in fact, think logically is an empirical question. A related empirical question is whether the characteristics of good reasoning differ depending on the context in which the reasoning occurs. Does good mathematical reasoning differ from good legal reasoning in significant ways? Does the reasoning that electricians do when trouble shooting an electrical wiring problem differ in fundamental ways – subject matter aside – from the reasoning that doctors do when attempting to find the cause of an illness or a set of symptoms? Does good reasoning, when done by highly trained professionals in the pursuit of their specialties, differ – again subject matter aside – from that which is done every day by people who are not professional specialists?

Many philosophers, including Aristotle, Descartes, Russell, and Kant, among a host of others, have considered reasoning to be a distinctively human ability. Even those who allow that

other species engage in reasoning are likely to acknowledge that the reasoning that humans do and that which other species do differ not only in degree but in kind. People can engage in counterfactual reasoning – reflect on what might have been – and can anticipate probable future consequences of alternative courses of action. They can form hypotheses and devise ways to test them. They can invent axiomatic systems and explicate their implications as mathematical theorems. There is little reason to believe that other species have these abilities or anything close to them.

Do People Think Logically?

How logic relates to the way people typically reason – in particular, whether people naturally think logically – has been discussed and debated by philosophers for centuries, and it has received a great deal of attention from cognitive psychologists in the more recent past. The idea that reasoning is guided by logic has been promoted in one or another form by many writers across the centuries, including notably British mathematician/philosopher George Boole, German philosopher Immanuel Kant, and Swiss psychologist Jean Piaget. One prominent view among contemporary psychologists is that, although people do not necessarily reason in accordance with the rules of a formal logical calculus, their reasoning gives evidence of being based on logical intuitions that are basically sound.

A contrasting view, also prominent, is that the reasoning that most people do most of the time gives little evidence of being based on sound logical intuitions. According to one variant of this view, the development of logic has had little to do with the problem of assessing the soundness, strength or conclusiveness of the kinds of arguments that are typically encountered in everyday life, or with the way people deal with problems the solving of which would seem to require reasoning.

Psychologists have published numerous empirical studies the results of which demonstrate various ways in which people's reasoning commonly violates the rules of logic or otherwise goes astray. Examples abound. Simple statements are readily misinterpreted (*All A are C* may be taken to mean also *All C are A*, a confusion that is sometimes referred to as the premise-conversion phenomenon). Conditional assertions (*If A then C*) are frequently interpreted as biconditional assertions (*If and only if A then C*). Conditional arguments sometimes take the invalid forms (mentioned above) of denying the antecedent (*If A then C; not A; therefore not C*) and affirming the consequent (*If A then C; C; therefore A*). People often fail to see the logical equivalence between a conditional assertion, *If A then C*, and its contrapositive, *If not C then not A*. Judgments of the validity of formal arguments are often influenced by features that are irrelevant to the question of validity (the truth or falsity of premises, the empirical plausibility of conclusions, personal preferences).

People find it easy to overgeneralize (to reach sweeping conclusions on the basis of small samples) and to draw conclusions from less-than-compelling evidence. They are more likely to accept the conclusion of a logical argument if it is consistent with what they already believe than if it is not, and this is true of both valid and invalid arguments; and in seeking

evidence that is relevant to beliefs, they are more likely to seek, and give more credence to, evidence that supports existing beliefs than evidence that tells against them. Similarly, they are more likely to judge an argument to be valid if it yields a conclusion they prefer than if it yields one they dislike. They are likely to believe they foresaw the outcome of uncertain events, when there is little evidence that they did so in fact. These and similar proclivities are often discussed under such rubrics as *confirmation bias*, *myside bias*, and *hindsight bias*, among others.

There are large individual differences among people with respect to their ability to reason in accordance with the rules of logic. But while the ability to reason well correlates with general cognitive ability, as indicated by IQ or other conventional measures, and with level of education, even people with high cognitive ability and advanced education are susceptible to many of the common biases that have been documented to plague human reasoning. And experts in specific areas – doctors, scientists, stock brokers – are not immune from such biases even when reasoning about matters pertaining to their areas of expertise.

For a long time philosophers, among others, have been interested in identifying forms of argumentation that are engaged to win disputes independently of their logical merits. Some of these forms are sufficiently in evidence to have been given names, sometimes even impressive-sounding Latin names. Examples include: *argumentum ad hominen* (attacking the character of the originator of a claim rather than evaluating the claim on its merits), *argumentum ad passiones* (appeal to one's passions or emotions), *argumentum ad misericordiam* (playing on feelings of pity or compassion), *argumentum ad populum* (appeal to popularity, to the idea that if many people believe it, it must be true), *straw man* (distorting an argument for the purpose of making it easier to refute), *false dilemma* (presentating a binary choice as though it were forced when it really is not), *red herring* (treating something that is irrelevant to an argument as though it were relevant), *reification* (treating names as though they necessarily refer to actual entities). There are many more examples of identified stratagems for defeating opponents in disputes other than by logical reasoning, but these suffice for present purposes.

Many 'failures' of people to reason logically are attributed by some psychologists to deference that is given to standard conventions of language usage, which take situational variables into account. Statements of the same form can convey different logical interpretations depending on their content and/or the context in which they are made. *If you make me a better offer than Company X did, I will take the job* and *If you go to University X, you will get a good education* have the same (conditional) form, but the first statement seems likely to be interpreted as a biconditional – *If and only if* – whereas the second one is not.

The Relationship Between Logic and Reasoning

Everyday reasoning tends to be more messy – less easily represented formally – than the kind of reasoning that is typically studied in the psychological laboratory. Moreover, it generally has the pragmatic goal of arriving at true conclusions, whether

or not it does so by means of formally valid arguments. Consequently, some scholars argue that logic has very little to do with the way people reason in dealing with the problems that they typically encounter in daily life. One argument supporting this view is that many, if not most, of the reasoning challenges that could be addressed with logic can also be addressed effectively with alternative cognitive tools, such as mental models, pragmatic reasoning schemas (scripts, frames) or social contracts, that codify situation-specific knowledge about what has proved to work in those situations. Problems the solutions of which appear to require reasoning are sometimes solvable by appeal to memories of personal experiences with similar problems in the past.

The perspective that logic has little to do with everyday reasoning also gains some credence from the ease with which arguments can be constructed that have a logically invalid form, but that yield conclusions that most people are likely to find acceptable. The following argument, for example, is invalid by virtue of denial of the antecedent, but people are likely to accept it despite that fact:

*If I leave before 4:00, I will miss the rush hour traffic.
I can't leave before 4:00.
Therefore, I won't miss the rush-hour traffic.*

It is also easy to construct valid arguments the conclusions to which people are likely to question with good reason. Conditional arguments of the form:

*If A then B
If B then C
Therefore, if A then C*

are generally considered valid. But consider the following argument:

*If he strikes the keys too hard, he will damage the piano.
If he damages the piano, it is not well made.
If he strikes the keys too hard, the piano is not well made.*

The argument unquestionably has the proper form, and one may find it hard to say precisely what is wrong with it, but the conclusion seems not to follow cleanly from the premises. Also it is easy to construct statements that have the same truth value according to the rules of logic, that people are not likely to consider to be equally true. In formal logic, if the conditional claim *If A then C* is true, then *If A and B then C* is also necessarily true. However, people who have no trouble accepting the claim:

If he arrives Friday evening, we will take him to the baseball game on Saturday

are likely to balk at accepting as equally true

If he arrives Friday evening and leaves the first thing Saturday morning, we will take him to the baseball game on Saturday.

What these examples, and many others that could be used, illustrate is that rules of logic that have unequivocal interpretations as long as one is dealing with abstract

assertions – *All A are B; If A then C* – can be problematic when applied to arguments involving meaningful natural-language assertions.

Opponents of the idea that everyday reasoning is logic-based make a variety of arguments against the possibility. They contend, for example, that conclusions drawn in everyday reasoning typically follow only tentatively from premises, and are defeasible – can be overturned by subsequent information – and because traditional logic makes no provision for this, it cannot accurately represent everyday inference. Logic-based theories of everyday reasoning also are ruled out by considerations of computational complexity, some theorists argue; because everyday reasoning makes use of large numbers of premises – essentially one's entire knowledge store – the consistency checking that logic would require would be computationally intractable. There is also the claim that allogical constraints restrict the inferences that people make to be a small subset of those that logic permits.

Although researchers have documented many ways in which human reasoning commonly strays from the dictates of logic, few would claim that logic plays no role in human reasoning at all. To demonstrate that the inferences that people make often reflect the influence of one or another type of bias or allogical factor is not to show that logic has no influence. Moreover, many students of human cognition have noted that the evidences of ineptness that have been obtained with reasoning tasks in the psychological laboratory are hard to reconcile with the fact that people generally function passably well – and often very well indeed – in their daily lives. It is difficult to believe that people are as generally irrational as a listing of the reasoning biases and infelicities that have been revealed in the laboratory suggests. Perhaps the safest generalization that one can make, taking all the evidence into account, is that human reasoning displays a complex mix of logical, illogical, and allogical influences. Logic plays a role in reasoning, but that role is complicated by the influences of linguistic conventions, contextual factors, one's knowledge of the subject on which reasoning is focused, and numerous other variables. People give evidence of having many sound logical intuitions, but they also resort to less-than-impeccable logic when engaged in everyday reasoning – even in situations that call for deductive inferences.

A continuing challenge to research is that of producing a better understanding of why people sometimes fail to apply logical principles that they appear not only to understand but to realize are relevant to the reasoning tasks that confront them. That many researchers believe that people do this is seen in the distinction that has been made between *competence* and *performance* and the claim that one's logical competence is not always reflected in one's performance of logical tasks. Presumably such failure can have a variety of causes, including oversight (failure to recognize the applicability of a principle in a specific context), linguistic confusion (misinterpretation of possibly ambiguous language), bias (reluctance to accept a particular conclusion as true), and carelessness or lack of motivation (unwillingness to make cognitive effort).

In formal logic, syntax is all one has to worry about. As in mathematics, the name of the game is symbol manipulation; what the symbols represent is irrelevant. The question of primary interest in formal logic is whether an argument is

valid, which is to say whether it has a legitimate form. In natural language interpretation, the situation is very different; when doing practical reasoning in real-life situations, one wants to know what a statement is intended to *mean*, and what the speaker's or writer's purpose was in making it. Syntax counts, but so do semantics and pragmatics.

The question of primary interest in practical reasoning is whether the conclusion of an argument is true. The answer depends not only on the argument's form but also on the meanings of the words that comprise it and on whether, given those meanings, its premises are true; and the meanings of words depend, in large measure, on the contexts in which they are used. While these types of considerations have little to do with logic, they cannot be ignored if one is to reason effectively in real-life situations.

Sometimes a distinction is made between *validity* and *soundness*. In terms of this distinction, an argument is said to be valid if, and only if, it has a logically legitimate form; it is said to be sound if, and only if, it has a logically legitimate form *and* its premises are true. By itself, logical validity ensures only that a conclusion follows from the premises; logical validity coupled with assurance that the premises are true ensures that the argument's conclusion is true – that the argument is sound.

It has been argued that responding to everyday language in strict accordance with the rules of logic would be maladaptive, because interpreting literally what people say would often have the effect of misconstruing their intentions. People may use conditional statements (*If you finish the project on time and within budget, you will get a bonus*) when they really mean to convey a biconditional relationship (*If and only if you finish the project on time and within budget, you will get a bonus*). They sometimes express themselves metaphorically, not intending to be taken literally. They often state arguments incompletely, expecting the listener or reader to fill in what is missing. Correct interpretation of messages conveyed in natural language often requires consideration of extra-linguistic aspects of the contexts in which the messages occur. Application of the rules of logic to what people explicitly say, without taking these and other nuances of language use into account, can yield erroneous, perhaps nonsensical, results.

Logic can tell us whether specific deductive arguments are valid or invalid, but it does not tell us which of the countless inferences that might be made from a set of premises are worth making. That the reasoning people do is guided by more than logic is apparent from the fact that most of the inferences that could be drawn from a set of premises are never considered, or even recognized as possibilities. Anything that follows logically from *If P then Q*, follows also from *If P and A then Q*, from *If P, A and B then Q*, from *If P, A, B and C, then Q*, and so on. Not only are the many logical implications of assertions generally not considered, if they were considered with concrete meaningful assertions, they would often be rejected. Consider that if *If Pete comes to the party, it will be a great success* is true, so, logically, is *If Pete comes to the party and insults the host, it will be a great success*; however, presumably few of the people who might believe the first assertion would believe the second.

This example illustrates that conditional assertions are likely to involve unstated conditions as well as those that are made explicit. When one says *If Pete comes to the party it will be a great success* one is, in effect, assuming not only that Pete will

not insult the host, or do any number of other objectionable things that he could conceivably do, but also that the countless other ways in which the party could be a disaster will not materialize.

The example also illustrates the point that practical reasoning generally leads to conclusions that are less than certainly true, but can be accepted with varying degrees of confidence. This is, in part, because natural-language assertions typically are not to be taken as literally true. *Birds fly* is true of most (live) birds, but not of all; it is not true of new-born birds, birds with broken wings, or emus. One understands that the prediction *If you take the cruise, you will have a wonderful time*, even when based on experience and made in good faith, is not guaranteed to be true. Consequently some scholars consider probability theory to be more appropriate than logic as a model for practical reasoning.

There are several theoretical accounts of reasoning. We have already noted the prevalence in these accounts of such concepts as mental logic, mental models, pragmatic reasoning schemas, and social contracts. Central to other prominent theoretical accounts of reasoning are information-theoretic concepts, relevance theory, and dual-process ideas. No single account has yet emerged as clearly dominant over all the others.

Much of the reasoning that people do is for the purpose of finding explanations – answering questions of what, how and why. As American philosopher/logician Charles Sanders Peirce, among others, argued, uncertainty and doubt appear to be states of mind that people find uncomfortable and attempt to avoid. The compulsion to have explanations can motivate investigations that lead to new knowledge; it can also yield beliefs in cause–effect relationships where only correlations, at most, exist.

Everybody arrives at conclusions, and everybody can give reasons for conclusions they have drawn. There are differences among people, however, with respect to the way in which they arrive at conclusions and the tenacity with which they defend a conclusion once it has been reached. At one extreme are those who characteristically jump to a conclusion very quickly, accepting the first possibility that comes to mind, and then defend it stubbornly against any counterindicative evidence that is offered against it. These individuals see their role as that of defending the conclusion against attack; therefore they are likely to try to gather whatever evidence they can that favors the conclusion and discredit any that would tend to cast doubt on it.

At the other extreme are those who attempt to weigh all the evidence that is available before making up their minds on any question, and then, having arrived at a conclusion, consider it subject to modification if further relevant evidence comes to light. These people may often appear to be indecisive, inasmuch as they are likely to find the evidence on specific questions to be inconclusive or insufficiently compellingly favorable to any one of the hypotheses being considered to justify taking a strong position on the issue.

Probably most of us fall somewhere between these extremes. We arrive at conclusions perhaps more quickly than we should, but not without some effort to weigh at least that evidence that is readily at hand. And we often persist in holding on to conclusions that we have drawn, but not to the point of being totally blind to counterindicative evidence and

completely incapable of changing our minds. As individuals we may be less than entirely consistent in our uses of evidence, and to find it easier, for example, to be relatively open and objective when the evidence in question pertains to a claim the truth or falsity of which is of little consequence to us than when it pertains to one in which we have considerable vested interest.

The relationship between logic and reasoning is, in short, a complicated one. On the one hand, people frequently violate widely recognized principles of logic in their everyday reasoning. So we cannot say that reason is ruled by logic. On the other hand, logic does influence everyday reasoning in a variety of ways. We all know, for example, that if two assertions contradict each other, they cannot both be true, and we are keen to find contradictions and inconsistencies in other people's arguments if not in our own. Moreover, in some fundamental sense, it *must* be the case that logic is the codification of human intuitions; perhaps most of us need to consult a logic textbook to learn how to think logically, but someone had to write the (first) textbook – and where are we to assume that author learned logic?

Improving Reasoning

It was once widely believed that an effective way to improve people's ability to reason logically was to subject them to training in some rigorously deductive discipline, such as geometry. While it is unquestionably true that one must engage in careful deductive reasoning in order to do well in geometry, the idea that training in this discipline will greatly improve the success with which people deal with the practical problems they encounter outside the classroom appears not to have many proponents today.

Educational researchers have given much attention to the question of how best to enhance people's problem-solving skills. One objective of this work has been to try to determine the effectiveness of teaching general, domain-independent, heuristic strategies relative to that of teaching domain-specific knowledge and techniques. Domain-independent strategies that have received attention include decomposing a problem into subproblems, finding one or more effective representations of a problem, finding a similar problem that is simpler or whose solution is known, and considering extreme instances of the problem type. Proponents of teaching domain-specific knowledge and techniques argue that general-purpose strategies may be generally helpful, but they seldom provide what is needed to solve difficult problems in the absence of knowledge and know-how that are specific to the problem area. While there has been a lively debate about the relative utility of domain-independent capabilities and domain-specific knowledge as determinants of effective reasoning – especially in problem-solving and decision-making contexts – there is also the view that both types of capabilities are likely to be involved in truly competent intellectual performance wherever it is found.

Does learning logic help students to become better reasoners? One may wonder what would be the point of offering courses in logic if the answer to this question were known or

assumed to be no. The evidence that people who have taken such courses are, on balance, better reasoners than those who have not is spotty, and psychologists who believe that formal logic has little to do with the way people reason in practical situations would not find this to be surprising. On the other hand, evidence that knowledge of logic does not make one a better reasoner also is not compelling. Perhaps the safest conclusion one can draw with respect to this issue is that learning logic can hardly do any harm and, for many people, is likely to do some good. However, to be most effective, knowledge of formal rules of logic should be supplemented with empirically derived knowledge of how people actually reason and especially knowledge of common ways in which reasoning can – and often does – go wrong.

Is it possible to teach people to be better – more effective – reasoners in a general sense? Presumably it is possible to teach people to be effective reasoners in specific domains – to be effective at medical diagnosis, at legal case building, at automotive fault analysis, at computer circuit design, but is it possible to teach people things that will make them better reasoners independently of the domains in which they function? Is it possible to identify principles that apply across different disciplinary contexts and situational specifics? Evidence supports the view that domain-general training can improve reasoning – make one a better reasoner in general – but that to be a truly effective reasoner in a specific domain requires, as well, considerable knowledge that is specific to that domain.

Glossary

Cross-sectional studies Data are collected comparing one set of individuals' responses to those of another set of individuals within a given population at a given time.

Longitudinal research methodology A form of repeated measures design in which a minimum of two data points are collected from the same individuals over some significant passage of time.

Meta-analysis Process of collecting and synthesizing a collection of related studies and statistically combining their results through the comparison of effect sizes.

Retrospective studies Data are collected from individuals in the form of memories about their past including experiences, opportunities, feelings, or aspirations.

Threats to validity Criteria for judging the degree to which the qualities of a method, design, or instrument may affect the accuracy of the study results.

Why Longitudinal Research?

Longitudinal research follows the same individual, group, or organization over time. Like the field of giftedness more generally, the roots of creativity research lie in the longitudinal study of high-IQ men and women begun by Lewis Terman in the 1920s and continuing throughout the subjects' lives. Terman's original questions continue to animate the field of creativity research. Are there any rigorous predictors of exceptional adult achievement? What conditions and experiences promote the fulfillment of early potential? How well do formal measures of high ability predict real-world behaviors and attainments?

Like the field of creativity in general, longitudinal research on creativity encompasses studies of individuals in particular professions or disciplines, a person's general style or approach to work or life, or a process that enhances creative productivity. Methodologically, longitudinal research is superior to cross-sectional and retrospective methods in its ability to address the development and expression of creativity across the lifespan. Cross-sectional studies, in which groups are examined at one point in time, are unable to connect characteristics and experiences across multiple intervals of time.

Retrospective studies and biographies of successful creative producers fail to explain why and how these individuals achieved more than age peers with similar characteristics. Retrospective studies also suffer from incomplete and biased memories of long-past experiences. Although quasi-longitudinal, most pre- and post-test research is too short in duration and includes too few data points to qualify as longitudinal research.

Longitudinal study is prospective, tracing the pathways of individuals who have not yet achieved exceptional adult outcomes. The question of who becomes a creative-productive adult, for instance, requires a method of following apparently equally promising children and youth to see which aspects of ability, family background, personality, and motivation differentiate the expression of creativity in adulthood. The repeated measures of longitudinal study enable scholars to investigate

processes, trajectories, and nodal periods in development. In addition, repeated measures studies can answer fundamental questions of change and stability in creativity over the life span. Does creativity inhere in the person? In the interaction of individuals with particular environmental conditions? Does creativity change systematically in quality or intensity in response to experiences, physical changes, or levels of responsibility associated with different life periods? How do developmental pathways vary in different domains of creativity such as music composition, scientific research, or political leadership?

These fundamental questions about the unfolding of creativity are paralleled by practical issues about how to support creativity. Identifying future creative producers requires longitudinal study of how well creativity tests and early creative behaviors predict later outcomes. Once the validity of identification methods is established, connecting information about experiences and outcomes becomes central to promoting creative behaviors. Longitudinal studies are ideally suited to investigate the long-term effects on creativity of educational interventions, family and mentor support, and organizational structures.

Methodological Challenges

Following the same individuals longitudinally overcomes many weaknesses that hamper other research methods. However, the considerable expense and time required in repeated measures research means that even the most rigorous and well planned longitudinal studies suffer from additional threats to validity. Some studies are hampered by small sample size either due to lack of sufficient funding or because of small numbers of qualified exceptional subjects. Participant drop-out from longitudinal studies is a major problem in validity, especially because attrition tends to be disproportionately high among lower-achieving and less physically and psychologically healthy subjects. Few scholars conducting longitudinal studies have the resources to follow appropriate comparison groups;

in other cases no clear comparison group exists. Other problems include testing effects whereby study findings are biased as a result of subjects' repeated exposure to measurement instruments, researcher interactions, or opportunities to reflect on their lives. Longitudinal studies that follow a single group suffer from period effects, in which results are entangled with the common historical period in which participants live. For example, women's career trajectories are deeply entwined with the social expectations of their time, restricting generalization about any single cohort's experiences. Researchers attempt to minimize these problems by studying more than one age cohort or comparing their results to other study samples. For instance, both the Grant Study of successful aging and Rena Subotnik and colleagues' follow-up of alumni from a school for the gifted used matched samples from the Terman study; Mark Runco and Robert Albert compared the trajectories of boys who were gifted in different domains.

Classic and Major Longitudinal Studies

Despite the challenges in conducting longitudinal research, longitudinal studies are centrally important to the field of creativity. Among early classic work, the Terman study of giftedness continues to be mined for information about creativity in adulthood, while Erik Erikson's theory of ego development and Warner Schaie's work on intellectual functioning over the life span remain foundational.

Most current longitudinal studies of general or domain-specific ability and achievement include some information about creativity. The Study of Mathematically Precocious Youth (SMPY) is a major, multiple cohort study that has investigated the antecedents and consequences of exceptional mathematics ability in the US as measured by high scores on the SAT college entrance examination taken in early adolescence. The Grant Study has been following the health, attainment, and aging outcomes of a group of men identified as exceptionally high-functioning during their Harvard undergraduate years in the 1940s. In Europe, the Munich Study of Giftedness and the Munich Longitudinal Study on the Ontogenesis of Individual Competencies (LOGIC) are major follow-up studies that include components of creativity.

Though not centrally focused on creativity, the SMPY, Grant, and Munich studies are examples of large, well-designed, long-running longitudinal investigations that have yielded findings about the development of creativity as well as the personal characteristics and environmental conditions that support sustained creative production. In contrast to these studies, Jacob Getzel and Mihaly Csikszentmihalyi directly investigated creativity in their classic longitudinal study connecting young artists' problem-finding (a central component of the creative process) on a given task and subsequent career success as a professional artist. Still ongoing is a 50-year follow-up investigation of the predictive validity of the Torrance Tests of Creativity. Other major longitudinal studies that center on creativity are the Mills Study of creative personality in women, begun in the late 1950s, and Albert and Runco's investigation of creative potential attainment in two groups of boys identified in the 1970s as exceptionally gifted in math/science or high-IQ.

Antecedents of Adult Creativity

Longitudinal studies of creative individuals have investigated the connections between mature creative production and a range of pre-adult measures of personality, family experiences, interests, and motivation. Most find connections between adult creative productivity and earlier evidence of openness, complexity, autonomy, unconventionality, and originality. Vitality is another commonly studied individual trait found to predict creative accomplishment among adults. The domain in which creativity is expressed makes a difference: connections between early personality traits and adult outcomes vary for scientists, artists, and other types of creative achievers. Most research using personality draws from standard psychological tests such as the California Psychological Inventory (CPI) or the Minnesota Multiphasic Personality Inventory (MMPI). An emerging approach is the use of the Five-Factor personality inventory, with particular emphasis on the personality cluster of openness to experience as predictive of creative productivity. The Grant Study of adult development follows subjects' use of psychological adaptation mechanisms as the major personality measure. Developmental assets, such as positive connections with others, high self-esteem, and strong skills, have been found to predict academic achievement, but this promising set of variables has not yet been used in repeated measures studies of creativity.

Mixed results come from the study of creative achievers' families. Some researchers reported that childhood experience of family tension or parental mental illness was associated with later productivity, while others found that highly functional and supportive families produced children with sustained creative achievement. Both the Mills Study and Albert and Runco's exceptional boys study found that parental traits continued to differentiate adult offspring's creative productivity and domain-specific creativity, respectively. The Grant study, in contrast, found no direct effects of family background on adult outcomes, although family experiences undoubtedly played a role in one's adult coping style.

Adolescent and young adult interests and preferences consistently emerge as predictors of mature career choices and creative accomplishments. In a representative Israeli sample, adults whose careers matched their age-18 leisure creative activities were more highly placed and more accomplished professionally than their peers. Mills study researchers found that women's creative activities immediately following college predicted creative achievement in mid-life. Csikszentmihalyi and colleagues reported that gifted teenagers were drawn to intensive immersion in their interest area. More recently, Tai and his colleagues' secondary analysis of a US national longitudinal study (NELS-88) found that high school students who expressed interest in science careers were much more likely to earn college degrees in science fields than classmates with identical course histories and tested ability who lacked such early aspirations. Finally, the Study of Mathematically Precocious Youth found that adolescent values and preferences combined with ability and motivation to determine the college majors and career direction of profoundly gifted individuals.

Unsurprisingly, various indicators of motivation emerge across studies as contributing to creative productivity; however, motivation has not been as extensively studied as other

antecedent variables. Ambition and high aspirations, characteristic tendencies to persist in a challenging task, seeking of flow states, and willingness to work long hours have all been linked to long-term positive outcomes. The emerging psychological construct of grit refers to the constellation of motivation and persistence variables that captures many of the motivation factors in the literature on creativity. Angela Duckworth demonstrated the explanatory power of this variable in a number of cross-sectional studies of talented populations. In studies of elite music education, Rena Subotnik and Linda Jarvin explored qualitatively the changing role of various psychosocial factors during transitions in the development of competencies, expertise, and artistry. These studies suggest the value of investigating grit and other conative factors as predictors of creative productivity in longitudinal research.

Development of Creativity

Longitudinal studies of creativity over the lifespan are appropriate for answering fundamental questions about the timing, shape, and stability of creative ability and creative productivity. The relatively few lifespan studies of creativity found that early evidence of creativity can predict continued creative potential and creative productivity in middle and old age. No overall developmental theory of the processes and trajectories of creativity emerges across longitudinal studies, however. E. Paul Torrance began a line of research on the shape of development in childhood. Although attempts to replicate his well-known claim of a fourth-grade slump in creativity have shown mixed results, longitudinal studies show that the progression of creativity does appear to involve peaks and troughs. Researchers have proposed different shapes and ages of transition for the trajectory but no empirical consensus has been reached across studies. In reviewing this literature, Runco and Charles concluded that the lack of consistency across studies results from differences in definitions and measurements of creativity, individual factors, and domain characteristics. There is general agreement that developmental, biological, and environmental factors interact with patterns of growth and change in creativity. For instance, childhood emergence of the concrete operations cognitive structure is likely to dampen divergent thinking, as is an environmental press for conventionality. In childhood, as throughout the lifespan, longitudinal research shows continued interplay between cognitive and conative processes.

An exception to the general stability of creativity over the lifespan is the finding that expression of novelty by very young children is generally not predictive of future creative productivity. Controversy persists as to whether apparently original products in early childhood are creative accomplishments or reflections of a lack of exposure to the rules and practical constraints in given domains. The development of early musical originality appears to be more continuous with later creative productivity than is the case in other domains.

Research that follows adults over time also demonstrates parallels between creativity and general developmental processes. Creative productivity in middle age and beyond has been linked to generativity in several studies. George Vaillant reported that the mentally and physically healthiest Grant Study men and Terman

women were those who used psychological coping mechanisms of altruism, humor, anticipation, suppression, and sublimation. These defenses were more characteristic of creatively productive older adults. Creativity also appears to be linked to successful aging, possibly through the use of creative adaptive responses. For instance, among elderly Grant Study men, high creativity in mid-life predicted long-term physical vitality in Grant Study men better than early general psychological adjustment or IQ. In the Mills study, Helson and colleagues found that women with strong identity achievement were more likely to be lifelong creative producers.

Long-term follow-up studies of adults are able to distinguish between the developmental trajectories of creative ability and creative production. This distinction has the potential to clear up some of the confusion about ages and patterns of decline in creativity after early adulthood. Cognitive and personality traits associated with creativity tend to show consistency over time. Creative productivity, on the other hand, is much less stable. Peaks and troughs in adult creative accomplishment have been linked to life roles and environmental demands, and to biological declines in physical vitality and sensory abilities. It could be, for example, that a peak in creative productivity among mathematicians in their early 20s results from a combination of optimal cognitive powers and physical stamina, professional demands to make one's name, and relative freedom from family responsibilities.

Identification and Predictive Validity

Educational efforts to enhance creative productivity require effective identification of individuals with creative potential. In one sense, all longitudinal research of creativity has to do with questions of external validity: the relation of indicators of creative potential to subsequent realization of potential in the form of creative achievements. As already noted, childhood or adolescent interests, preferences, and leisure activities have been found to predict later creative productivity. However, most of this research concerns the match between early inclinations and later career pursuits, rather than relative levels of creative potential and ensuing outcomes. The relationship between tested ability and subsequent creative accomplishment, on the other hand, is a well-established topic of longitudinal study that directly addresses the issue of predictive validity of identification methods.

The Study of Mathematically Precocious Youth (SMPY) and the longitudinal follow-ups of the Torrance Tests of Creative Thinking are the most sustained and definitive follow-up studies of early identification of exceptional ability. The Study of Mathematically Precocious Youth has completed the first 35 years of a planned 50-year longitudinal study of five cohorts of men and women (~5000 individuals) who were identified at age 12 or 13 as exceptionally intellectually gifted. Follow-up data collections after five, ten, and 25 years indicate that SAT scores of gifted young adolescents are predictive of college and adult accomplishments. A quarter of the variability in college major/degree and occupation was predicted by the two SAT scores (in conjunction with smaller contributions of spatial ability and adolescent preferences). SMPY participants were much more highly accomplished than unselected college graduates in

creative productivity as measured by their record of patents, publications, and tenured positions at top universities.

Psychometric approaches to the identification of creativity have focused on individual traits posited to underlie creative productivity. Current perspectives on creativity view person-level variables as part of more complex systems and contextual interactions. However, the long history of divergent thinking measures and their continued use in educational program identification warrant examination of the validity of creativity tests. The longest-term predictive validity research on an instrument designed to measure creativity is the collection of follow-up studies of the Torrance Tests of Creative Thinking (TTCT). Initially published in 1966 and subsequently revised, the TTCT measures divergent thinking as operationalized by the degree to which subjects' ideas and problem-solving exhibit fluency, flexibility, originality, and elaboration. Torrance and his colleagues followed groups of elementary and high school students who were first tested in 1958–1965 with repeated TTCT results, intelligence and achievement test data, and demographic information. High school subjects were followed up after seven and 12 years. Elementary school subjects were followed 22, 40, and 50 years after the original testing. Adult outcomes included measures of the quantity and quality of adult creative achievements.

In a review of research on the predictive validity of divergent thinking measures, Jonathan Plucker concluded that methodological weaknesses in previous longitudinal work was the source of mixed findings across studies. To remedy this problem, Plucker reanalyzed the 22-year elementary school follow-up data using structural equation models. His finding that just under half of the variability in adult creative productivity was attributable to TTCT scores in childhood is close to the (not yet published) results from the 50-year follow-up by Runco. IQ added to the predictive validity of the TTCT in all cases; however, the contribution of divergent thinking to adult creative achievement was more than three times that of IQ. Both Plucker's 22-year reanalysis and Bonnie Cramond and colleagues' findings from a subsequent 40 year follow-up found that quality and quantity of creative products were highly correlated, but that different aspects of divergent thinking predicted quality and quantity of adult creative achievements. Both researchers concluded that tests of divergent thinking are predictive of creative achievement over and beyond tested intelligence.

Arthur Cropley's investigation of the psychometric properties of creativity tests revealed no examples of long-term predictive validity studies as extensive as the Torrance TTCT research program. When available, correlations between creativity tests and subsequent creative achievement were generally around 0.50. Like Plucker, Cropley concluded that psychometric efforts to measure creativity yield useful predictions of real-life accomplishment, but that unmeasured psychological and environmental factors also play important roles in adult outcomes. For this reason, researchers caution that the currently available instruments are really tests of creative potential rather than creativity and call for multifaceted longitudinal studies to measure the more comprehensive theoretical models of creativity that currently characterize the field.

The predictive validity of early creative behaviors has also been investigated by longitudinal researchers. For example,

Subotnik and her colleagues studied the consequences of scientific reasoning in a long-term follow-up study of Westinghouse (later Intel) science competition winners. Karen Arnold investigated the career outcomes of high school valedictorians. As in creativity test results, these studies demonstrated links between early domain-specific creative behavior and adult outcomes, and drew attention to the decisive role of environmental and conative factors in actualizing high potential.

Ideal longitudinal study designs would include measured ability and behavioral variables, along with personality. Gregory Feist and Frank Barron used such a model in a follow-up study of University of California-Berkeley Ph.D. students who were identified in 1950 as having high potential to make creative contributions to their field. Judges' ratings of creative behavior, psychometric measures of intelligence and divergent thinking, and personality at age 27 all predicted adult lifetime creative achievement by age 72. With only two data points, this study's longitudinal design is not ideal; however, the usefulness of exploring multiple types of predictive variables is clear.

Conditions for Creative Productivity

Study of the antecedents, developmental trajectories, and early manifestations of creativity constitutes important basic research that can lead to practical applications. The conditions that foster creative achievement have been widely investigated. Studies of environmental effects on creativity include longitudinal investigations of family experiences, educational programs, creativity training activities, schooling, and work conditions.

The environmental conditions for eminence (big-C creativity that transforms a domain) have generally been studied retrospectively, as in Dean Simonton's biographical studies of eminence and Bloom's research on top achievers under the age of 30. A few prospective studies have attempted to identify highly gifted individuals with the potential for exceptional creative achievement in order to trace the effects of varied environmental conditions. Albert and Runco, for example, concluded that family and social environments differed systematically across early adolescent boys with high-IQ and those who were exceptionally able in mathematics. The two groups experienced different trajectories of personality, development, and accomplishment in response to early environments shaped by parental personality. In another example of environmental conditions for big-C creativity, Subotnik *et al.* found that the organizational structure and culture of undergraduate science played an important role in maintaining science interest for young adult Westinghouse science winners who had previously exhibited exceptional early creativity in science research. The Westinghouse research is an example of studies that investigate the conditions for eminence at the point of advanced training among individuals who are already exceptionally high performing, motivated, and on the verge of definitive career experiences and decisions. Berkeley study men, for instance, were within a year of receiving their doctorate when faculty judged their potential for outstanding scholarly careers. Such studies demonstrate the advantages of following members of select groups from which eminent achievers typically emerge.

More common are longitudinal studies of educational and training programs intended to foster little-c creative traits

and creative products. For example, researchers found positive effects on creative productivity resulting from participation in programs using the Renzulli Schoolwide Enrichment Triad Model and Feldhusen's Purdue Creative Training Program. SMPY subjects who participated in intensive summer educational programs showed long-term advantages in creative accomplishment as compared to nonparticipants. Maker's studies of low-income and minority elementary school students in the DISCOVER curriculum found that the program's nontraditional pedagogy had a positive effect on student creativity when teachers implemented the program and students experienced a stable level of implementation across grades. In their 1994 analysis of longitudinal studies of giftedness and talent, Subotnik and Arnold concluded that identification criteria and educational program characteristics were closely associated with long-term treatment outcomes. Programs that identified high-IQ or academically gifted students were predictive of intellectual and educational accomplishment but not of creativity. For instance, Arnold found that high school valedictorians were excellent university and career achievers but not particularly creative as adults. The connection between selection criteria, program characteristics, and outcomes continues to emerge in more recent studies, suggesting the need for identification methods and educational interventions that target creativity explicitly.

True longitudinal studies of treatment effects are rare in the literature on creativity. Much more common are pre- and post-test studies of creativity training programs. Three meta-analyses that examined studies of creativity training effectiveness found positive effects of training on divergent thinking and creative problem-solving. Creativity training has also been found to result in positive gains in creative performance and attitudes and behaviors, though these effects are smaller than those for cognitive outcomes. The largest effects come from programs with cognitive approaches. Training program studies generally include only two data points, collected over a short period of time. Two years was the longest reported interval between intervention and post-test in the meta-analysis reports of training studies. With more data points and extended duration, true longitudinal studies have the potential to establish the connection between educational interventions and subsequent creative productivity. One promising direction is the secondary analysis of national longitudinal databases, exemplified by the work of Tai and his colleagues using the NELS-88. Although this comparison of science career aspirations and college degrees currently only includes two data points, the design of the longitudinal study allows for additional follow-ups. The value of such studies to creativity research is limited because none of the longitudinal databases explicitly target variables associated with creativity.

Longitudinal researchers can also explore the effects of innovative schools by following the lives of graduates. Some of these studies are basically pre- and post-test designs with alumni outcomes as the criterion variable. Others are genuinely longitudinal, such as Arnold's Big Picture Longitudinal Study that traces the adult lives of over 1000 graduates of a network of alternative high schools. Big Picture Learning high schools feature an innovative model of personalized curricula intended to capitalize on the interests and creativity of socio-economically disadvantaged secondary school students. In the first five years of a planned 15-year longitudinal follow-up of

Big Picture alumni, elements of the educational model were found to connect to adult creative behaviors and attitudes. Specifically, Big Picture high schools require students to design and demonstrate their own learning within highly individualized school and internship settings. The resulting ability of students to name and follow their own passions and interests is a widely-found characteristic of creative individuals.

Everyday creativity in the workplace is a growing area in studies of creativity, although most of this work features cross-sectional or pre- and post-test designs. Amabile and colleagues conducted a notable longitudinal study of workplace creativity that enabled investigation of temporal effects in creativity and affect. Subjects were professionals at several companies who belonged to teams working on potentially creative projects. Researchers coded incidences of creativity and affect in nearly 64000 specific incidents reported in daily narrative diaries of each participant's work day. Results showed that positive affect was associated in a linear fashion with creativity: creative thoughts and actions followed an incubation period of one to two days after a positive emotional state. Amabile and her colleagues proposed a cycle of positive affect and creativity in the workplace in which individuals' positive emotional states and organizational receptivity to originality foster creativity. More specifically, this study suggests, high workplace morale and affirmative reception of employees' creative insights might maximize creativity in project teams. Longitudinal studies of creativity in work settings is a ripe area for further work.

Future Directions in Longitudinal Research on Creativity

In their 1994 overview of longitudinal studies of giftedness and talent, Subotnik and Arnold criticized the field as overly dependent on small, single-cohort samples without control groups. These criticisms continue to pertain to the literature published in the intervening period. Overcoming threats to validity through the use of multiple measures, cohorts, and data collections remains an expensive proposition. Studies that include large samples, extended durations, multiple domains of creativity, and appropriate comparison groups also require extensive resources. The Study of Mathematically Precocious Youth is the most robust longitudinal study and overcomes many of these difficulties. Like national longitudinal studies, however, SMPY was not designed primarily as a study of creativity. Researchers of smaller scale studies address threats to validity by constructing comparison groups, occasionally within a single study and more commonly with cohorts from other longitudinal studies. Continued variability across studies on criterion (outcome) measures of creative potential and creative performance is still an obstacle to the potential power of longitudinal research. Most importantly, longitudinal studies of creativity remain rare.

Longitudinal research has made progress in the last 15 years. Methodologically, researchers are using more sophisticated analytic techniques than the correlational analyses of many earlier repeated measures studies. Structural equation models, meta-analysis, MANOVA, and growth-curve modeling are now routine statistical techniques in longitudinal studies. In addition to statistical methods that allow for greater complexity, measures of creative ability and performance are following theoretical

advances to become more multi-dimensional. Intelligence, divergent thinking, personality, motivation, and observed behaviors have all been shown to affect creative productivity; scholars need to incorporate these multiple and interacting person-level factors into longitudinal study designs. Environmental factors are equally complex, with research designs lagging behind theory in investigating the interactions between personal experiences and domain and field effects. Some researchers have introduced innovative data collection methods, such as the Experience Sampling Methodology introduced by Csikszentmihalyi and adapted by Amabile in Electronic Event Sampling Methodology. New technology-enabled forms of data collection offer the promise of making longitudinal data collection more financially feasible and grounded in everyday contexts.

Other trends are worth noting. Burgeoning interest in creativity in organizations is part of a larger move to consider creativity in context as opposed to the creative person. The role of affect and creativity in the personal realm are emerging areas in the field. Longitudinal study of underrepresented populations is still sparse, but studies like the DISCOVER program and Big Picture follow-ups are beginning to address this gap in the literature. Domain-specific studies are increasingly the rule, including longitudinal research on creativity in music, science, and technical creativity. Although there are very few cross-cultural studies, longitudinal studies in many countries reflect international interest in fostering creativity. Germany has been a leader in Europe as a longitudinal study center. Chinese researchers have carried out cross-cultural studies of technical creativity. Asia is emerging as a major research player in the field of creativity studies, although almost all of the research to date is cross-sectional. Finally, creativity researchers are connecting to the fields of brain research, aging, and organizational development.

Taken as a whole, the longitudinal research literature on creativity indicates the value of prospective study of creative potential. Widespread convergence across studies point to several key findings about creative potential and creative productivity. Because individual traits of creative producers are fairly stable across the life span, creative potential can be identified as early as elementary school as a meaningful indicator of future creative productivity. Psychometric identification methods have long term validity as predictors of creative accomplishment. Contemporary researchers are following theory in developing increasingly multifaceted identification models that incorporate cognitive, conative, demographic, and environmental factors. The collected studies suggest that creative potential can be best identified through combinations of general and domain-specific ability, personality, self-perceptions, and external judgments. Following identification, intentional

educational and training experiences have a positive effect on creative productivity.

Researchers in the field of creativity recognize the need for studies that encompass the domain-specific, multiplicative models of creativity that have emerged since most published longitudinal work was conducted. Theoretical and methodological advances hold considerable promise for accomplishing this work. Most importantly, the field needs longitudinal studies of creativity that make use of theoretical and methodological advances. New longitudinal investigations, comparisons across studies, and incorporation of creativity measures into national representative longitudinal studies are important directions for advancing knowledge in the field.

Glossary

Creativity The ability to produce new and valued ideas, products, devices, or works of art.

Faculty psychology A school of thought, associated primarily with the eighteenth and nineteenth centuries, that explained human behavior and the mental processes associated with these behaviors by reference to a number of more or less distinct mental powers or faculties, such as the faculties of reason, imagination, memory, or moral taste.

While some faculty psychologists believed that these mental powers could be improved through exercise, it was typically held that a pronounced display of strength in any one faculty, such as an individual's ability for abstract reasoning, was the result, primarily, of a native disposition in the form of a powerful faculty of reason.

Genius When used by reference to people, the term is reserved for those individuals in possession of an extraordinary capacity for imaginative creation, original thought, invention, or discovery. As such, it is applied to those select persons deemed greatest in any branch of art, speculation, or practice.

Humoral theory An early Western physiological theory, one that remained current in the Middle Ages and later, that rested on the idea that the variant mixtures of four primary humors, or fluids of the body (blood, phlegm, yellow bile, and black bile), determined the physical and mental qualities and dispositions of people.

Mad When used as an adjective, the term is in reference to behavior that arises from, is indicative of, or marked by mental disorder.

Manic-depressive illness A mental disorder (also called bipolar disorder) characterized by alternating periods of abnormally intense excitement (mania) and depression.

Psychological empiricism A school of thought, associated primarily with the eighteenth and nineteenth centuries, that believed all human knowledge to be derived from sense experience. As such, it stood in stark opposition to Faculty Psychology and the belief that knowledge is in some way innate to humans or the result of inherent dispositions.

Psychopathology The study of mental disorders and unusual or maladaptive behaviors. In informal use, psychopathology also refers to the condition of mental illness.

Romanticism A literary, artistic, and philosophical movement that flourished in Western society over a period from the late eighteenth to the mid-nineteenth century but with continuing influence today. It is characterized by emphasis on individualism, imagination, a deep appreciation of the beauties of nature, the exaltation of the emotions over reason, and a preoccupation with the exceptional figure in history, such as the genius, the gifted artist and the hero more generally.

Self-fulfilling prophesy A concept that refers to the idea that a strongly held expectation, a prediction, or a prophesy may inadvertently create the conditions for that prediction to become reality.

Introduction

A common assumption in Western society is the idea that profound creativity has an intimate connection to psychopathology. Despite speculations from Greek antiquity to the Renaissance and the Enlightenment regarding the mental state of individuals during the act of creation, the association of creativity with clinical madness is a modern phenomenon that does not predate the 1830s. As we shall see, it was the romantic movement in literature that was indispensable to the establishment of this medical verdict. Faced with obstacles to their

existence, the romantics engaged in the selective redefinition of certain cultural beliefs they inherited from the past. These redefinitions, although they tended to benefit the romantics by providing them with a clearer sense of their own identity (one that established their intellectual and artistic independence from the past), simultaneously invited a system of logic that left them defenseless against the label of clinical madness.

This logic was so compelling, in fact, that self-admissions of mental anguish and actual manifestations of madness on the part of many romantics may be seen as little more than adherence to what had become part of a role expectation deemed

appropriate for artists, writers, and other creative individuals. Moreover, evidence abounds that the expectation of madness continues to be part of a professional ideology of what it means to be truly creative. Given such, it is not unreasonable to assume that even contemporary writers and artists, far from disavowing any connection to madness, may actually invite it and inadvertently volunteer evidence of madness in diagnostic and psychological examinations.

Speculations on the Mental State of Creative Individuals Prior to the Romantic Age

Critical to an understanding of the ancient Greeks' speculations regarding the nature of the creative process are the concepts of demonic possession and melancholia. The 'demon,' which the Greeks conceived as a semideity that presided over a person, a locality, or some other discrete entity, was believed to be endowed with powers to shape the destiny of each in either a positive or negative fashion. Somewhat different from this general view of the term, Socrates regarded the demon as a divine gift granted to a few select individuals only. According to this view, the poet, priest, philosopher, and sage communicated with the gods through the intervention of their demon. It is in this sense that Socrates called upon his demon and attributed most of his knowledge to intimations from it. This conception of demons as the benevolent agents of the gods was generally endorsed by Plato and others and found support in Plato's doctrine of divine madness or 'enthousiasmos.' In this view, the poet, who himself is devoid of talent, is seen as divinely inspired, as an agent or servant of the gods. Inspiration and the gift of prophesy, however, were attainable only during particular states of mind, such as the loss of consciousness due to sleep or a mind affected by illness or possession. Importantly, to Socrates, Plato, and other contemporaries, the divine disturbance that invited prophetic or poetic activity was clearly distinguished from clinical insanity. Unlike the latter, the inspired madness of seers and poets was conceived as a virtue, a state of mind greatly desired. To quote from Plato:

Madness, provided it comes as a gift of heaven, is the channel by which we receive the greatest blessings. . . . [It] is a nobler thing than sober sense . . . madness comes from God, whereas sober sense is merely human.

Also, Aristotle's assertion that extraordinary talent is characterized by a melancholic temperament does not mean, as is frequently asserted, that Aristotle viewed insanity as concurrent with creativity. Insanity, according to Aristotle's reformulation of the Hippocratic humoral theory, did not occur in all melancholic individuals. To Aristotle, the term 'melancholia' was descriptive of a type of individual, the 'homo melancholicus,' who, depending upon the particular balance of his 'humors,' could be either a sane person of distinction or a madman.

Quite different from the subsequent Roman era and the Middle Ages, where there was relatively little concern or fascination with uncommonly creative individuals, the Italian Renaissance produced a renewed interest in those persons esteemed most highly in the arts. For these possessors of superior creative ability the term 'genio' was reserved. However,

creativity was thought of primarily in terms of an imitation of the established masters and of nature. Unlike the modern conception of the genius, one that stresses originality as the distinguishing feature of the creative individual, the standard of the humanistic tradition involved the 'imitatio-ideal.' While some, like Leonardo and Vasari, insisted that the 'genio' should not be just imitatively creative, but newly creative, these attacks on the 'imitatio-ideal' did not become commonly accepted during the late Renaissance.

Similar to the Greek descriptions of the poet, philosopher, and sage, the unique attributes of the Renaissance 'genio' commonly were described in terms of melancholia and 'pazzia,' or madness. But again, a distinction was maintained between the sane melancholics capable of rare accomplishments and those condemned to insanity. Ficino, who popularized the Aristotelian idea of melancholy, regarded this type of temperament, in its application to distinguished persons, as a divine gift. Accordingly, only the melancholic temperament was considered capable of creative enthusiasm. Hence, assessments of scholars and artists in terms of 'pazzia' were generally not intended to convey the notion of insanity. When applied to great people, the term referred to qualities associated with the melancholic temperament, such as eccentricity, sensitivity, moodiness, and solitariness. Far from being regarded as negative qualities, displays of these characteristics of melancholic behavior were turned into a fad in sixteenth century Europe.

It was during the eighteenth century that the term 'genius' was introduced in reference to individuals who displayed a high degree of creative ability. Different from the Renaissance 'genio' and the associated 'imitatio-ideal,' the Enlightenment genius was defined as one who was in possession of an innate power that manifested itself in works of great imaginative creation where the decisive characteristic was profound novelty and the originally creative. Although most commentators on genius acknowledged certain subrational components, the leit-motif most frequently encountered stressed the rational processes of genius.

Perhaps the model exposition of the Enlightenment conception of genius is Alexander Gerard's *An Essay on Genius*. Defined as the faculty of invention "by means of which a man is qualified for making new discoveries in science, or for producing original works of art," the creative power in genius was conceived as originating in an active imagination. Asserting that an unbridled imagination constitutes a capricious and irresponsible faculty, he stipulated that it must be "subject to established laws." True genius, to Gerard, was only possible as a result of a synthesis or subtle interplay of four powers: imagination, judgment, sense, and memory. He argued:

Mere imagination will not constitute genius. . . . As fancy [imagination] has an indirect dependence both on sense and memory, from which it received the first elements of all its conceptions, so when it exerts itself in the way of genius, it has an immediate connexion with judgment, which must constantly attend it, and correct and regulate its suggestions. This connexion is so intimate, that a man can scarce be said to have invented till he has exercised his judgment.

Gerard was not alone in viewing genius as an interplay of different mental powers. To Duff, it was a balance of imagination, judgment, and taste; Voltaire saw imagination in conjunction with memory and judgment; Kant, in a first

version of his theory of genius, viewed it as a favorable proportion of sensibility, judgment, creative spirit, and taste; to Moses Mendelssohn, genius corresponded to a state of perfection of all mental powers working in harmony; to Shaftesbury, while he stressed the irrational traits of genius in terms of revelation and enthusiasm, a true genius did not infringe upon the rules of art; he needed knowledge and good sense.

The prevailing Enlightenment conception of genius did, therefore, recognize certain natural or subrational components rooted primarily in the creative imagination. However, it pointedly established judgment, or reason, as a counterweight to these components and buttressed judgment with memory, taste, sense, sensibility, and so forth. Judgment was not only capable of averting caprice and extravagance, but made madness a virtual impossibility for genius. As Gerard observed, "A perfect judgment is seldom bestowed by Nature, even on her most favored sons; but a very considerable degree of it always belongs to real genius."

The conception of the man of genius as 'rational' not only constituted an Enlightenment ideal but also, apparently, reflected the actual behavior of such men. As Rudolf Wittkower observed, for example, even artists, known since antiquity for their propensity for eccentric behavior, complied with an image of the conforming artist. Since the Renaissance concept of the 'melancholicus' had been supplanted by this newer image, "none of the great seventeenth-century masters – Rubens and Bernini, Rembrandt and Velasquez – was ever described as melancholic. . . . It was not until the romantic era . . . that melancholy appears once again as a condition of mental and emotional catharsis."

The Romantics' Redefinition of Genius and the Functions It Tended to Serve

The late eighteenth and early nineteenth centuries, under the impact of the romantic movement, saw a profound change in the prevailing conception of genius. This change, as we shall see, was intimately tied to the precarious state of existence of the romantic poets and men of letters.

The application of the term 'genius' to select individuals during the eighteenth century marked, as we have seen, the arrival of a new model for man. Generally deprived of wealth or privileged status, men of genius, or those who aspired to be such, tended to challenge the existing hierarchial order by substituting innate creative ability as a superior criterion for the evaluation of men. D'Alembert, an Enlightenment spokesperson for the man of letters, recognized three factors separating people: birth, wealth, and intelligence, but only intelligence was deemed worthy of true esteem. Unlike the others, he argued, intelligence is a dependable national 'resource,' by its nature inexhaustible and incapable of being 'taken' from its possessors. De Saint-Simon, writing a few years after the demise of the Old Regime in France, was less guarded in his vision of the future society; it was to be dominated by men of genius: scientists, artists, men of ideas. In fact, he cautioned the power holders and the propertied classes not to impede the geniuses' quest for power, 'great prestige,' and money. Failure to comply with this warning, he feared, would lead to the almost certain extinction of the ruling elites: "To be convinced of the truth of what I have

said, you have only to reflect on the course of events in France since [the Revolution of] 1789."

The period of reaction to all 'revolutionary' ideas initiated by Napoleon's defeat and the creation of the Quadruple Alliance meant, of course, that prospects of establishing intelligence as a foremost legitimate criterion for the ranking of men had received a serious setback. The Metternich era refused to comply with the demands of this new, self-appointed intellectual aristocracy. Indeed, the events of the late eighteenth and early nineteenth centuries made the position of this aspiring group rather precarious. The disappearance of the traditional 'sponsor' class, the nobility and the aristocratized bourgeoisie, and the subsequent hazards of commercialization and the modern marketplace, left the status of the man of genius in question. Generally impoverished and deprived of political power throughout most of the nineteenth century, the aspiring artist and man of ideas felt himself engulfed by the anonymous masses. Although the idea of genius may have commanded a degree of respect, even reverence, the men of genius themselves, faced with a practical world, lacked the special sense of identity necessary to separate themselves effectively from the masses.

It was the idea of a special kind of madness that could serve as a distinguishing factor, one that could mark a person as separate, unique, and even divinely chosen. The romantic artists and men of letters, in particular, revived the classical notion of divine mania or inspiration, and established it as a defining mark of the extraordinary individual. It was the aura of mania that endowed the genius with a mystical and inexplicable quality that differentiated him from the typical man, the bourgeois, the philistine, and the merely talented. It established the genius as the modern heir of the ancient Greek poet and seer and, like his classical counterpart, enabled him to claim some of the powers and privileges granted the 'possessed' prophet. In this role, the man of genius could counsel kings and blaspheme with impunity. Importantly also, the idea of mania conveyed to the romantics the notions of possession, suffering, and a mood of sentimental sadness, and the display of these qualities confirmed an individual's identity as a true genius. The theme of the blessedness of some special kind of madness is clearly reflected in Poe's 'Eleanora':

I am come from a race noted for vigor of fancy and ardor of passion. Men have called me mad; but the question is not yet settled, whether madness is or is not the loftiest intelligence; whether much that is glorious, whether all that is profound, does not spring from disease of thought.

Similarly, the poet Wieland spoke of the 'amiable insanity of the muses,' and the clergyman Beecher commented on the desirability of at least some degree of madness on the part of poets.

The desire of the romantics for an affirmed identity, however, constituted only one of their aspirations; a second closely connected goal was to establish their intellectual independence from the past. Although the conception of the innately creative genius did much to advance the cause of originality in intellectual life, those engaged in literature and the arts remained tied to the authority of the academies and the ancient masters. Therefore, the romantics' attempt to appropriate certain supposed qualities of the ancients had to be effected without assuming a subservient role to traditional authority. This necessitated a redefinition of genius.

Prior to the eighteenth century, it was commonly accepted that the human imagination constituted a capricious and dangerous element in the lives of men. Recognized as the source of original creativity, it was simultaneously admired and feared. Pascal, writing in the mid-seventeenth century, reflects this ambivalence clearly:

Imagination – it is this dominant part in man, this mistress of error and falsity, and more often trickster than not. . . . But being most often false, it gives no mark of its quality, marking the true and the false with the same nature.

To benefit from imagination and yet contain its great potential for disaster and evil meant, as Pascal cautioned the ‘wisest of men,’ that one had to consciously ‘resist’ its intoxicating powers with all one’s strength. It is not surprising, therefore, that during the eighteenth century, when the genius first became recognized by many as a model of a superior man, the nature of genius was defined in a way that virtually precluded victimization by his own imagination. As we have seen, in the typical Enlightenment explication of genius, the imagination was seen as constrained by a number of powers or faculties that were particularly developed in the great person. Indispensable to the harmonious interplay of mental powers was the faculty of judgment, or reason, which in conjunction with memory, taste and sense averted not only caprice and extravagance but also, as Gerard observed, made ‘madness and frenzy’ a near impossibility for genius.

The dominant Enlightenment view of the genius as an educated individual whose abundant imagination was properly tempered by good taste, training in the classics and an appreciation for the masters proved unacceptable to the romantic spirit. To create a new independence, genius could no longer be seen in the Enlightenment terms of balance, proportion, and a synthesis of mental powers. The romantics, therefore, granted the imagination a clear predominance over those faculties traditionally seen as the rational counterweights to the imagination. Like the Schlegels, Lessing, and others, Schiller proposed that the deliberate application, far from being beneficial, would serve to obstruct the imagination and bind the potential for profound creativity:

It is not well in works of creation that reason should too closely challenge the ideas that come thronging to the doors. Taken by itself, an idea may be highly unsuitable, even venturesome, and yet in conjunction with others, themselves equally absurd alone, it may furnish a suitable link in the chain of thought. Reason can not see this. . . . In a creative brain reason has withdrawn her watch at the doors, and ideas crowd in pell-mell.

To suspend the “laws of rationally thinking reason” meant, as the Schlegels observed, to be transported “into the lovely vagaries of fancy and the primitive chaos of human nature.”

Psychology, Physician-Psychiatrists, and the Clinical Association of Genius and Madness

The romantic redefinition of genius in terms of the imagination reigning supreme satisfied two goals simultaneously. Through its stress on the spontaneous and irrational imagination, it made possible the appropriation of ‘mania’ from the

past, but it did so while insuring intellectual independence in the present. There was, however, a critical byproduct: while the new definition liberated the romantics from the past, it also disassociated them from the very qualities that previously had been seen as establishing and safeguarding sanity. Given the commonality of the belief concerning the relation of sanity to the balance of mental faculties, the romantic reformulation of genius, which removed this balance, established a logical foundation for the association of genius and madness. And, most ironically, perhaps, the romantics, trapped by their premises and system of logic, began to suspect that clinical madness is indeed a likely if not inevitable end of the condition of genius.

The need of the romantics, then, for a sense of identity and for their own intellectual and artistic independence, led them to adopt a system of premises that left them defenseless against the label of madness. Trapped by their own logic, they came to see their madness as inevitable. Accordingly, the romantic men of genius were among the first to suggest (e.g., Lamartine, Schopenhauer, Wieland, Poe, and others), in reference to themselves and other eminent individuals, that the ancients were indeed correct in their assessment: the ‘demon of madness’ was more than just a stranger among their ranks. Although many of these confessions or pronouncements on the nature of genius were expressed in more general than specific terms, and referred to the ‘inspired’ madness of the ancients, some testified, quite clearly, to the fear of clinical insanity. Coleridge, for example, commented specifically on the dire consequences of a suspended judgment or reason:

The reason may resist for a long time . . . but too often, at length, it yields for a moment, and the man is mad forever. . . . I think it was Bishop Butler who said that he was all his life struggling against the devilish suggestions on his senses, which would have maddened him if he had relaxed the stern wakefulness of his reason for a single moment.

Similarly, Byron, although often appearing to revel in a professed madness, nevertheless spoke with considerable apprehension about his future: “I picture myself slowly expiring on a bed of torture, or terminating my days like [Jonathan] Swift – a grinning idiot.”

It would be erroneous to assume, however, that such trepidations and self-admissions on the part of geniuses were sufficient to establish as a medical fact the connection between genius and madness. For such to occur there had to exist a close correspondence between the intellectual grounds on which these trepidations were based and the specialized knowledge claims associated with the rising fields of psychology and the medical-psychiatric profession. It should be noted in passing that at least one dominant philosophical-psychological tradition was unfavorably disposed and frequently hostile to the romantic conception of the extraordinary individual. The psychological empiricism of Hobbes, Locke, and Hume (which, in the hands of Hartley, Bentham, James and John Stuart Mill, was transformed into psychological associationism) was unalterably opposed to the view that knowledge is in some way innate to humans or the result of inherent dispositions. Instead, these empiricists stressed the extrinsic nature of all human knowledge. The support the romantics needed to help articulate and legitimate their view of the extraordinary individual and the workings of his mind was

located in a highly speculative psychological tradition which predated the critical empiricism of Locke and Hume.

Before 1700, Western scholars attempted to understand the nature of the mind, learning and creativity from a modified Aristotelian position. This position recognized the existence of some half-dozen more or less distinct mental components or 'faculties,' which, to some degree, were subject to improvement through their exercise. The belief in mental faculties was gradually expanded and formalized during the eighteenth and nineteenth centuries and, through the writings of Wolff, Reid, Sully, and others, became established as a school of thought known as faculty psychology. In Reid's reformulation of this perspective, for example, the number of components of the mind was expanded to 24 but retained such traditionally recognized intellectual powers as perception, judgment, memory, and moral taste. Although Reid and other faculty psychologists concurred that the mental powers could be improved through training, they believed that a pronounced display of strength in any faculty is rooted, overwhelmingly, in a powerfully endowed instinct or native disposition. Accordingly, an individual distinguished by an extraordinary ability to memorize facts was seen to possess an unusually vigorous instinct or faculty of memory. The belief in inherent mental dispositions supported not only the inception of the genius ideal but its subsequent romantic reformulation.

Unlike the school of psychological empiricism, therefore, the faculty psychology of Reid, Wolff, and others, with its stress on innate powers and inherent mental dispositions, was sufficiently vague and mystical to accommodate most of the romantics' assertions regarding the transcendental nature of profound creativity. Importantly, also, faculty psychology even concurred with the romantics' position that the genius's dependence on an 'overcharged' and highly impulsive imagination constitutes a form of madness, divine or otherwise. It had long been an established principle, particularly for faculty psychologists, that an excessive stimulation of any faculty of mind is incompatible with perfect health and mental adjustment.

Whether or not, however, the supposed infirmities of genius constitute clinical pathology rather than a divine gift or mania remained, until the middle of the nineteenth century, a matter more of philosophical speculation than of supposedly scientific fact. The individuals, overwhelmingly, who were to establish the verdict of clinical madness as a medical fact were those who had earned a medical degree and are classifiable under the general category of physician-psychiatrist. These specialists, although they embraced many of the assumptions of faculty psychology and brought to bear what then were regarded as the latest clinical concepts and diagnostic categories, relied quite heavily in their determination of genius as clinically mad on the self-admissions of illness on the part of the 'gifted.' And while many of these self-admissions were expressed in terms of the inspired madness of the ancients, these physician-psychiatrists took the men of genius at their words, they decidedly were not like ordinary, healthy humans.

The first examination of genius as a purely medical problem may be dated to Lélut, a French psychiatrist, who in 1836 scandalized the world of letters with the first clinical history of genius in which he claimed that Socrates's inclination "to take the inspirations of his conscience for the voice of a supernatural agent [his demon]" was evidence of a

"most undeniable form of madness." Other psychiatrists and scholars soon followed suit with their own views and analyses of other 'gifted' persons (e.g., Galton, Lombroso, Maudsley, Moreau, Stekel), with the result that within a century such works numbered in the hundreds. Importantly, the judgment of genius as pathological was the dominant position on the issue, one that derived its overwhelming support from members of the medical and the developing psychiatric professions. Those who projected the image of sickness distinguished themselves from each other by identification of different types of mental illness largely in step with the rise and fall of diagnostic categories in psychiatry then currently in favor. Whereas diagnostic labels such as psycho-physical disequilibrium, monomania, degeneracy, neurasthenia, and neurosis prevailed in the years up to 1950, the disease categories that have gained ascendancy since that time are those, such as schizophrenia and manic-depressive illness, that figure prominently in the contemporary lexicon of psychiatry.

Implications for the Contemporary Debate

As we have seen, the romantic poets and men of letters were among the first to suggest, in referring to themselves and other eminent individuals, that the ancients were indeed correct in their assessment: The demon of madness was hardly a stranger in their ranks. These pronouncements, as previously noted, played an integral part in the past in the determination of the genius as clinically afflicted. This tendency to take the gifted at their word regarding their own condition applies as well to contemporary examinations of the issue. Kay Jamison's book, *Touched with Fire: Manic-Depressive Illness and the Artistic Temperament*, provides demonstration of this fact. Jamison builds a clinical connection between creativity and manic-depressive illness by allowing scores of artists, composers, and writers from across time in Western society to reflect on their own changes of mood ranging from melancholic states to feelings of euphoria, their obsessions and fears of going mad, their thoughts about suicide, their addictions to alcohol and drugs: those and other behaviors and mental states, in other words, identified by the author as symptomatic of mood disorders.

One of the problems of treating such self-admissions as essentially reliable descriptions of mental illness is that it tends to overlook one critical fact: These pronouncements on the part of the creative individuals may involve self-serving descriptions and projections of images that were made in the context of cultural assumptions often quite different from those of contemporary society. In light of these facts, it remains unclear what meaning should be attached to the tendency on the part of many poets and other creative persons to admit to a 'touch' of madness.

Two examples illustrate the difficulties involved in the interpretations of such admissions. The first concerns an excerpt of a poem from Drayton, a poem written in praise of another poet, Drayton's friend Reynolds:

His raptures were
All air, and fire, which made his verses clear,
For that *fine madness* [italics added] still he did retain,
Which *rightly should* [italics added] possess a poet's brain.

This excerpt is open to a number of interpretations which include the reference to the divine mania of the ancients, a condition, as previously noted, that was not synonymous with clinical madness. Rather, it was a state of mind greatly desired. Given this fact, are we justified in treating this excerpt, as Jamison did, as an essentially reliable description of illness. Or is it not equally possible that Drayton's reference to the presence of a 'fine madness' on the part of Reynolds has little if nothing to do with clinical illness and was intended as an ultimate compliment a poet could be paid, one that confirmed his membership in the tribe of truly eminent poets?

Similarly, what are we to make of Coleridge's pronouncement who, in a defense of Swedenborg, proposed that, unlike ordinary madness, his was the madness of genius: "a madness, indeed celestial, and glowing from a divine mind." Is it not likely, as Kretschmer has argued, that pronouncements such as these are confirmation of the fact that "many men of genius themselves prize madness and insanity as the highest distinction of the exceptional man." After all, Kretschmer observes, "the mentally normal man is, according to the conception itself, identical with the typical man, the average man, the philistine."

Consistent with this line of argument, the association of creativity and madness deserves to be seen as a kind of role expectation appropriate for artists and writers that originated in antiquity and received powerful reinforcement as a result of the romantics' redefinitions of the nature of genius. In the way that contemporary scientists, accountants, and engineers are expected to display attributes of objectivity, reason, and emotional stability, for poets, writers, and artists the expectations involve manifestations of intuitiveness, a fanciful imagination, sensitivity, temperament, and emotional expressiveness, in short, manifestation of a kind of madness. It is not at all unreasonable to assume that, to the extent that these expectations continue to be part of a professional ideology of what it means to be truly creative, even contemporary writers and artists, far from disavowing the label of madness, may actually invite it. Indeed, they may even inadvertently volunteer evidence of madness in diagnostic and psychological examinations. Moreover, is it not possible that these expectations may involve the elements of a self-fulfilling prophesy? In a rephrasing of a line from Orwell, "they are wearing a mask, and their faces grow to fit it."

Such possibilities have implications for the issue of creativity and psychopathology. Indeed, they may invite conclusions at odds with the conventional association regarding these two variables. One of such conclusions is associated with the existentialist philosopher, Jaspers, who maintained that the greater manifestation of mental illness in geniuses was the result of society's selective granting of fame. To Jaspers, in other words, the term genius was a socially applied label primarily reserved for those talented individuals who displayed certain attributes of sickness closely tied to the role expectations noted above. He did not believe that the notion of the mad genius was

applicable to all historical periods. Rather, what distinguishes the nineteenth and twentieth centuries from the seventeenth and eighteenth, Jaspers reasoned, is a general mood or inclination in Western society that craves the mysterious, the unusual, the undefinable, and the blatantly diseased. Accordingly, although the Enlightenment tended to reward creative individuals who were healthy and rational with the distinction of genius, the nineteenth and twentieth centuries (since the time of romanticism, that is) have shown a distinct preference for those creative individuals who are diseased.

All of this is not to suggest that the display of symptoms of mental illness on the part of the creative are the result of nothing more than deliberate role playing and adherence to role expectations deemed appropriate for artists and writers. Rather, it is a reminder that examinations regarding the relation of creativity to mental illness must take full measure of relevant historical and socio-cultural developments as well as their impact on contemporary conceptions regarding the nature of creative individuals and the creative process. To the extent that these conceptions find expression in a pervasive societal belief in the existence of a close connection between the creative arts and some form of madness, as is the case in Western society, they are likely to be of consequence and become intimately tied to the acknowledged mind-body connection in the causation of genuine illness. As such, they are indispensable to a thorough understanding regarding the relationship between creativity and mental health.

Glossary

Bradford's law An area-specific formulation regarding the percentage of total coverage by various journals in a field. When periodicals are ranked in order of decreasing productivity in a field, the sum of articles not produced by the most prolific authors of that field is proportional to the logarithm of the number of their producers.

Cumulative advantage A principle referring to the accumulation of personal or institutional advantages as a result of the social mechanisms of scientists.

Lotka's law Alfred Lotka's formulation about the distribution of productivity stating that the number of individuals making n contributions in a domain is inversely proportional to n^2 .

Matthew effect index (MI) Shows the national win or loss for citations in positive or negative percentage numbers. The index was formulated as a ratio of the deviation of the observed citation impact from the expected citation impact divided by the expected citation impact calculated from the impact factors of all journals used for publication by a country. The index is a positive number when the observed number of citations exceeds the number of expected

citations, indicating a gain situation, and a negative number when the observed number of citations is smaller than expected, implying a loss situation.

One-pass versus multi-pass processes *One-pass process* refers to the consideration of a scientific discovery as being made by the person who performed the last or most critical step. *Multi-pass process* acknowledges that several contributions and phases of reworking, reconceptualization, or rejection may be involved in the ultimate discovery. It recognizes interactive networks among scientists.

Pareto's law Vilfredo Pareto's empirical generalization stating that a minority of a population owns the majority of the resources, while the majority of the population shares the rest.

Price's law Derek Price's empirical generalization that the square root of the number of all contributors produces half of all contributions.

Self-fulfilling prophecy The situations in which one's expectations can influence an outcome on the expected direction. If one defines a situation as real, it consequently becomes real.

Introduction

Creativity was once regarded as elusive, obscure, magical, and beyond the sciences. In the past several decades the field of creativity studies has become more and more scientific. This implies objectivity, some of which is a result of careful experimentation. Such experimentation is usually intended towards the isolation of causes and effects. Not surprisingly, several broad 'effects' are believed to govern creativity. Several terms have been coined to describe effects that explain various mechanisms with relevance to creativity. The effects to be discussed here focus on mainly noncognitive and external aspects of creativity. They are the Matthew, Pygmalion, and Founder Effects. They explain the social mechanisms of scientists, the role of significant others, and the timing or primacy of scientific discoveries, respectively.

Matthew Effect

There has been debate about the relative importance of internal versus external influences on the development of scientific interests. Internal influences refer to the influence of scientists' work as isolated from others' influences. External influences refer to social, cultural, and contextual influences. Creativity is often studied in terms of internal influences: the majority of studies on creativity depend on cognitive and personality aspects of creativity. External influences have been less studied

but did become the primary interest of the sociology of science. One result was the concept of the Matthew effect. The *Matthew effect* describes the reward and communication system of science based on the passage in the Gospel according to St Matthew, which states, "For unto every one that hath shall be given, and he shall have abundance: but from him that hath not shall be taken away even that which he hath."

Put in the context of scientific creativity and productivity, this statement addresses the issues related to the major criteria of success in academia such as publications, grants, and facilities. A dramatic expression of the competition in academia is the phrase 'publish or perish.' According to Merton, who coined the term *Matthew effects*, this game is not played fairly, with some people winning every time disproportionately to their superior skills, ability, and work. He pointed to various social processes responsible for the biased evaluation system that leads "the accruing of greater increments of recognition for particular scientific contributions to scientists of considerable repute and the withholding of such recognition from scientists who have not yet made their mark." As a sociologist, he attempted to explain the reward and communication system in science in sociological terms: "the reward system [...] influences the 'class structure' of science by providing a stratified distribution of chances, among scientists, for enlarging their role as investigators."

According to Merton, science is public, not private, and the Matthew effect reflects the social climate that influences the degree to which scientists will be known by others. Merton's

view emphasized external influences on recognition of scientific creativity rather than individuals' real potentials. By external influences, Merton referred to the community of scientists that may disrupt the rightful distribution of credits because of their systematically biased ascriptions.

A corollary to this proposition is differential access to facilities and opportunities called *misallocation of resources* that works in favor of more established and famous scientists. Inequality in the reward system provides further opportunities for known scientists and penalizes the unknown names in the field. The Matthew effect simply represents the equivalent claim as the proposition "the rich get richer and the poor get poorer" in economics. This situation reflects a sort of monopoly held by the famous scientists.

Some of the first evidence of the Matthew effect came from Harriet Zuckerman's interviews with Nobel laureates in the early 1960s. These indicated that 'ultra-elite' scientists receive disproportionately more credit for their contributions to science whereas obscure scientists get disproportionately little. The distribution of the number of publications is highly skewed: there are many Ph.D. holders who publish one or no articles while a small number of scientists publish hundreds of papers as well as books. Although the skewed numbers can be attributed to other factors such as a scientist's differential ability, efforts, and career expectations, Zuckerman's findings raised some questions about the fairness of the mechanism.

Cumulative Advantage

The idea of *cumulative advantage* is relevant to Matthew Effects. Career trajectories of the scientists depend, to a great extent, on their cumulative advantage, defined as the social processes that determine the allocation of resources and opportunities such as laboratories, research grants, and talented research assistants and their accumulation among particular scientists and institutions. The advantages can be personal such as reputation and age of the scientists or contextual such as institutions and available resources.

Reputation is the most significant personal advantage. Social processes favor reputable authors over lesser-known authors even when both produced publications of equal quality. Even in collaborative works in which well-known scientists contributed very little, such scientists are credited with most of the work because of their reputations while other contributors receive little credit even if they invested more effort. This is true even when the famous scientist is listed last in cases where the order of authorship reflects the level of the contribution from highest to lowest. This situation persists because of the underlying preconception among the community of scientists that the famous one provided the idea, resources, and connections. This misperception paves the way for other critical decisions that help the known scientists.

When positions become available, they usually are awarded to the scientists with higher recognition, publication, and fame, who are thus able to do more research and further increase their reputations. The less-known scientist, on the other hand, will have a very limited opportunity to stay in the current position because of limited resources and facilities. Once scientists are Nobel laureates, they are Nobel laureates throughout their lives, and this title often increases the

influence of their work beyond that work's merits. Their books will sell better because of the 'Nobel laureate' designation, and no journal will want to reject their papers (journals may even ask them to write papers). The ideas in the book will be read by many other people and more people will be convinced about those ideas and cite them in their own works.

Cumulative advantage specifically refers to the benefit of the early bloomers in sciences because of their relative advantages in trained capacities and locations enabling their access to resources. Studies of creativity and age show that researchers who publish earlier attain a greater number of publications than those who publish at older ages. Moreover, early publishers also produce higher quality contributions. This phenomenon can simply be regarded as normal because early bloomers will have more time to produce. From the perspective of cumulative advantage, however, this is related to the precocity bias that promotes early bloomers since early publications are assumed to reflect overall productivity. While there are scientists who cannot keep up their earlier performances and those who perform better in later years, they are fewer in number. The role of cumulative advantage is evident among older and younger scientists. Longitudinal studies of 2000 American scientists from several fields showed that the inequality between older and younger scientists has risen with respect to their number of publications and number of citations, which underlined a marked stratification.

As for the institutionalized advantages, lesser-known scientists can break the cycle if they are at major universities where their publications can be disseminated among the elites of the field. Statistics indicate that a good proportion of the research grants are provided to particular universities. Grants often yield more original papers and attract more high-ability novice researchers. Likewise, many of the Nobel laureates work at particular universities such as Harvard, Columbia, Berkeley, and Chicago. In a recent empirical study controlling author quality, journal quality, and article-specific characteristics, researchers found that there are 19 elite universities that have a positive impact on the initial reception of an article and on peer recognition for its contributions. Specifically, scholars affiliated with two universities, Harvard University and University of Chicago, have a greater chance for peer recognition. This finding was limited to the departments of economics, and similar studies can be extended to other departments as well.

The critical factor that distinguishes certain scientists from others is the limited awards, opportunities, and facilities provided to scientists. If only three Nobel Prizes can be granted in a year in a given category, this does not mean that only those three scientists may deserve them. However, the recognition of the scientists after they win the Prize differs disproportionately to the quality and significance of their works. The problem is that there are a few prestigious awards that could be granted to many successful and aspiring scientists. Another example is inequality in scientists' access to laboratory and financial support to maintain their research. Although scientists working in less-known or liberal arts colleges might come up with very bright ideas, they cannot carry out their research because of teaching requirements or lack of facilities. The same situation rules when it comes to publishing papers. Academic journals have strict rules such as publishing only a certain number of articles in each volume – to the extent that only 10–25%

of submissions are accepted in the essential journals. The limited space in the journals tends to be allocated for the prolific minority rather than the novice or less prolific researchers. Furthermore, when two rival scientists with and without articles apply for a grant, their publications will be taken into consideration as well as other qualifications. Success, awards, and opportunity breed further success, awards, and opportunity, just as money breeds more money. Limited prizes, money, and facilities allotted to famous scientists distinguish them from the other colleagues.

The role of reputation for further recognition exhibits itself in the cases of 'multiples' when two or more researchers discover the same thing. Even though each scientist who developed or discovered the same thing deserves an equal amount of credit, respect, and recognition, the more famous one is associated with the discovery rather than the others. Some theories, such as the Darwinian Theory of Evolution, are named after the scientist, while many other discoverers who contributed to the development of the theory will not be even known and recalled by later generations. This cycle keeps going for the benefit of the more famous, and the disparity between famous and obscure researchers will increase independently from their capacities as scientists. However, Donald T. Campbell and Herman Tauscher noted the other direction for the attribution processes for 'multiples.' They indicated that scientists with unique or few contributions can be credited with a discovery rather than other scientists with many contributions because singularity of contribution provides unequivocal in the communication.

The Matthew effect is influential in the communication system through its manipulation of the visibility of scientific works. Like the influence of marketing strategies and advertisements for commercial products on their sales, reputations and the quality of previous work increase the possibility of recognition, appreciation, and dissemination of new work in comparison to a new scientist with no distinguished work beforehand. The names of the innovators sometimes overshadow the quality and importance of the innovations. When one thinks of professional conferences in any field, the presentations of the prominent figures in the field are followed by many researchers whereas novice researchers have fewer followers even when they sometimes introduce more original works.

Formalized Effects

Cumulative advantage may be related to various parallel effects. The so-called skewed distribution of productivity, for instance, was formalized by Alfred J. Lotka as 'inverse square law' based on his bibliographical studies in physics and chemistry. This formula states that the number of scientists with n publications is inversely proportional to n^2 . This formula yields a curve with many people with one or zero publications whereas a couple of researchers produce hundreds of publications. If there are 100 scientists with only one paper, there can be 25 people producing two, and approximately 11 with three papers. The number of scientists with a higher number of publications decreases asymptotically. The resulting graph is a left-skewed distribution. This formula implies that approximately 5% of scientists produce about half of all papers and the others share the other half. On the other hand, the

proportion of all contributors with only one publication is about 60%. Even though Lotka's law does not apply to all areas, recent studies about productivity proposed that it is useful in understanding the underlying pattern of author productivity.

Lack of universality in Lotka's law has been addressed by Bradford's law (or law of scatter) which was developed based on journals and articles grouped to identify the number of periodicals related to particular subjects. The process yielded a constant representing the subject area within the following formula, and used to determine the percentage of total coverage by various numbers of journals in a field: $R(n) = N \log n/s$ ($1 \leq n \leq N$), where $R(n)$ represents total number of journal articles, N represent total number of journals, and s is the constant for a subject area.

Derek DeSolla Price proposed another formula for the distribution of scientific productivity. According to it, half of the total number of papers published by N scientists belongs to \sqrt{N} scientists. Assuming that there are 1000 articles in a field published by 100 scientists, 500 of them belong to the 10 most prolific scientists. Price suggested that two-thirds of the scientists publish only one paper and do not produce any more. There was a slight difference in the underlying assumption of his formalization: success increases the probability of further success, but failure does not increase the probability of later failure because lack of publication is a 'nonevent' and it cannot be counted as a publication (any event) is counted. Therefore, he suggested a cumulative advantage distribution, which is an increasing function, rather than negative binomial distribution which can be an increasing or decreasing function, reflecting the failures and successes.

Another principle that is applied to scientific productivity is Pareto's law (also known as the 80/20 rule) originated in economics. Italian economist Vilfredo Pareto observed that 20% of the population owns 80% of the land in Italy. The remaining 20% of the land is shared among 80% of the population. This imbalance between the 'vital few' and 'trivial many' as described in Pareto principle seems to fit the distribution of the productivity of the scientists as well. A small percent of scientists own the majority of publications and resources, while the majority of scientists own only a little.

These 'laws' reflect the inequality in productivity. Inequality in citations is even more drastic. Eugene Garfield counted the citations of 19 million articles. Of all articles cited, less than 1% were cited more than 100 times; another 3% were cited between 25 and 100 times; and 58% were cited only once in a 20-year period. Therefore, distribution in citations is more uneven than publications. However, research shows that the inequality in citations is not related to professional age, which was claimed to influence productivity in favor of early bloomers because of precocity bias.

Extension to Countries and Journals

Other than personal and institutional aspects, the Matthew effect has also been detected at the macro level, leading some to ask if there are Matthew effects for countries. Ideally, scientific publication is only related to the content of the scientific works rather than their regional origins. However, this ideal situation may not be the case because of economic, cultural,

and institutional reasons. Thus, a few countries can receive citations predominantly higher than the many other countries, which receive only a few. A Matthew Effect Index (MI) was developed that yields a positive or negative number indicating the win/loss status of the country in citations. The MI index is higher based on the extent to which the observed number of citations can exceed the number of expected citations. The expected number of citation is determined based on impact factors of all journals in a country. The MI index is equal to the difference between observed and expected citations divided by expected citations. The resulting value is a percentage. In a study comprising 40 countries and 2712 journals, only ten countries (Switzerland, Denmark, the Netherlands, Sweden, United States, United Kingdom, New Zealand, Ireland, Germany, and Finland) had positive MI values (higher than expected citations). Analyses of the Matthew effect for countries allowed a new type of journals, called 'Matthew core journals,' which refer to 145 journals accounting for 50% of the citation wins and losses. Those journals were critical for gaining or losing excessive amount of citations.

In an empirical study, the role of the journals in which the articles are published was assessed by comparing the citations of identical papers in journals with high impact factor versus low impact factor. Analyses showed that impact factor of the journals played a significant role in getting citations: papers published in high impact journals received twice as many citations as their identical copies published in journals with lower impact factors. Matthew effects as associated with journals influence the citation and therefore visibility of the scientific works.

Evaluation

The Matthew effect was seen as pathology because it conflicts with meritocracy in science. Monopoly is as undesirable in science as it is in economics. However, Michael Strevens argued that the Matthew effect can be good for society and science. He argued that rewards are proportional to their contribution to society so that contribution to society is maximized. The contribution to society, then, is proportional to its epistemic security, that is, trustworthiness of the discovery or contribution. For example, a new medical treatment for an illness can have good epistemic security after it has been observed to cure the illness successfully. There should be no problem with receiving more rewards if the contributor has resolved an important problem of human beings. Based on this line of reasoning, allocation of credit proportional to the rewards is not at odds with scientific norms since this mechanism is helpful in maximizing science's contribution to humanity. According to this rival hypothesis, the Matthew effect does not seem to violate the fair distribution of credit in particular fields in which the consequences of the discoveries and their epistemic security can be tested. However, this may not be the case in many fields in the social sciences, and the Matthew effect can rule more strictly.

Limitations

The Matthew effect cannot be easily generalized to fields other than the hard sciences because some do not require many

resources. For example, in the fields of the arts and literature, the Matthew effect is not dramatically observed in terms of access to resources, since the cost of writing a poem or making a musical composition requires only a pen or a musical instrument in comparison to hard sciences, which require a laboratory and grants. Nonetheless, previous works or publications in arts and literature can still determine the acceptance of future works.

Second, empirical results supporting the cumulative advantage hypothesis can be explained by some other perspectives as well. For example, some explained creativity with multiplicative functions that propose a log-normal distribution because the product of several factors that influence creativity produces a highly skewed distribution, which is different from simple addition of the same factors. The combination of normally distributed factors such as creativity, intelligence, and motivation, yields more complex effects than suggested by the cumulative advantage model.

Third, some models that are more personal in nature explain the continuity of creative productivity better than the cumulative advantage model. Simonton showed that latent factor of creative ability can successfully explain longitudinal stability of the individual differences in sciences. This argumentation takes us back to the beginning of the discussion where I dichotomized the ways of understanding creativity as internal and external. A seemingly consistent hypothesis relying on external influences can well be explained by a totally different model. Furthermore, Simonton's rival hypothesis rejects the early bloomer's advantage in producing more output. According to his findings, the age curve shifts but follows a similar pattern for late bloomers when their creative potential is assumed to be zero. It is the creative potential that makes the difference for productivity rather than the age of first publications.

Pygmalion Effect

A person's perception is sometimes as important as what they are observing or considering. In part for this reason, a great deal of research has examined the ways various psychological constructs, such as intelligence, creativity, or personality, are understood by various lay groups. These understandings represent what are called *implicit theories*. Explicit theories, which refer to views held by scientists and researchers, are shared, tested, disseminated, and discussed. All of the theories mean they are explicit, and they may have impact on scientific work and theory construction. Implicit theories are also potentially important. They are stable yet not shared or tested. The implicit theories of teachers about creativity are extremely important. They no doubt shape teachers' expectations about students, and those expectations are critical for students' academic achievement and intellectual growth.

The *Pygmalion effect* occurs when expectations lead to actual changes in behavior. The label Pygmalion comes from a Greek myth that tells the story of a sculptor from the island of Cyprus who carved an ivory statue of a woman. She was so beautiful that Pygmalion fell in love with her. Pygmalion treated the statue as if it were an actual woman and wanted it to be real. He prayed to Aphrodite, the 'goddess of love,' who brought

the statue to life. Social psychologist Robert Rosenthal was the first to name this effect, and thus it is also known as the *Rosenthal effect*.

The role of expectations on human behaviors is discussed not only in the concept of the Pygmalion effect. There are other effects related to expectations, such as the Hawthorne and Placebo effects. However, the concept most closely related to the role of expectations on human behavior and that on which Rosenthal bases his definition is *Self-fulfilling Prophecy*. Understanding the Pygmalion effect is easier when self-fulfilling prophecy is well-understood.

Self-Fulfilling Prophecy

Like the Matthew effect, the concept of self-fulfilling prophecy was introduced by Robert K. Merton. In his book, *Social Theory and Social Structure*, he defined it as the situations in which people's expectations can alter realities in the expected direction because the target person acts in accordance with the expectations. Self-fulfilling prophecy highlights the importance of definition of situations: "If men define situations as real, they are real in their consequences." This principle, however, works in many cases of subjective reality regarding human affairs, but not for natural affairs. Note that the definition of the situation does not have to be correct. Hence, a false definition of the situation may trigger a new behavior which can make the false definition become true.

There are plenty of examples self-fulfilling prophecies. Think of the banking system. Can a bank go bankrupt because of rumors that it is going bankrupt? According to self-fulfilling prophecy, that is very possible! If a good majority of the investors are convinced that the bank is going to collapse soon and that they may not be able to withdraw their money unless they do that as soon as possible, it may become a reality. Their expectations, which were not true beforehand, led to a new behavior which, in turn, resulted in what they expected. Some researchers explain underachievement of the black population in the United States with the concept of self-fulfilling prophecies. Prophesized underachievement becomes a reality.

There is empirical support for the concept of self-fulfilling prophecy. Ray C. Rist was interested in teacher-student relations based on the premise that students' variations in success, rewards, and creativity should be considered in a larger scope, the social structure surrounding them. He, therefore, argued that the dynamics of the interaction are not uniform and hypothesized that initial presuppositions of teachers about their students' abilities and their expectations are critical for academic achievement. Teachers, informed that certain students were 'fast learners' or 'slow learners,' treated those two groups of students differently and had different expectations. He observed that teachers have recognized that their expectations were biased and influenced by their social status and ethnicity.

How is it possible? One answer is that these expectations about others are communicated to those who are expected to behave in particular ways and that those who receive the message then react in accordance with this message and consequently confirm the expectations. The power of the message communicated is related to the subjective status of the message sender. If the person who claims a prophecy has

high status in the eye of the message receiver, the message is perceived and followed as if true.

The overlapping aspects of the Pygmalion effect and self-fulfilling prophecies are clear: the power of expectations. But how are they different? The Pygmalion effect could be defined as a self-fulfilling prophecy that occurs at an interpersonal level. "One person's expectation for another person's behavior can quite unwittingly become a more accurate prediction simply for its having been made." Whereas self-fulfilling prophecies explain the influence of beliefs on the consequent behavior, the Pygmalion effect specifically focuses on how one person's expectations about another person's behavior can turn out to be a reality just for having been expected.

The Pygmalion effect is more intriguing when it is applied to creativity. First, there are some settings, like school or business environments, in which creativity is markedly influenced by interpersonal relations. In those settings, power relations and the status of the others might play a significant role on the manifestation of creativity. The question above can be altered with that in mind: "What would happen if, for instance, teachers could change their expectations about the creativity of their students?" "Could this lead to a positive change for the students?"

Teachers and Students' Creativity

Teachers' expectations are especially important when it comes to creativity because studies show that there is already a mismatch between teachers' perceptions of creativity and creativity as a construct and its correlates. Erik L. Westby and V. L. Dawson examined teachers' understanding of creativity in comparison to the definition of creativity in previous studies. Teachers were also asked to identify their most and least favorite students. They found that teachers' perceptions of creativity were different from those in the prior studies. Interestingly, students who are unappealing to teachers exhibited the characteristics of creative people. Teachers tend to see their favorite students as creative students, whereas they do not regard their least favorite students as creative. It is not hard to imagine that teachers' expectations about those favorite but not very creative students will be high and that the expectations about those not favored but nevertheless creative will be low. In other words, the Pygmalion effect seems to influence some students but not all, especially the creative ones.

R. Pippert conducted an experimental design to test the Pygmalion effect for creativity. *Torrance Tests of Creative Thinking* were administered to 20 fourth-grade and 20 sixth-graders who were randomly assigned to experimental groups. The results of this test were given to teachers as pretest results so that they could 'know' which students were 'highly creative.' Teachers were encouraged to observe those highly creative students for their creative potential. Those names were brought up again over a period of several months. The pretest was administered again and results showed that students in the experimental group classified as creative improved their creativity scores more than those in the control group. In interviews with teachers, they were asked if they suspected the stated purpose of the study. The creativity scores of pupils whose teachers did not doubt the stated purpose were higher than the pupils whose teachers did.

In another study by Rosenthal and his colleagues, all children in grades one through six received a test that supposedly discovers creative potential. Also, they were asked to draw a man and to draw as many things as they could. Twenty percent of the children were randomly selected as 'bloomers' in terms of creative ability, and the teachers were informed that those children had unusual creative ability. The tests were administered again at the end of the academic year, and classrooms and teacher-student interactions were observed. Even though no overall difference was found for teacher expectancy effect, 'bloomers' in the fifth grade performed at higher levels than those not identified as unusually creative. Even though those results did not convincingly demonstrate the Pygmalion effect for creativity, another finding from this study underlined the role of teachers: the students with the highest score gains had teachers who are likeable, interested in children, enthusiastic, professional, and inclined to give encouragement.

Prophecy Creativity

Can we manipulate the creative performance of people by changing our expectations about them in other settings? An empirical study by Samuel J. Marwit and James E. Marcia provides an answer. They used responses to inkblot tests as an indicator of intellectual ability. Since inkblot tests involve obscure stimuli, the responses to them can be viewed as a measure of divergent thinking ability, which has been regarded as a good estimate of creativity. They hypothesized that the number of responses given by a subject is influenced by the examiner's expectations. In the study one group of examiners predicted many responses while another group predicted few. The results showed that subjects of the former group provided 54% more responses than the latter group. In another study, examiner's expectations were manipulated regarding the possible responses from the inkblot tests by letting a group of them know that more animal percepts should be obtained than human percepts. The other group was told the opposite. The ratio of animal to human percepts was 33% higher in the former group than in the latter group. These two studies indicated that expectations about others can influence the creative responses as well as change the content of the responses.

Pamela Tierney and Steven M. Farmer tested the role the Pygmalion effect has on employee creativity in organizations. Supervisors who have high expectations about employee creativity were perceived by employees as supportive of creativity. The correlation between supervisor and employee expectations for employees' creative performance was moderate and significant. According to this study, expectations manifest their influence through intermediate steps like motivational effects and self-efficacy. Employees' self-efficacy on creativity mediated the Pygmalion effects (supervisors' expectations). This means employees who were seen as highly creative by their supervisors and reported about themselves that they had a strong creative capacity demonstrated more creativity in their works. This finding confirms the proposition that the expectations of others are communicated to them.

In another study in an organization setting, researchers hypothesized that leadership, individual problem-solving style, and work group relations influence innovative behavior through their influence on perceptions of the climate for

innovation: the more supervisors expect innovative behaviors, the more a subordinate becomes innovative. The analyses showed that expectations of supervisors influenced individual innovative behavior even though this effect is specific to certain tasks such as technical tasks.

Studies of the role of expectations on creativity showed that assuming creative potential in everyone is conducive to creativity. Recognizing the significance of Pygmalion effects for creativity, thus, would be a significant addition to the implicit theories of teachers and supervisors.

Founder Effect

Recall that the Matthew effect emphasized the social mechanism of sciences that favor the famous scientists. Nickles defined another term, the *Founder effect*, also known as the *Historical Priority effect*, which refers to the importance of the timing or primacy of the scientific works. The idea is that some works of obscure scientists can make them famous just because of the triggering effect of the works. The Founder effect is best understood along with the Matthew effect and sometimes competes with it. Both involve the distribution of credit among discoverers. The Matthew effect highlights the role of reputation and other advantages on the distribution of credit while the Founder effect underscores the role of initiation or foundation of a new line of thought. The Founder effect represents cases where scientists made a name for themselves just because their work launched a new idea or series of research and triggered others scientists' works that in turn may have yielded a discovery. Hence the Founder may not have himself actually discover the key finding.

According to Nickles, two different models of creativity are possible: traditional/enlightenment and romantic models. He argued that all discoveries fall into one of these. The Enlightenment model relies more on empirical proofs which are evaluated through inductive or deductive reasoning. Because of heavy emphasis on rational means, scientists are viewed as calculating engines. Romantic reaction to enlightenment view relies more on intuition. Instead of tracking the empirical evidence through rational processes, sensitivity to the lack of fit on the whole is viewed as responsible for the discovery. Oft-cited 'Aha!' moment in the creativity literature was a romantic understanding of creativity.

The two perspectives merge on their conception of science as a *one-pass process*. This suggests that scientific works are presented as if they become knowledge when they are finished like a snapshot of the final scene without elaborating on the processes of reworking, reconceptualization, or rejection. This is a simplification that reduces a whole process into 'scientist A made discovery Z' thinking. In actuality, scientific discovery is a *multi-pass process*. Several investigators usually make contributions, additions, or reinterpretations, each taking the problem into a different point. Because of the heavy cognitive overload involved with multipass thinking, and the emphasis on the individual in the history of science, it is easy and typical to recall the 'heroes' of science and ignore the complex networks that each added small blocks to the huge building. Jose Ortega y Gasset actually proposed that modern science owes much of the contribution to mediocre scientists who constitute the

majority of the community. One last point about Founder effects: the initial step that provides the initiators with credit can be in the wrong direction with respect to scientific correctness, or it may be misunderstood by the real contributors who followed the founder. Some prominent examples for Founder effect are Max Planck and Frederick Banting.

Example Cases

Max Planck is known as the discoverer of quantum of energy because of Einstein and Ehrenfest, who started their works with (and misread) Planck's works. The discovery of quantum of energy, in fact, emerged years later, and Planck's solution to the problem was abandoned. Max Planck initiated his work and got credit because he coined the term 'quantum,' while his solution eventually was not accepted. In this example, association of the discovery of quantum energy with Planck rather than Einstein can be explained by Planck's reputation (therefore, the Matthew effect is relevant in this situation because Einstein was not well known at that time) as well as his initiative for a new line of thought even though his naming was just accidental and [his] solution was not correct. In Planck's case, both Matthew and Founder effects operate together.

Frederick G. Banting's case (along with Charles Best) represents how an enthusiastic but unknown scientist can get credit for his initial work that gave birth to a significant discovery. Even though Banting was credited with the discovery and received the Nobel Prize, his work was not on the right track in terms of the resulting discovery. His hypothesis, based on the idea of duct ligation to isolate internal secretion in the

pancreas, did not comply with the established facts in physiology. He was correct in addressing the problem (which concerned enzyme action) even though his work did not solve it. However, that deficit did not change the fact that Banting's idea was the first step that led other researchers to contribute to the solution. Banting was an unknown scientist when he came up with his idea. Therefore, his case represents the sole operation of the Founder effect without the Matthew effect.

Similar to the Matthew effect, the central idea of the Founder effect is the suggestion that there is more innovation in science to be recognized and, therefore, more credit to be shared among many more contributors. Nickles noted that the problem of cognitive overload can be handled by de-emphasizing the individual scientists so that the role of social 'state variables' and 'forces' can be better understood.

Margaret Mead 1901–1978

Introduction

In the image we have of her later years, she moves determinedly with her trademark walking aid – no ordinary cane but a forked stick of British cherry wood, as high as her shoulder. Her figure is short and unshapely, and she might easily be described as dowdy (unless one notices the careful attempts to take account of fashion in her dress). Despite her superficially nondescript appearance, this woman is no more ordinary than her cane. Her appearance, whether on New York streets or on TV, made her a popular eponym for a sojourner in primitive, exotic territory. The field trips that she completed before her middle age left in their wake countless young persons who dreamed of becoming ‘another Margaret Mead.’

Four decades earlier, she was slight with traces of recent illness that caused her mentor to impose some restrictions on her first field trip. The year was 1925, and the prominent anthropologist, Franz Boas, was sending Margaret on her way to Samoa to study ‘how the young girls react to the constraints of custom,’ and the related topics of adolescent crushes and the budding of romantic love.

In more than one sense her academic discipline was almost as young and professionally uncultivated as Margaret herself. There was a strong sense of urgency to investigate unstudied cultures at the point of vanishing before the advances of modern civilization. (Margaret reported that “When I was a graduate student, I used to wake up saying to myself, ‘The last man on Paratonga who knows anything about the past will probably die today. I must hurry’” (Mead, 1972: 338).) Despite the temporal pressures, little money was available for the purpose. There were few graduate students currently pursuing anthropology (only four of them at Columbia, where Margaret was working on her doctorate). There was a paucity of instructors; Boas taught almost all of Margaret’s courses. While prior investigations had tended to be male oriented, Margaret would be a female studying other females. And, perhaps the greatest challenge of all, as Margaret noted, there had been little or no ‘how’ in her previous education for field work; thus, she was forced to invent her methods of study literally on the spot. It is her creativity in this respect and its wellsprings – rather than the facts of her research – on which this article will focus.

In her autobiography, *Blackberry Winter*, Margaret speculated about who and what accounted for being “brought up within [her] own culture two generations ahead of [her] time” (Mead, 1972: 2) – testimony to a certain creativity of which her parents were continuing exemplars. Certain aspects of that childhood are undeniably significant in Margaret’s developing creativity. As detailed in what follows, information about Margaret’s growing years will come – unless otherwise explicitly indicated – from the composite of Mead’s autobiography and Jane Howard’s biography of her in 1984.

Growing Up as a Future Anthropologist

Born on 16 December 1901, Margaret was the first of her parents’ children and the first baby born in a new hospital in Philadelphia (at a time when hospital births were still considered *avant garde*). In her reflections on her childhood, Margaret seizes initially on her status as the child of two social scientists, concerned in their different ways with the condition of the world.

Margaret’s mother continued her research toward a doctorate in sociology while raising a family that would eventually include four children. (A fifth died in infancy.) Margaret’s mother, Emily Fogg Mead, was in several ways a prototypic feminist, valuing her career objectives, although finding herself with little time to spare for them. Her agenda embraced numerous household tasks even though fluctuating levels of domestic finances did allow some household help, including a series of cooks. She was an attractive woman but not inclined to spend money (or have it spent) on unnecessary clothing, hair styling, furs, or personal ornament.

Margaret’s father, Edward Sherwood Mead, was an economist on the faculty of the University of Pennsylvania’s Wharton School of Finance and Commerce. However, he was more peripatetic than the average academic, as he helped to establish extension branches of the university, and this – like his wife’s research needs – occasioned a number of temporary but recurring moves of the Mead household. Despite his professional focus on economic matters, he seemed to let money slip between his fingers and was financially strapped when Margaret was ready for college and planning to attend Wellesley. Only an atypical intervention on the part of Mrs. Mead persuaded him to relent from his initial opposition to any college plans and allow his daughter to enter De Pauw University, his undergraduate school. (He permitted Margaret to transfer to Barnard the following year.) According to Margaret, the temporary resistance to her academic ambitions was pecuniary and not associated with minimization of female intellectual potential. On the contrary, “. . . he thought of purely intellectual endeavor as feminine. He had barely known his father and he had the same kind of mind as his mother. Characteristically, he was very proud of my mother’s achievements and honors . . .” (Mead, 1972: 45).

The third significant adult and the ‘most decisive influence’ in Margaret’s childhood was her paternal grandmother, who lived with the family throughout Margaret’s transitions from infancy to adulthood. Margaret was home schooled for the majority of her preadolescent years, attending formal schools only sporadically, and her chief teacher was that grandmother, Martha Ramsay Mead. Martha was well suited to undertake her granddaughter’s education. She had been a schoolteacher as a young woman, went to college with her husband after their post-Civil War marriage, and after graduation taught at both early and high school levels.

Her methods of instruction were different from what Margaret might have encountered in contemporary public instruction; she deemphasized rote memorization and emphasized observation and inductive skill. She was also significantly free of the sort of social consciousness that Margaret's mother demonstrated.

Seeds of Later Work

What were the repercussions of this early environment for Margaret's later work? There are several possibilities:

Margaret seems to have had an early disposition to compare her own social experience to that of others without immediately assuming the superiority of the more familiar circumstances. She attributed her ambivalence to her sense of difference: "I took pride in being unlike other children and in living in a household that was itself unique. But at the same time I longed to share in every culturally normal experience ..." (Mead, 1972: 21). Margaret's ease with an itinerant life style facilitated Margaret's work across cultures. Her daughter, Mary Catherine Bateson, suggested a complementary benefit of Margaret's frequent changes of venue in adulthood: "By her peripatetic life, she created a kind of multilogue to which individuals contributed who would otherwise have been in isolation, their ideas never juxtaposed in fruitful ways" (Bateson, 1984: 198) Bateson added that "the greatest part of her originality lay in the invention of ways of listening and synthesizing" (Bateson, p. 198). There is an interesting echo here of what Margaret said she respected most in her father, namely, his capacity to listen (Mead, 1972). Listening is, of course, an essential component in the process of observation and note-taking.

Nancy McDowell in 1980, Jane Howard in 1984, and Sydel Silverman in 2004 all pay tribute to Margaret's distinctiveness in those composite skills. Howard considers Mead's notes to be the most important souvenir of her field trips: "With each field trip, she refined her note-taking techniques, distinguishing more and more precisely the events from the patterns they represented, and supplementing each record with letters home" (p. 430). Margaret received an early grooming in note taking from her grandmother, who assigned her the task of taking notes on the behavior of her two younger sisters, Elizabeth and Priscilla, born respectively when Margaret was between seven and ten years old. Margaret viewed this note taking as a continuation of her mother's journaling of her own infant achievements (13 filled notebooks) and that of her younger brother, Richard, born some two years after Margaret, his achievements – as is typical of second borns – receiving diminished maternal attention, although still occupying four notebooks. Margaret began to think of her younger sisters as her own children, whom she could not only observe but also "teach and cultivate" (Mead, 1972: 69).

Parentification and Creativity

This childhood fantasy of playing the parental role is one aspect of the phenomenon of parentification which has been noted to contribute significantly to the development of other

creative women. Margaret's recruitment by her grandmother to help her with the younger Mead daughters likely fed Margaret's parenting fantasies, but the experience of her own rearing by her parents was also a strong potential contributant. In the prologue to her autobiography Margaret recalled the words of one of her oldest friends: "In my house I was a child. In your family's house I was a person" (Mead, 1972: 2). The friend's description of the Mead household has its parallel in Margaret's reflection toward the end of her autobiography, "In my family I was treated as a person . . . It might be necessary to keep me . . . from reading too much or sitting up too late. But it was never suggested that because I was a child I could not understand the world around me and respond to it responsibly . . ." (p. 301).

Temperamentally strong willed, Margaret was able to capitalize on the degree of autonomy her parents granted. She related several pertinent anecdotes: Sent from the table for not having washed properly, she banged every one of the six doors between the dining room and her "third floor refuge" (Mead, 1972: 40). Margaret was three years old when she was walking with her father who rebuked her for kicking wet leaves as she walked. After he walked off in frustration, Margaret sat down on the wet pavement and, with some evident calculation, bewailed her abandonment to a small audience of other Sunday strollers. This early sense that in some way she "had always been a match for Father" (1972: 42) may have fortified her throughout a lifetime in what other women might have considered a redoubtable 'man's world.'

A year or two after the latter incident Margaret decided, for reasons that are unclear, to organize a secession from the household, involving herself, her small brother, and an infant sister, Katherine. Defeated by the logistics of securing food and bathroom necessities while keeping doors locked, she finally yielded to her quietly pleading mother. The undercurrent of precocious control in these tales from the nursery has a potentially important relationship to creativity insofar as it signals a cognitive flexibility, a freshness of perspective that fortunately was not wedded to interpersonal insensitivity.

The infant sister in the abortive secession attempt seems the catalyst for what, following Jefferson A Singer and Peter Salovey in 1993, might be called a self-defining memory in Margaret's history – one which, curiously enough, became prominent when Margaret was already an adult. Baby Katherine, the delight of her family, died suddenly before she was a year old. Margaret responded to the loss with a series of daydreams, culminating, in her twenties, with the fantasy "of being stolen away to educate a child; when she was grown, my friends recognized that she must have been my pupil, for only I could have brought her up" (Mead, 1972: 67). This memory is not precisely dated, but we may suppose that it occurred within a few years before she stole away (figuratively) for work that would become intimately joined to her idiosyncratic educative goals – work that would not only bring her the recognition of her friends but also the attention of the world.

Although Mead was not among the exemplars of creativity considered by Mihaly Csikszentmihalyi in 1996, his reflections may be pertinent to an examination of her early years. While he repeatedly asserts the high variability of precursors of adult creativity, among those he found worth mentioning were the parent(s) treating the child like a fellow adult and the incidence of 'missing fathers' in the individual history. In exploring

the latter phenomenon Csikszentmihalyi contends that it is not the actual paternal death (or, one is tempted to add, prolonged absence or noninvolvement) that is crucial, but the effect it has on the child's assumption of adult responsibilities. Mead's father was not missing from her life, but as the foregoing account of her development indicates, parentification was prominent in her activities, and household values encouraged a certain egalitarianism in her interactions with adults.

Csikszentmihalyi notes that, strange as it may seem, creative persons' formal schooling appeared to have little effect on their lives. Individual teachers, on the other hand, were often an important source of inspiration. Thus, Margaret could not be considered disadvantaged by her dearth of formal education. The influential educator in her early life was, of course, her grandmother. It was that grandmother who was the imaginary audience for her first letters from the field (cf. Mead, 1977).

Coming of Age in Samoa

One might find an unintended *double entendre* in the title of Mead's first book (1928/1973) – the report of her first field trip, which was to make her at least a minor celebrity while she was still in her twenties. Doubtless, Mead ripened as an anthropologist-in-the-field during her solitary investigation of Tau, a site in American Samoa. The observational techniques, including mode of recording, that she developed – and the focus of the observation itself – would have a significant impact on future anthropological field work. Although her interpretation of her data would stimulate considerable controversy throughout her career life and particularly in the decade after her death, what Silverman in 2004 described as the fastidiousness of her field work is likely among her greatest legacies to her fellow professionals. In Silverman's words: "Mead was in many ways a pioneer ... scrupulous about detailed recording, about keeping data in a form that made them usable by other scientists, and about stating explicitly the method she used and the circumstances under which her data were collected" (Metraux and Silverman, 2004: 212).

Mead only gradually found her way to anthropology. As an undergraduate at Barnard she considered various career possibilities, including writing, politics, sociology, and psychology. She took her master's degree in psychology, using the population (Italian American immigrants) that her mother had studied for a master's degree in sociology, but with a distinctively psychological topic (intelligence testing). The eminent anthropologist, Franz Boas, whom Mead initially encountered in her undergraduate course work, suggested the topic; his interest in issues related to mental life may well have eased Mead's transition from one to another of the social sciences. Indeed in his 'Foreword' to *Coming of Age in Samoa*. Boas summarized what he regarded as an outstanding gap in previous anthropological research: "The personal side of the life of the individual is almost eliminated in the systematic presentation of the cultural life of the people ... yet the way in which the personality reacts to culture is a matter that should concern us deeply ..." (Mead, 1963: iii).

Mead was attracted to anthropology by Boas and, to an even greater degree by Ruth Benedict, an older graduate

student and instructor at the time. Benedict told Mead that all she and Boas could offer the younger woman was the opportunity to do meaningful work. No enticement could have been more compelling.

When the time arrived for Mead to go into the field, Boas steered her toward work with American Indians, but Mead's preferred target was Polynesia. Her doctoral dissertation, a traditional library effort, had involved that part of the world. Margaret described herself as a graduate student "when [she] dimly understood anthropology as a salvage operation" (1972: 338) concerned principally with elders' memories, peculiarities of kinship systems, consequences of primitive myths, etc. Boas agreed to a compromise on the site for her work; she could go to American Samoa, devoting her days to work among the natives but would have overnight residence in an American naval home, a resolution of his concerns about Mead's physical frailty. He also offered her an atypical topic – the relationship between culture and the presence or absence of adolescent stress.

It might appear that Boas was using Mead's prospective work to capitalize on his own projects, but it seems likely that the topic reflected a coincidence of interests in the mentor and the former student as well as laying the groundwork for what Mead retrospectively considered a pioneering focus, namely, the study of women by a woman. Moreover, it represented an extension of what had been her sustained focus since her own childhood – a preoccupation with child rearing.

Of course, Boas was not without a working hypothesis when he sent Mead off on her maiden investigation. Simply put, he believed there was no biological necessity undergirding the experience of the adolescent stress that was frequently reported in American culture. After all her observational forays, Mead returned with what appeared to be data confirming the existence of a smoother, less troubled adolescence in the Samoan culture. Initially, the book on Mead's Samoan venture grabbed the popular imagination. Highly readable, it was to become a best seller.

Prior to publication, Mead's publisher persuaded her to enhance the book's appeal by adding two chapters in which she made educational suggestions in the light of her findings. She was quite amenable to this suggestion which was entirely consistent with her childhood fantasy of being in a privileged position with regard to offering child rearing recommendations.

The recognition Mead received from the book and consequent speaking engagements gave her an early start in what would be an important component of her professional lifetime – interpreting her scientific work for the public and introducing that public to her professional field. Unfortunately, her advice may have entailed some premature generalizations, and this could be viewed as a scientific misstep.

Margaret returned from her Samoan adventure with something she was less inclined to discuss publicly – the seeds of what would be a new romance. Before leaving for Samoa, Margaret married her high school sweetheart, Luther Cressman. A dock strike in England had affected the itinerary of the ship on which she was traveling, and a consequent layover in Sydney left Margaret and a few other passengers whiling away the extra time aboard ship rather than touring the city. Among them was Reo Fortune, a New Zealander, bound for Cambridge. The two young people struck a chord that

resounded in Margaret's mind for months after they parted, and what began as a friendship culminated finally in divorce and remarriage for Margaret. The ease with which Margaret secured a nonacrimonious divorce and made the marital transition from Luther to Reo is somewhat remarkable. She supplied few details in her autobiography (and, indeed, had tried earnestly to keep the matter private for decades).

The divorce is given short shrift, but what Margaret does say in 1972 is illuminating. She recalled an early unshared fantasy of hers and Luther's which had them living with six children in a country rectory where they could serve a parish that depended on them heavily. However, when on the basis of her tipped uterus, a gynecologist warned her to expect nothing but miscarriages, her vision of the future changed: "... if there was to be no motherhood, then a professional partnership of field work with Reo, who was actively interested in the problems I cared about, made more sense than cooperation with Luther in his career of teaching..." (1972: 189). Again, there is evidence of the *idée fixe* of child rearing potential which had a pivotal position in both her professional and her marital decisions.

Stranded on a Mountain Top

Mead was never again without a professional partner on her field trips, and in the most widely known of these shared ventures – her work in New Guinea – she would address a hitherto largely untreated topic, the anthropology of sex and gender. Initially, both the site and the topic (like the acquisition of Reo Fortune, her first field partner) owed much to chance. Mead and Fortune were on their way to a site Reo selected to suit his research purposes, with Margaret evidently prepared to adjust her research to the site. Their route involved crossing a mountain ridge that, because Margaret had a weak ankle, required the use of native porters for her transport as well as the transfer of material necessities. For some reason the carriers deserted their task, stranding Mead and Fortune on the mountain top. Since movement forward was not immediately possible, the researchers decided to make the best of their situation in a small and unpromising community. Thus began Mead's investigation of the Arapesh and her long-run reflections on the relationship between sex and culture.

Mead ultimately considered *Sex and Temperament*, the book that emerged from her work with the Arapesh, and subsequently the Mundugumor and Tchambuli, to be her "most misunderstood work" (1963). For years readers would be impressed by the striking contrasts evident in her description of the three groups. Mead herself had been struck by the different ways in which they either attended to or ignored sex differences. Among the Arapesh she found that qualities considered stereotypically feminine in American culture were valued in members of both sexes. Among the Mundugumor, on the other hand, aggression thought to be more characteristically masculine in the Western world was cultivated in both sexes. In the third group, the Tchambuli, there was differentiation of expected behavior, but it was the reverse of that in Mead's home culture. Yet Mead seemed to feel her readers did not fully appreciate that the real target of her research was the discovery of personality traits as variations among

individuals that were not necessarily the consequence of sex. In her words (1963, Preface to 1950 edition, unpaginated) she asserted that initially she had "hoped that [her] investigation would throw light on sex difference" but "found after two years' work, that the material ... threw more light on *temperamental* differences, i.e., differences among *innate* individual endowments, irrespective of sex." Betty Friedan, in her classic feminist work of 1963, *The Feminist Mystique*, indicated the potential value of Mead's work to the recrudescence of the feminist movement more than three decades after the first edition of *Sex and Temperament*. Friedan maintained that societal images of the female could have benefited from Mead's "vision of the infinite variety of sexual patterns and the enormous plasticity of human nature" (Friedan, 1963/1974: 127), coupled with Mead's "truly revolutionary vision of women finally free to realize their full capabilities in a society which replaced arbitrary sexual definitions with a recognition of genuine intellectual gifts as they occur in either sex" (Friedan, 1963/1974: 127–128). Friedan pointed out a relevant passage in *Sex and Temperament*: "... many, if not all, of the personality traits which we have called masculine or feminine are as lightly linked to sex as are the clothing, the manners, and the form of head-dress that a society at a given period assigns to either sex" (Mead, 1935/1963: 280)

By the time Friedan's magnum opus appeared, Mead had written another semi-popular work, *Male and Female* published in 1949, in which she revisited her earlier field work and specifically focused on questions of maleness and femaleness. For many persons who, like Friedan, subsequently examined trends in Mead's thinking (e.g., Lyons and Lyons, 2004), *Male and Female* may have seemed like a virtual *volte face* from the conception of wide-ranging role plasticity in *Sex and Temperament*. Friedan expressed her disappointment: "At times she seems to be arguing ... that while women's potential is as great and various as the unlimited human potential, it is better to preserve the sexual biological limitations established by a culture" (1963/1974: 128).

It seems possible to adopt a more generous perspective on Mead's stance in this work of the late 1940s. A close look at some of the pages that Friedan cites in reporting her frustration reveals that Mead was speaking interrogatively and not declaratively. In other words, she was raising questions that have continued to occupy scholars in the psychology of gender for decades.

In attempting to consider the relationship between and among sexual biology, individual temperament, and cultural influences on each of those factors, Mead was undertaking an enormously complex task. As Peggy Reeves Sanday said in 1980, "The manner in which she treated the interaction between biology and culture ... was unparalleled for someone writing on a subject fraught with so much waffling in Western thought. The complexity of her approach greatly confused reviewers, who wanted her to decide once and for all whether it was either-or" (p. 340). The questions she raised were not popular when she initially posed them, and her daring to abide with multidimensionality and ambiguity is a challenge for many readers.

In 1996, Mihaly Csikszentmihalyi describes low gender stereotypy and high tolerance for complexity as characteristics of creative individuals. The presence of both qualities in Margaret's makeup would seem to have equipped her well for work on what

would come to be called the psychology of gender. The three most significant adults in her childhood primed her to enact the female role in a nonstereotypic way. At the same time both her mother and her grandmother were constant examples of the importance of child rearing. It is hardly surprising that a 'continuing passion for the nurturance of children' sporadically invaded Mead's writings on female roles and, in turn, excited the animus of some feminist critics who regarded it as undesirable support for traditional thinking.

By 1963 – the same year that Friedan challenged the feminine mystique – Mead also indicated her growing concern with excessive adherence to traditional concepts of sex role dictates. In the preface to the 1963 edition of *Sex and Temperament*, she expressed the hope that "exploitation of the way in which simple primitive cultures have been able to rely upon temperamental clues may be useful in shifting the present extreme emphasis upon sex roles to a new emphasis on human beings as distinct personalities" (Mead, 1963, Preface, unpaginated).

The 'Quantum Leap' and Other Ventures

The married couple that left New Guinea after their mutual adventure with the three tribes were not the Margaret and Reo who had encountered each other years earlier on the docked ship. Stress and gradual estrangement supplanted their earlier attraction, and this time they went their separate ways.

After divorcing Fortune, Mead married anthropologist Gregory Bateson, whom she and Fortune met in New Guinea. The last years of Mead's intensive field work involved joint endeavors with Bateson in Bali and Iatmul. During this period they advanced ideas of anthropological record keeping by investing in equipment that permitted taking pictures in rapid succession. This allowed the photographs to constitute visual field notes that could be integrated with the corresponding verbal record – a procedure that Mead referred to as a 'quantum leap' and that has been hailed by other anthropologists for its inventiveness.

If Mead's autobiography slighted the unfolding of her career over the last several decades of her life, she did not neglect her maternal milestones, musing on the births of her daughter and granddaughter, to each of which she devoted a chapter. What she had seen of the active dislike of children among the Mundugumor, coupled with her distaste for the values of that culture, had fueled her yearning for children in an environment in which they would be appreciated and her determination to attempt pregnancy, despite the risk of repeated miscarriages. That desire was finally satisfied by the birth of her daughter, Mary Catherine, born in 1939 of Mead's marriage to Bateson. That marriage also ended in divorce. Again, few details are available, but there is reason to infer that this time the dissolution of the marriage was less agreeable to Mead than in earlier instances.

What Margaret herself recognized as an unusually intensive span of data collection in the field (1925–1938) turned out to be the period of her greatest inventiveness. These are undoubtedly the years in which and on which her public fame was founded. Those were also the years which she focused on in her autobiography.

Certainly, her remaining years were highly creditable by usual academic standards, that is, close to four decades filled with numerous well-received scholarly papers, interdisciplinary efforts, curatorial work, college teaching, and bidden and unbidden consultation with government officials and groups. In 1980, Dillon labeled her a citizen scholar and notes that there is probably no citizen who appeared more often on a greater variety of topics. Her public ministry also expanded to include television appearances and a monthly column in the women's magazine, *Redbook*.

A Rope So High

What were the most outstanding examples of Mead's inventiveness?

Margaret herself had something to say about this: She was convinced that she "had invented a new kind of field work, I knew how to study children and place their rearing within the total culture, in this way giving a dynamic element to what would otherwise be a fairly flat picture of the life of another society" (Mead, 1972: 231). This emphasis on the life of the individual within a given society – and not merely on the characteristics and practices of that society as a whole – was a reflection of Mead's interests in psychology. Those interests would spur Mead's various attempts to inspire interdisciplinary studies of anthropological subjects, which never seemed to excite as much cooperation across professions as she might have hoped.

The distinctiveness of Mead's field work was, of course, complemented by the meticulousness of her recording procedures, including her insistence on detailed note taking. Her notes were those of an "exceptionally honest ethnographer" (McDowell, 1980: 283) – and one might add, an exceptionally thorough one – including, for example, the conditions in which field work was conducted; the composition of field work teams; the division of labor among team members; and individual examples, that is, descriptions of actual persons; and situations in which she not only observed but also intervened in some way (McDowell, 1980). Eventually Mead's and Bateson's qualitative leap in photographic procedures enriched the meticulous record keeping.

As Nancy McDowell also indicated, Mead was careful to note the extent to which the presence of the investigator might distort data collection and interpretation. Reviewers of her work often seem to ignore this anticipation (by decades) of what would later be described elsewhere as the examiner/experimenter effect in the social sciences. In fact, in 1972 Mead suggested that differences between herself and her second husband, Reo Fortune, in their divergent observations on the Arapesh might be related to their temperamental differences. Margaret was more likely to seize upon nurturant components of the culture, while her husband, whom she saw as the more aggressive of the pair, might be more sensitive to the less frequent aggressive cultural elements. At more than one point, Mead expressed the hope that the effect of the investigator on the collection and report of data might become a regular part of anthropological research, but this was not to happen in her lifetime.

Another example of the effect of Mead's personality on her field work involves the issue of 'deviancy.' When Mead used

the term, she seemed to be referring not to psychopathology but, rather, to operation against the grain of the culture in which the individual was imbedded. Mead's interest in this subject was, again, ahead of her time. McDowell contended in 1980 that the frequent well-chosen and clearly labeled use of deviant examples in Mead's writing helps clarify the general operation of the culture, with the reader apparently learning from the exceptional cases. In their discussion of the significance of cultural deviation in Margaret's work, neither Mead nor McDowell makes what could be an interesting connection with Margaret's life: Margaret regarded herself as a "deviant" (Mead, 1972). It might be supposed that this self-perception of deviance referred to her following a career path that was relatively unusual for her time and, particularly in her youthful solitary field of work, required a degree of derring-do that was stereotypically male. However, this was not Margaret's view. For her the deviation worth noticing was in the reverse direction: "I was a deviant in the sense that I had much greater interest in the kinds of things in which most women, not committed to a career, were interested" (Mead, 1972: 227). In the content of Mead's body of writings, it seems quite valid to assume, as Howard did in 1984, that Mead was referring to what might be considered a preoccupation with children unusual in a career woman.

Mead's conception of deviancy was inextricably linked with her interest in temperamental variation. Her corresponding interest in innate dispositions belies any insinuation that she discounted the role of biology in the behavior of human beings. Indeed, her focus on temperament allowed her to visualize how biologically based tendencies could interfere with realization of cultural values or even promote resistance to them. On the other hand, she was attentive to the ways in which child rearing could modify the expression of temperament in the direction of cultural conformity. The picture she painted was a complex one. Research in the service of that complexity was her goal, although she repeatedly fell short of that ideal in the publicly oriented portion of her work. In a sense she was always the child self rendered in her exhilarated verses during the year of her first field trip, the child whose skipping rope got caught in trees as she attempted to tear a star from the star-studded sky. She closed those youthful verses with this image:

God only smiled at one whose glee
Could fling a rope so high (Mead, 1972: 145)

The gods of the social sciences were less forgiving when Margaret made a reach-too-far in her public pronouncements, whether in print or in her personal appearances. Many of her colleagues were disturbed by her premature generalizations, her supplementing incomplete knowledge with astute guesswork, and her readiness to speak as an anthropologist on almost any question (see the work of Rhoda Métraux and Sydel Silverman in 2004). However posthumous reappraisal of her career lifetime, for example, in the memorial issue of the

American Anthropologist (1986, vol. 82, no. 2), yielded a balanced perspective which honored her contributions without ignoring her limitations.

In 1984, Howard reported Friedan's verdict after Margaret's death on 15 November 1978: "I felt that Mead, who was born twenty years before me, had gone as far as she could with feminism and that I, in reacting to her, took it a step further and was in a way her heir. I felt part of a procession" (p. 426). The procession of social scientists has moved forward, but it is worth looking back occasionally at this singular figure who, depending on one's vantage point, appears as a young researcher, a citizen scholar, a champion of children, or the ghost of the child she once was – rope in hand and star in view.

Glossary

Encoding Assigning a specific label to the information that is to be stored in long term memory, in order to make it suitable for storage, retrieval, and further processing.

Long term memory (LTM) A system able to hold a large amount of episodic or semantic information permanently, organized as a network.

Retrieval Activation of the information retained in long term memory, presumably with the use of valid retrieval cues or specific mental strategies.

Storage The intermediate phase of the memory process, which consists in keeping the memorized information in the latent form that potentially allows retrieval and further processing.

Working memory (WM) System responsible for maintaining a restricted number of pieces of information for up to a few minutes; also acts as an information processing unit, responsible for the manipulation of symbols during problem solving and other types of cognitive activity.

Memory is a psychological structure that, apart from its many other functions, takes part in the cognitive mechanism of insight in creative problem solving and determines the specificity of information processing observed among creative individuals. The importance of memory phenomena to understanding of creativity is enormous, for obvious reasons: creativity is an activity of mind, and activities of mind are executed through memory. Therefore, creativity cannot occur without the participation of memory processes and structures. However, psychological theory concerning the relationship of memory to creativity is not well developed, and empirical results are rather scarce. For these reasons, the present article outlines the map of the problem at a very high level of abstraction and with a large amount of speculation. The order of presentation is determined by the stages of memory processes, corresponding to the stages of information processing.

Sensory Memory and Creativity

Stimuli arriving from the external world are first memorized for a short time by two structures: sensory store and short-term store. The sensory store (e.g., iconic memory for images or echoic memory for sounds) holds the information for less than one second. Because of its extremely short duration, the sensory memory is not accessible for introspection, and people usually do not realize that they possess such an ability. Both iconic and echoic memory act at the preparatory stage of stimulus elaboration, thanks to which the next stages are not swamped by a surplus of information.

There is no evidence whatsoever that sensory memory is connected in any way with creative processes or creative abilities. Interestingly, though, the sensory memory may play an important role in perception and appreciation of creative performances, particularly in music, ballet, and visual arts. From the evolutionary point of view, the sensory memory is still mysterious, but it is possible that it evolved in the service of speech perception. An ability to keep in mind sounds that have

already disappeared probably allows human beings to perceive spoken language smoothly and rapidly. Without echoic memory it would be perceived as a staccato of separate sounds. Keeping past sounds in mind for a moment makes this process much more efficient. Words are perceived as complex structures rather than sets of unconnected vowels and consonants; therefore they are recognized with enormous speed and efficiency. Moreover, holistic perception of words makes it possible to use prosody and intonation as a means of speech perception and, in consequence, as a means of language comprehension.

This is just a hypothesis but if the reconstruction of adaptive functions of the sensory memory outlined above is close to reality, we could speculate about relationships between echoic memory and music perception, as well as between iconic memory and ballet dancing perception. The same mechanism that makes speech perception speedy and efficient can produce greater appreciation of music (echoic memory) or ballet dancing (iconic memory). One can even doubt whether human beings would invent music and ballet as important domains of creativity if they were not able to perceive sounds and movements smoothly. Production of sounds and structured body movements obviously serve important social ends, such as communication, but these reasons seem insufficient to invent the art of music or dancing. For that, our ancestors had to be able to appreciate esthetic rather than social aspects of sounds and movements, which – according to my hypothesis – would not be possible without the phenomenon of sensory memory.

These speculations lead to yet another hypothesis, namely, that musical abilities (or just being fond of music) are rooted in individual parameters of echoic memory. People who can keep in their echoic memory more information for a slightly longer time may be better prepared to appreciate and understand music when compared with persons characterized by less efficient mechanisms of sensory memory. However, this hypothesis may be difficult to verify because individual differences in sensory memory have not been investigated at all.

Even if such differences really do exist, their range may be very restricted, as it usually is in the case of basic, evolutionarily old, and biologically rooted mechanisms.

Working Memory and Creativity

The short-term memory (STM) store is able to retain information for limited intervals of time, ranging from a few seconds to several minutes. This system is now called *working memory* (WM) because it is responsible for both maintaining pieces of information and manipulating them, which is synonymous with human information processing. Metaphorically speaking, WM is a central processing unit of the human mind, or 'the blackboard of the mind.' Less metaphorically, it is an active part of memory consisting of a number of pieces of information that are either in the state of readiness for upcoming processing or in the state of just being processed. It is unlikely that the central processing unit of the human mind would not take part in the cognitive mechanics of creative processes. Some theoretical models assume such an engagement in an explicit way. There is, however, little empirical evidence about how and to what extent working memory processes affect creativity.

Characteristically, WM is very limited not only in time but also in its capacity, because it is able to manipulate fewer than ten pieces of information (words, numbers, etc.) simultaneously. Short-term memory capacity is traditionally defined as the 'magical' number seven (plus or minus two) but this value is probably overestimated. Recent estimates (e.g., Nelson Cowan's) suggest that working memory cannot retain and manipulate more than four elements simultaneously. Although this is a very small number, people still differ in working memory capacity (WMC), and these differences result in different ability levels. It has been convincingly shown that WMC determines the general cognitive ability level (i.e., intelligence). Unfortunately, no evidence concerning the relationship of WMC to creativity has been obtained, although in some studies both intelligence and creativity tests were used to check this hypothesis.

The difference is probably rooted in the particularity of cognitive mechanisms of intelligence and creativity as two distinct dimensions of human intellect. Intelligence is the ability to tackle convergent, well-defined problems of average complexity and average novelty. Such problems are well described in terms of a number of separate 'chunks' of information, which have to be memorized and manipulated for a short time in order to let the problem solver reach the solution. In other words, an intelligent problem solver has to split the problem into separate portions of information, keep these portions in working memory, and manipulate them in order to achieve a suitable solution. In such cases, the more items a problem solver is able to keep in the short-term store, the more competent he or she is in tests consisting of convergent, well-defined problems of average complexity and novelty. On the contrary, if a problem solver's WM capacity is small by nature, or declines for any reason, he or she inevitably loses some part of his or her intellectual ability, because tasks that are critical for the person's intellectual level may surpass the actual limitations of WM.

Nothing like this seems to exist in the case of creativity. It is usually assessed with tests consisting of divergent tasks of low complexity (e.g., Unusual Uses, Alternative Definitions, etc.),

which do not exploit working memory thoroughly. As far as the limited capacity of WM is concerned, such problems may even be regarded as relatively 'easy.' No surprise, then, that creative abilities assessed with divergent thinking tests do not correlate with WMC.

Of course, creativity is not reduced to simply divergent thinking ability, particularly if real creative endeavors rather than basic cognitive skills are taken into account. However, there is no point in looking for the working memory determinants of 'real' or eminent creativity, either. The problems undertaken by exceptionally gifted creators and great achievers are usually divergent, too, but also ill-defined and very complex in nature. In fact, problem finding and problem definition constitute the vital part of creative processes in real life, that is, outside the psychological laboratory. Finding, definition, redefinition, and solution of such problems usually take a lot of time, effort, and motivation, but they do not seem to require extended capacity of working memory. Individual differences in WMC may matter in the case of problems of average complexity, because – for instance – if a problem needs four items to be kept and manipulated in memory, a person with a capacity of four is naturally endowed to tackle such a problem, whereas a person whose capacity is only three is naturally unable to deal with it. But both hypothetical persons are structurally unable to deal with a problem consisting of 100 or 1000 items of information, that is, with very complex, unclear, ill-defined problems that require a creative approach.

This does not mean that such complex problems are unworkable for any human being, whose WM capacity – even relatively large – usually does not exceed four portions of information. Rather rarely, a very complex and ill-defined problem is solved by a very creative individual by means of his or her exceptional capacities, but not necessarily by means of WM capacity, as it seems. Such creative achievements are attainable through specific strategies of problem solving, and through inventive manipulations with problem structure and problem definition. Such manipulations are sometimes referred to as *metacognitive strategies*. For instance, a creative person organizes his or her knowledge of the problem hierarchically: a relatively small number of higher-order, abstract portions of information may contain many lower-order chunks of information, accessible for processing only after having been 'unwrapped.' Another metacognitive strategy used by creative individuals amounts to simplification of the problem structure so that it is workable with WM of limited capacity. However, such manipulations refer to long-term memory processes, mainly selective encoding and 'familiarization.'

There is a paradoxical tension between the structural limitations of WM in terms of the very small number of items that can be effectively maintained and processed, on the one hand, and the requirements of complex and ill-defined problems that are typically undertaken in mature creativity, on the other hand. If 'creative problems' are much too complex for human working memory, no matter how efficient and capacious it is in the case of a given person, how can such problems be solved at all? An interesting solution to this paradox comes from the theory of long-term working memory (LTWM), developed by K. Anders Ericsson and Walter Kintsch. LTWM is conceptualized as a part of long-term store that is activated by retrieving cues maintained in working memory proper. In other words,

WM does not need to retain anything that is directly used in problem solving. It retains only retrieval cues, thanks to which the vital information is quickly and easily retrieved from LTM. Long-term store is not structurally limited, so there is no threat of it being overloaded. And a person must keep in mind only a few hints that make it possible to use a kind of 'highway' between WM and LTM. Ericsson and Kintsch believe that their model accounts for expert performance in a variety of domains, as well as for language comprehension. Since mature creativity is a form of expertise, their model should be explored more thoroughly in creativity studies.

Models of working memory usually assume that this structure shows two aspects: one purely mnemonic and another pertaining to cognitive control. For instance, in the model developed by Alan Baddeley the mnemonic functions are performed by such 'devices' as the articulatory loop and the visuo-spatial scratch pad, whereas the control functions are performed by the central executive, which is described as a 'device' of attention deployment. The dual nature of working memory suggests that creative thinking and creative performance may be determined by efficiency of cognitive control rather than by capacity of working memory understood as the number of 'chunks' that can be memorized for a short period of time. Or, possibly working memory capacity should be defined as an ability to perform mnemonic functions under the auspices of control mechanisms. For instance, switching between tasks is a popular means of investigating cognitive control. It seems that creativity requires switching between thoughts rather than tasks. An ability to switch from one mental activity to another is probably vital for flexibility of thinking and resistance to mental blocks. Such relationships have not been systematically studied, although there are data suggesting that a high level of dopamine increases the strength of cognitive control, reduces switch costs in the task switching paradigm, and improves performance on divergent thinking tasks, particularly if flexibility is taken into account. Creativity probably needs both increased and reduced cognitive control, depending on the phase of working on a problem at hand. Such studies, if performed systematically, should broaden knowledge about the relationship between creativity and working memory.

Long Term Memory and Creativity

Contrary to working memory, long term memory is able to retain information for an unlimited period; it is also assumed to possess unlimited capacity. This does not mean that the human mind is able to remember everything; however, forgetting and other imperfections of memory do not result from the capacity of the LTM store but from other sources, such as interference, inefficient strategies of remembering, etc.

Three basic categories of memory processes define the efficiency of operations in LTM: encoding, storage, and retrieval. These operations, or stages of the memory process, determine the way in which LTM performs its basic functions, including the ones connected with creativity, problem solving, and insight.

Encoding

Information cannot be placed in long-term store without having been encoded. This is an operation analogous to labeling

products in a department store or allocating new books to appropriate shelves in a library. Only after the information is encoded can it be stored in memory as a part of related knowledge structures. In most cases, encoding amounts to categorization. For instance, the scene shown in a news headline is categorized as a 'street accident,' a portion of textbook knowledge as 'the quantum theory of particles,' etc. The psychological function of encoding is obvious: it allows assigning the information to the appropriate parts of the LTM store. In this way, it makes it possible to arrange LTM as an organized system of knowledge. It is also a necessary condition for future retrieval, because nothing can be regained from the store without being properly labeled.

Creativity is probably connected with, and affected by, the specificity of encoding in three ways. First, a person can *encode information in a peculiar way*, different from other people. For instance, a child can categorize the animals familiar to him or her into the categories of nice, shaggy, and awesome. This kind of categorization, though illogical and far from what biology offers, probably serves some important cognitive needs of the child. Such categorization is also unusual, different from what the majority of people think about animals and how they classify them. This is probably why small children perceive the world so originally. Children's originality is normally accounted for in terms of their being free from obstacles, conventions, and inhibitions typical of adult life. However, this phenomenon should also be regarded as a manifestation of the unusual way in which children categorize objects, and in consequence as a result of the specific way of encoding information that is stored in their LTM.

In the case of adult creative individuals, the instances of bizarre categorization are probably accompanied by the conventional, 'uncreative' way of perceiving the world. In other words, an adult creative person is able to categorize the world in the 'official,' objective, commonly accepted way, as well as in the unusual, subjective, and personalized manner. This is the second exemplification of how the activity of this stage of LTM operations affects creativity: *alternative encoding*. A person who encodes alternatively is able to take advantage of unusual encoding (making unpredictable associations, discerning similarities, etc.), while still being close to reality and conventions – a phenomenon recognized by Ernst Kris as "regression in the service of the ego." Some techniques of creativity training deliberately focus on the phenomenon of alternative encoding, with the conviction that divergent thinking and unexpected associations are more likely to result from the ability to memorize the same item of information in many different ways.

The third property of encoding found in creative persons is *selectivity*. It is particularly important for the construction of the cognitive representation of the problem. Problems worth creative endeavor are usually too complex and ill defined to be memorized completely and categorized with the use of clear-cut terms. Selection of information is therefore necessary; however, successful problem solvers are able to memorize only the important elements of the problem, while ignoring less important and superfluous ones. Less efficient solvers try to memorize everything, thus being unable to focus on the gist of the problem situation. It is very unclear what the origins and determinants of this ability to encode information in the

selective way are, as well as to what extent it is susceptible to development and training. However, the selectivity with which some people store information in their LTM store inevitably makes them more efficient solvers of complex, ill-defined problems; therefore, it makes them more creative.

Peculiar, alternative, and selective encoding are responsible for creative behavior in many ways. They help people produce original associations, they are responsible for 'perceiving things' differently, and they allow simplification of the structure of excessively complex problems through selectivity of encoding. In many instances, creative behavior is a result of natural, effortless use of specific encoding, although from the observer's perspective it may give the impression of being a result of rather difficult and complex processes. In other words, creative processes are sometimes less 'exotic' than they seem to be from the point of view of somebody who normally does not encode information in a peculiar way.

Creativity also benefits from so called *prospective encoding*, which involves setting up criteria for future acquisition of knowledge that might be relevant to a problem at hand. Careful examination of the problem and its requirements helps establish exact criteria of information needed for the continuation of creative problem solving. Such knowledge may not be available at the moment, but it can be easily acquired upon the appearance of particular learning opportunities. The mental set established by prospective encoding induces highly selective acquisition of knowledge; consequently, it enhances the likelihood of sudden and insightful recognition of new possibilities for dealing with the problem.

Storage

Storage amounts to keeping previously encoded information for a long time. Contrary to naive conceptions of storage, it is an active process, likely to impose unexpected changes on the seemingly dormant information kept in LTM. Three phenomena connected with storage are worth investigation from the creativity point of view: selective forgetting, familiarization, and spontaneous recovery.

Selective forgetting may account for the phenomenon of 'incubation.' According to the classical four-stage model of creative thinking, incubation is a stage of unconscious idea production, following preparation but preceding illumination and elaboration. Modern cognitive approaches do not deny the empirical evidence that the 'incubational' break sometimes helps in the creation of new ideas, although they usually do not accept the notion of subconscious 'incubation' of solutions. It has therefore been suggested that, during the 'incubational' break, people selectively forget superfluous information, particularly the unnecessary elements of the cognitive representation of the problem. The memory preserves only a part of the information that has been gathered concerning the problem: its definition, requirements, and context. After having forgotten a huge part of this information, people are more likely to 'view the problem from a new perspective,' that is, to experience sudden and holistic understanding of the problem, synonymous with insight.

'*Familiarization*' is another term introduced by Herbert Simon in order to account for the phenomenon of 'incubation.' Simon assumed that problems worth creative endeavors

are complex and difficult, requiring a lot of time and effort to be solved. During the long process of problem solving, almost all trials seeking a solution are unsuccessful, except the final ones that result in solutions. This does not mean that earlier trials are worthless: their function amounts to 'familiarization' with the problem, that is, making it more and more understandable, clear, and simple. Simplification of the problem structure and definition makes it possible to grasp it with a small number of items of information. This, in turn, makes it possible to manipulate the problem within the system of short-term memory, which has very limited capacity to handle information. In other words, every instance of problem solving relies on the vital operations of working memory, which performs the basic operations of information processing. But in order to be suitable for such operations the problem has to be simplified to a great extent; otherwise, the working memory system is likely to be flooded. Familiarization is a means of making the problem simple enough to be dealt with by the system of working memory. Thus, numerous unsuccessful trials seeking a solution have an important simplifying function, due to which problems originally too complex become more and more workable for the very limited capacity of the memory system.

Spontaneous recovery consists in an increase of the likelihood of recall of information if it is kept dormant for some period of time, compared to the likelihood of recall at the beginning of the learning process. It is assumed that vital information is blocked by other pieces of knowledge, learned more recently or acquired through the learner's conviction of their importance. After some period of time the blocking pieces of information lose their activation, thus yielding access to the previously inaccessible knowledge. It is also assumed that the LTM store becomes more and more organized with time, a process taking place without any intention or effort on the learner's part. Due to such hypothetical processes, people can sometimes remember more information after some time has passed than at the beginning of the learning process – a phenomenon known as 'reminiscence.' These phenomena are important for creative thinking and problem solving because they may be responsible for the elimination of mental sets, blocks, and other obstacles often preventing people from attaining original solutions. This is why 'incubational' breaks probably help work out creative solutions, although there are other cognitive mechanisms that operate with similar results (e.g., selective forgetting, familiarization).

Selective forgetting, familiarization, and spontaneous recovery are possible mechanisms of insight, which – according to modern cognitive theories – is basically a memory phenomenon. From the phenomenological perspective, insight is a sudden flash of understanding ('Aha!' response). From the cognitive perspective, however, its mechanisms are probably rooted in operations taking place in long-term memory during the storage phase. However, recognition of such a theoretical possibility requires that storage be viewed as an active, purposeful, and 'creative' phase of LTM operations. Spontaneous changes of the LTM structure during the storage phase do not guarantee that insight will occur and help people solve the problem in a creative way, but without these cognitive operations the phenomenon of insight would be very difficult to account for beyond its purely phenomenological aspects.

Retrieval

Retrieval consists in recalling information previously encoded and then kept in the LTM store. It is the reverse process to encoding, and its efficiency mostly depends on encoding strategies used in the first stage of the memory process.

The main problem of retrieval amounts to *accessibility* of information stored in LTM. Creative ideas are often just recovered from memory, or they result from uncommon combination of stored memories, although they may create the impression of being crafted out of nothing. In other words, a creative idea – or at least the very core of it – remains in the LTM store for a long time, ‘waiting’ to be noticed and used. The difficulty lies in accessing such an idea or its bud, because it is not kept in memory in its ready-made, easy to retrieve form. If it were like this, it would probably be memorized and retrieved easily by many people; as a result, such an idea would reappear frequently and, by definition, could not be called creative. So, the act of creation consists, by and large, in the use of effective retrieval strategies, through which vital information may be accessed and used in problem solving.

Hence, the problem lies in making already stored information accessible, so that it can take part in the creative process. This aim is achieved in two ways: by the use of appropriate retrieval cues and by the application of effective strategies of search of the LTM store. The *retrieval cue* is a means of decoding information kept in the LTM store, analogous to the operation of taking away an item from the shelf in the real storehouse, library, or other kind of depot. Normally, the information is retrieved from LTM with the use of exactly the same code (e.g., a category or label) with which it was put into the LTM store. These are the instances of the commonplace use of memory, resulting in uncreative behavior. However, the information may be retrieved with the use of entirely new codes, providing that a problem solver is able to recode the items constituting his or her knowledge, that is, to label the pieces of information kept in the LTM store in a new way, different from the initial encoding. Analogical thinking is enhanced in this way, since notions, memorized events, and other pieces of knowledge can be retrieved on the basis of their similarity to other areas of experience. It is a process particularly important for creativity if the analogies and similes are remote and unusual, which means that the pieces of knowledge utilized for the building of the analogy have to be retrieved with cues other than the ones used during the acquisition of knowledge.

As to the *LTM search strategies*, the problem consists in making the search as global as possible. Robert Weisberg suggests that the inability to use previous experience while solving a new problem, a phenomenon frequently described in the literature on mental ‘ruts’ and other blocks to creativity, may result from ‘local’ memory search. This kind of search is limited to the narrow, well-defined areas of knowledge stored in the long-term memory, and does not apply to other areas of knowledge, even though these regions could be highly relevant to the problem at hand. A problem solver is unable to use some fragments of his or her knowledge because they are ‘too distant’ from the areas defined by the problem space, and thus look ‘irrelevant’ to the problem. Of course, the distance between the knowledge responsible for problem representation and some potentially useful but neglected areas of experience may be

superficial or only seem to exist. Furthermore, the boundaries between different fields of knowledge and expertise are usually fuzzy and conventional, sometimes artificial; however, they define the boundaries within which the memory search is normally performed. In consequence, the search is likely to be ‘local,’ that is, limited to the knowledge base that is directly applicable to the problem being currently solved. In order to make the search ‘global,’ that is, referring to the whole network of semantic memory and conceptual knowledge as well as to the vast number of episodes stored in LTM, the problem solver has to surpass the between-domain boundaries through analogy, metaphorical grasp, and mostly through the redefinition of the problem statement.

The creative search of memory does not have to be entirely global; sometimes it suffices to make the search less local, that is, less limited to the narrow conceptual boundaries defined by the initial problem statement. Redefinition of the problem statement naturally makes a problem solver more likely to cross the conceptual boundaries, as the newly defined problem requires a new set of information and provokes new associations. However, making the search ‘less local’ may be a deliberate strategy used by the problem solver, and trained during sessions of creative problem solving, not necessarily preceded by problem redefinition. On the other hand, redefinition of the problem is unlikely to occur without the global (or ‘less local’) search, because only the truly uncommon information retrieved from memory is able to make people perceive the problem in a fresh way.

Highly creative individuals are more inclined to global memory search than less creative people. The network of semantic memory of creative people is more compound, and thus more apt to make remote, unusual associations. The creative semantic memory is also more likely to be activated as a whole network rather than restricted associative regions if a priming stimulus is presented. The higher the general activation of the semantic network, the more likely it is that a person will perform a global search of the information needed during the problem solving session. Conversely, if the activation is limited to small areas of the semantic network, defined by the routine meaning of the priming stimulus, it is likely that a person will perform only a local search, with all its uncreative consequences.

Conclusions

Obviously, creativity is not just the proper use of one’s memory. However, the purely creative phenomena known from the studies of creative problem solving, like insight, analogical transfer of knowledge, or unusual remote associations, probably result from the peculiarity of memory processes. It is therefore justifiable to conclude that the memory of creative individuals differs qualitatively from the memory of less creative people. The quantitative differences (for instance, the sheer amount of knowledge about some topic) are probably less important because there is no evidence that the more one knows the more creative one is. On the contrary, experts are frequent victims of rigidity and mental ruts, unless their knowledge is flexible and creative due to the specificity of its organization.

Glossary

Affect Often used synonymously with emotions and feelings. 'Mood' sometimes refers to more general, diffuse and long term feeling states, as opposed to shorter-term affects or emotions. Feelings do vary over time periods varying from very short to very long.

Bipolar disorder A mood disorder characterized by periods of 'up' or elevated affect, generally as well as 'low' or depressed affect.

Depression Refers both to diagnostic categories characterized by low mood and specific cognitive and behavioral symptoms, as well as to these symptoms themselves. Symptoms include sad mood, cognitive symptoms of negative self-evaluation and attributions, and behavioral symptoms including slowed movement; it also can include physiological symptoms of sleep and appetite disturbance, and anhedonia, or lack of experienced pleasure.

Eminence Fame or recognition. Much early research on creativity and psychopathology was troubled by the confounding of eminence and social judgments with a person's actual level of creativity.

Everyday creativity A term used by Ruth Richards and colleagues to refer to creative activities, in work and avocations, of normal, non-eminent, non-extraordinary people in their day to day lives.

Flat affect A lack of emotion, either 'up' or 'down,' observed in people with schizophrenia and some other diagnoses. Overlaps with the lack of pleasure or anhedonia observed in people with a variety of diagnoses.

Mania, manic episode, hypomania Periods of 'up,' excited, or elated mood and associated behavior (including poor judgment and impulsivity). A manic or hypomanic (or mixed) episode is one of the criteria of the bipolar disorders. Hypomania refers to more mild forms of elevated mood.

Romanticism A philosophical and artistic movement, strongest in the eighteenth century, that emphasized the importance of 'primitivism,' nature and the natural, child-like innocence and a wild sensibility, and direct experience of the world. These were seen as fundamentals of life and of creative activity. A romanticist picture of creativity is held by many today, although there are other (e.g., modernist and post-modern) conceptions of artistic creativity.

Schizophrenia A severe mental disorder characterized by disturbances in several areas of functioning but predominantly defined by disturbances in perception (hallucinations, most common auditory), and cognition, the content (delusions) and form of thought. Related symptoms also occur in the less severe disorder, Schizotypal Personality Disorder.

Thought disorder Disturbances of thinking that mainly include formal thought disorder (how the person puts ideas together, reasons, and expresses ideas), which overlaps with unusual language. While formal thought disorder, particularly as assessed with psychological tests and procedures, was long held to be the defining characteristic of schizophrenia, it is now clear that it occurs in different forms across other diagnostic categories, including the mood disorders.

Introduction

Since at least the time of the ancient Greek philosophers people have noted similarities between the activities of creative people, particularly artists, and the disordered behaviors of madness. Aristotle observed a connection between what he called the melancholic temperament and genius, and this was famously expressed much later in Shakespeare's equating "madman, lover, and poet." During the nineteenth century the movement of romanticism valued madness – along with 'primitive,' 'natural,' and 'childlike' states and raw experience – as a route to art. Contemporary approaches attempt to ground the connection between creativity and psychopathology in empirical data; this research has taken up the complicated and rather vexing questions of trying to define madness, particularly in geniuses of the past, and the question of what constitutes creativity, again with problems of retrospective recognition of another kind. Moreover, some authors, notably George Becker, have argued that the connection between madness and genius is artificial, a myth reinforced or even created precisely by people's belief in it, the romanticist tenet that

artists and gifted people should be erratic and even insane. This prompted biased observation, self-fulfilling prophecy, and make-believe, creating geniuses and would-be geniuses who have appeared or pretended to be mad.

This article explores the possible connections between affective disorders – and related subclinical phenomena – and creativity (and related, sub-genius-level phenomena). It describes the strengths and weaknesses of the evidence and addresses questions regarding whether or not there are specific forms of creativity and of madness with different relationships among them. When considering mental disorders, it is useful to think in two ways: Diagnostically, where the emphasis is on categories of disorder, perhaps akin to physical illnesses; and, conceptually, regarding the characteristics and traits comprising these disorders. With creativity it is possible to focus solely on recognized geniuses (those who have been 'diagnosed,' via recognition, with creativity, and have achieved eminence either during their lifetimes or later), or on the more general (and sometimes less intense) characteristics of creative thinking and activity shared to varying degrees by everyone and observable in everyday life. The first approach, in the case of both madness

and creativity, looks at categories, the second at continua. Relevant affective disorder phenomena include depressed thoughts, feelings (e.g., sadness), and behaviors, as well as manic and hypomanic traits of vivid perception, elation, and behavioral and cognitive acceleration.

At a very basic level creativity and mental disorder are similar in being characterized by the living of unusual human lives in the realms of behavior, thoughts, feelings, spiritual activity, and, some might argue, physical health, form (for example, from a perspective of 'body performance'), or deformity. Physical illness also bears some connections to creativity, most likely inspiring or producing it, providing enforced contemplation, resulting from a hard lifestyle, as well as simply co-occurring with greatness. Genius and madness share being considered unusual; yet, later I will discuss Everyday Creativity, the way all of us, whether or not mad, famous, eminent, recognized, or particularly gifted, can be creative, and also sometimes somewhat mad.

Genius and Madness

Mental disorders are generally characterized as including unusual and troublesome components in three realms, behavior, thought or perception, and feeling. Creativity is usually defined as doing or producing something novel and original, with the caveat that this 'product' is of high quality. The latter introduces a confound with social recognition, customs, culture, and the judgment by others regarding the value and quality of a work; it is well-acknowledged that favorable judgment may not occur in the lifetime of the creative individual. People may not be well-known, well-regarded, famous, or eminent in their own lifetimes, but their work may be judged positively later, resulting in eminence after death. 'Outsider artists' may never be recognized, and there is current interest in unrecognized and belatedly-acknowledged women creatives and other 'outsiders.' Similarly, much work in this area has relied not only on *post-hoc* judgments of the creative work but also on retrospective diagnosis of psychopathology from biographical and historical evidence about a person's life in the past.

Creativity is usually judged on the basis of productive behavioral activity manifested in the course of the creative person's life and likely to last through the generations. This can be an artistic creation but can also consist of activities in the areas of leadership, achievement, or attainment, for example in the military or in business. Much of the research on the genius-madness controversy is muddy and confusing because it has required judging the validity or quality of a creative product as well as the assessment mental disorders retrospectively.

This said, there is a wide-ranging empirical and biographical literature that draws connections between psychological disorders and creative activity. Creative individuals have been judged retrospectively to have had grim and pathological life histories, including tumultuous and difficult childhoods and later lives, schizophrenia, antisocial-like behavior, alcoholism and drug addiction, depression and the bipolar disorders, and a variety of 'neurotic' disorders. When retrospectively diagnosed, many psychiatric categories are not easy to tell apart. In particular, the boundaries between schizophrenia and the mood disorders have been porous and controversial over the years.

Biographical studies focus on possible symptoms and diagnoses of creative and famous individuals in the past. Early research emphasized characterological disorders, but perhaps the strongest early research and theorizing drew connections between schizophrenia – and the disordered thinking associated with it – and creative work. In the 1970s empirical support for the connection between mental disorders and creativity came from literature suggesting genetic connectedness between mental disorders – mainly in the 'schizophrenia spectrum' (which at the time included some of the diagnoses now considered mood disorders) – and creativity and achievement. With psychiatric disorders in general some have argued for 'compensatory benefits' (such as creative thinking and drive) that may account for the persistence in the population of mental disorders with severe negative consequences for many carriers. Much as the sickle cell trait is linked to resistance to malaria, there may be positive selection pressure for traits genetically linked with mental disorders.

Biographical studies tended to find large numbers of people with schizophrenia among retrospectively diagnosed creative and eminent individuals, and to draw parallels between creative activity and schizophrenic cognition. Schizophrenia has been a compelling and fascinating concept, and in the earlier days of psychiatric diagnosis it remained a broad and rather ill-defined category encompassing much abnormal behavior and experience. In addition, psychoanalytic accounts of the creative process emphasized the power and utility of what Ernst Kris termed 'Adaptive Regression in the Service of the Ego,' the creative person's gaining access to 'Primary Process' cognitive and emotional activity operating as part of the Id and below the control of the ego. Primary process cognitions were thought to contain material that was raw, illogical (or a-logical), possibly child-like or developmentally early, uncontrolled, full of the primary drives of sex and aggression, and unedited. It was asserted that people with schizophrenia had easier and often unintended access to this material – possibly essential as the raw material of creativity – than did others, who might only access their unconscious lives in their dreams.

Cognitive approaches tended to focus on the relationship between creative divergent thinking (as it was conceptualized by Guilford) and the disordered thought of schizophrenia (thought disorder, TD). Keefe and Magaro noted that both thought disorder and divergent thinking (TD and DT) may be indistinguishable conceptually and represent an 'equality' of cognitive activities; both refer to nonnormative production of ideas that are statistically unusual. An additional question concerns the 'quality' and the shareability of these unusual ideas.

Over time the diagnostic category of schizophrenia has shrunk somewhat, particularly in the United States, and has moved away from a position where most affective symptoms could often be considered part of either the core schizophrenia syndrome or of the 'schizophrenia spectrum.' However, Eysenck lumps together both schizophrenia and mood symptoms as related to a single (creativity-relevant) construct he calls 'psychoticism,' and important mixed and in-between categories of 'schizoaffective disorder' still exist in the DSM. Schizophrenia's core symptoms also include affective features, today associated with the 'negative' or 'deficit' syndrome of schizophrenia. While depressive symptoms do occur in schizophrenia, the affective negative symptoms of schizophrenia – flat,

absent, or inappropriate affect and anhedonia – mainly reflect absences of emotion, as opposed to depressed low mood.

There remain questions, however, as to how much (and whether) schizophrenic cognition is ‘adaptive,’ ‘in the service of the ego,’ child-like, or strictly-speaking regressive. While schizophrenia has waned in popularity as the primary mental disorder related to creativity, others, for example Louis Sass, argue that schizophrenic flat affect combined with thought disorder is particularly suited to creative work in areas such as abstract art. Here a ‘distanced’ and ‘alienated’ perspective is important, as well as in mathematics, analytic philosophy, literature, and the pictorial and plastic arts in the eras of modernism and then post modernism.

In recent years much of the work on creativity and psychopathology has focused on contemporary individuals, lessening the effect of retrospective bias, as well as using psychological test or interview assessments of both creativity and psychopathology. As an example of the latter approach, Frank Barron, Harrison Gough, Donald Mackinnon and others, starting at the Institute of Personality Assessment and Research (now the Institute of Personality and Social Research) at the University of California, Berkeley examined personality characteristics – both positive and negative – of creative and sometimes also less creative individuals in various fields, notably architects. Barron did further work on writers and student artists and found high levels of self-reported psychopathology in creative architects, writers, and art students. While it is impossible to list all those contributing to this vibrant research area, it is important to mention the work of Arnold Rothenberg, who looked at ‘Janusian thinking,’ where someone is able to hold two opposing thoughts simultaneously, and its role in the creative process; this is another area where a ‘mixed’ state may be particularly important. In addition, my own work examined psychometric assessments of manic, hypomanic, and schizophrenia-like traits, as well as paper and pencil measures of ‘normal level,’ non-eminent creativity.

Affective Symptoms and Disorders

More recent work has also looked specifically at mood disorders and noted apparently genetically mediated connections of these affective disorders with creativity, socioeconomic, status and achievement. This entry focuses on the affective disorders, which are mental health disorders characterized by unusual and troublesome variations in mood that interfere with a person’s functioning. In the DSM-IV-TR (the current edition of the psychiatric diagnostic manual), the relevant categories are termed mood disorders. Although there is currently a great deal of interest and controversy involving the diagnosis and treatment of bipolar disorder in children, this entry refers only to disorders of adults.

Symptoms

Symptoms and characteristics of the mood disorders can occur at subclinical levels in normal individuals and nonpatients, as well as in those with diagnosed mental disorders. These symptoms occur on continua, and it is important to consider subthreshold characteristics in relationship to creativity, not

just symptoms that meet the criteria for a diagnosis. These symptoms include both low or ‘down’ affect and related experiences associated with depression, ‘up’ or ‘high’ and related symptoms associated with manic or hypomanic episodes, as well as the sequential or simultaneous experience of different emotions.

Depressive symptoms include: behavioral and physiological characteristics of slowness, lethargy, insomnia or hypersomnia, change (increase or decrease) in appetite, loss of interest in pleasant activities, and characteristic ‘sad’ facial expression and posture; emotional characteristics of sadness, unhappiness, and feelings of worthlessness. Cognitive features include negative self-evaluation, global, internal and negative attributions regarding events and the self, as well as suicidal thoughts and impulses.

Symptoms of mania and less severe hypomania include impulsive and rapid behavior characterized by poor judgment and inattention to consequences, elated or ‘high’ affect, and sometimes infectious good mood (although some clinicians comment on a desperate and depressed quality underlying this mood). Additional symptoms are racing thoughts, pressured speech, grandiosity, high self-esteem, often decreased need for sleep, and inaccurately positive judgments about the self. A hypomanic episode is similar, but less severe.

Diagnostic Categories

The current psychiatric diagnostic manual, the DSM-IV-TR, begins by defining the symptoms and clinical phenomenology of ‘mood episodes,’ major depressive episode, and manic, mixed, and hypomanic episodes. A major depressive episode consists of a period of depressed (sad, hopeless, demoralized) mood or of lack of pleasure, accompanied by significant impairment and by other depressive symptoms. A manic episode is characterized by elevated or expansive, euphoric or excessively enthusiastic, or irritable mood. Mixed episodes are defined as periods when the person meets criteria for both a major depressive and manic episode in the same day, nearly every day for a week. Periods of alternating or simultaneously mixed mood will also be important to the discussion of emotions and creativity.

The mood disorders themselves include the depressive disorders, major depressive disorder and dysthymic disorder (for simplicity, such categories as ‘not otherwise specified’ are omitted from the discussion). Major depressive disorder is diagnosed if a person has experienced one or more major depressive episodes, but no manic, mixed, or hypomanic episodes. Dysthymic disorder refers to a person with chronically low mood, whose depressive symptoms are generally less severe but of greater persistence and longer duration than in individuals with major depressive disorder.

Next are the bipolar disorders, bipolar disorder type I and bipolar disorder type II, as well as cyclothymic disorder. Bipolar I disorder is diagnosed if someone has had at least one lifetime manic or mixed episode, and often the person will have had major depressive episodes as well. Bipolar I disorder can come with a most recent episode of manic, hypomanic, depressed, or mixed. In contrast, individuals with bipolar II disorder have had one or more major depressive episodes, have never had a full-blown manic (or mixed) episode in their lifetimes, but have experienced at least one of the more moderate hypomanic episodes. Cyclothymic disorder is characterized by more mild alternations in mood, with numerous periods of

hypomanic and depressive symptoms. Bipolar disorders I and II, and major depressive disorder, can also have psychotic features.

Changes in mood can also be due to medical and other physiological conditions (including substance or prescribed medication use), and the DSM-IV-TR includes groups of 'other' mood disorders attributable to general medical condition, and substance induced mood disorders. These are important for this discussion due to literature on physical illness in creative individuals and the relationship between medical illness and creativity. This possible connection in 'the wounded artist' is exemplified by Edmund Wilson's essay, 'The Wound and the Bow,' which discusses Sophocles' play *Philoctetes*, the story of a wounded and morbidly ill master archer, who had been a companion of Odysseus. (Note that *Philoctetes* is now also being read as a story of recovery from war-related trauma.) Linkages between physical illness and creativity have also been the subject of systematic study. Finally, mood symptoms can also occur with a variety of other psychological disorders. The focus here is on the bipolar affective disorders and hypomanic disorder, as well as major depression and dysthymia.

Bipolar Disorders

Some of the strongest statistical findings and conceptual arguments regarding the relationships between categories of mental disorder and kinds of creativity concern the bipolar mood disorders. Empirical research in this area started in earnest with the path-breaking work of Dr Nancy Andreasen, who studied creative writers who had attended the Iowa Writers' Workshop and found higher rates of affective disorders and symptoms in writers and their relatives than in control individuals. Dr Kay Jamison, who did extensive work emphasizing writers and composers, also documented an alarmingly high rate of suicide in these populations, something others found in abstract expressionist artists. She has also written a beautiful autobiographical account of life with bipolar disorder in *An Unquiet Mind*.

Dr Ruth Richards and her colleagues studied creativity in manic-depressive and cyclothymic participants (under DSM-II and DSM-III criteria), their normal relatives, and control participants. Richards' focus is on noneminent (what she calls 'Everyday') creativity, and this expands the debate away from famous geniuses, and somewhat away from diagnosed psychiatric patients as well. Her work also removes some of the confounds with social evaluation and self-promotion that can be introduced into evaluating creative work. Richards and her coworkers suggested nonlinear, 'inverted-U' relationships linking indicators of symptom intensity and levels of creativity. They made explicit connections between creativity and psychological health, as well as connecting the construct of everyday creativity to well-lived life in general and the overall makeup of human beings.

Especially important is Richard's and colleagues' work on 'inverted-U' relationships and Jamison's suggestions that optimal creative functioning is not associated with full-blown, extra high, manic states but may mainly occur between – not during – manic or depressive states, or at more moderate levels of affective and cognitive symptoms. In other words, while creativity may be associated with mood disorder, it does not necessarily occur at its peak levels in periods of maximally

'high' or 'low' affect. This suggests nonlinear relationships between symptom levels and creative functioning, perhaps with moderate levels of symptomatology as 'optimal.'

Depression

The term depression refers to the set of mood disorders indexed by the diagnoses of major depression or dysthymia. In addition, as noted above, the word depression also refers to 'normal' and nonpathological experiences of 'down' affect. A number of authors have suggested an association between depression and creative functioning. There are convincing anecdotal and biographical reports of how depressed states may sensitize someone to the nuances of the natural and social worlds; depression can seem to create an almost agonizing sensitivity. Graham Greene noted in *The End of the Affair*:

In misery we seem aware of our own existence, even though it may be in the form of a monstrous egotism: This pain of mine is individual, this nerve that winces belong to me and to no other. (1975 Penguin edition, p. 47)

This also touches on a sense of grandiosity and narcissism that may also be associated with creativity and with depression. (Note that while Aristotle's ideas regarding genius and madness referred to a 'melancholic' temperament, the relationship between this use of 'melancholia' and current ones is complex.)

The literature reports many individuals who have had high-level creative careers and also experienced severe depression. There is also a large literature on suicide and creative individuals, including painters, authors, and others. An important and unresolved question concerns the relationship between suicidal thoughts and feelings and creativity itself, and a crucial concern of treatment is managing the suicidal thoughts and feelings that can be dangerous symptoms of the mood disorders. Some artists fear that treating their depressive and other mood symptoms will compromise their creativity, but – writing as a clinician – I believe that it is important that the creative person continue to live!

Depression may not only contribute to a vividness of perception but also facilitate periods of incubation in the creative process, a role that has also been argued for physical illness. However, psychometric associations between depressive experiences and creative functioning – at least over the normal range of depressive symptoms – have been mixed. There is, however, important empirical work on 'paradoxical' positive effects of negative mood on creative functioning, finding that negative emotions can enhance creative performance.

Other Mental Disorders

Possible associations between the norm-breaking behavior of people who could be diagnosed with antisocial personality disorder and creativity have been mentioned above; there is conceptual overlap between a norm-breaking lifestyle, genre-busting creativity, unconventional and ground-breaking artistic products. There have also been associations suggested with narcissistic personality disorder, with the argument that to feel one's creative work is valuable and worth showing to the wider world it is necessary to have at least some narcissistic characteristics, such as belief in one's own worth, grandiosity, and

exhibitionism. There have also been suggestions that creative individuals are especially likely to demonstrate flamboyant, exhibitionistic, and emotionally and interpersonally labile characteristics of borderline or histrionic personality disorder. Asperger's syndrome is also an area of intense current interest.

Recent work has extended historical accounts of traumatic or abusive childhoods in eminent creatives and posited a connection with post traumatic stress disorder (PTSD). Linkages with substance and alcohol abuse have already been mentioned, and there is a rich anecdotal literature on associations between alcoholism and the use and abuse of other substances and creative functioning. However, a more recent and popular stream of literature has focused on the documented ill effects of addiction on creativity, creative individuals, and those around them, and on the role of recovery from substance abuse in tapping personal creativity and also recovering from traumatic events.

As noted, over time and the course of study in this area, focus has shifted from characteristics of personality disorder to those of schizophrenia and then mood disorders. The question of which specific mental health diagnoses or which symptoms may be most associated with creativity is complicated by several things. First, diagnostic categories overlap substantially; this has been referred to as the 'horizontal spectrum' of disorders. For example, symptoms of depression may occur in a number of different diagnoses. Second, a number of diagnoses often tend to co-occur, to be 'co-morbid.' Thus, affective disorders and substance abuse often co-occur, as do depression and PTSD. Finally, we are coming to realize that there are distinctly different forms of creativity in different fields or domains, in different cultures, and during different epochs; there does appear to be some specificity in the linkages between particular diagnoses and symptoms and creativity of particular kinds in particular endeavors, something investigated by Arnold Ludwig and Robert Prentky.

A More Fine-Grained View

Psychometric Indices of Psychopathology

Research on diagnosed mood disorders has been summarized above, and it is important now to extend this discussion to symptoms and characteristics of mood disorders more broadly construed, including subclinical intensities and experiences. Symptoms can be viewed on continua, as ranging from non-significant to normal-range to subclinical to severe. This is sometimes referred to as the 'vertical spectrum' of mental disorder. When symptoms and related characteristics are viewed as varying in intensity along different continuous dimensions, they can then be measured using psychological tests and rating scales. For example, hypomanic and schizotypal characteristics, as well as depression, can be assessed in this way.

There is an extensive literature which looks at these psychometric indices of psychopathology rather than at all-or-none categorical diagnosis. Some of this work also looks at creativity test scores that vary along continua in normal people, rather than using fame, eminence, or nominations of others as criteria of creative endeavor. This research has found positive correlations between test indices of mood disorder symptoms and experiences – generally below the clinical threshold for

diagnosis – and indices of creativity. The research also finds associations between psychometric indices of schizophrenia-like thought disorder (again at subclinical levels and in normal, nondiagnosed individuals) and functioning on paper and pencil measures of creativity.

Types of Psychopathology-Like Experience and Varieties of Creativity

Positive and negative affect

Motivational and affective factors, for example willingness to go out on a limb and take risks, self confidence, and energy, are important components of the creative process. However, a creative product is more usually viewed as coming from thinking or perhaps (in such cases as 'unconscious' or 'automatic' writing or painting) from behavior alone. While the focus of this entry is on affect, much research has focused on specific aspects of cognition and their relationships to creative functioning, which is often viewed as a cognitive process, for example, divergent thinking. The mood disorders appear to be associated with particular types of thinking as well as with affect, and it was noted earlier that both manic and depressive disorders have cognitive and behavioral, as well as emotional, symptoms. 'Primary process' contains both affective and cognitive elements; emotion and reason are intertwined. Sandra Russ has explored both of these aspects of children's play in relation to creativity. The treatment approach of cognitive behavior therapy emphasizes the linkages among thoughts, feelings, and behaviors and tends to focus on thoughts in framing interventions. It is now becoming apparent that 'thought disorder' is not limited to schizophrenia and schizotypal personality disorder and can occur in mood disorders as well.

Nevertheless, it is possible that an important connection between bipolar disorder and creativity is specifically related to the affective factors found in the forms of this disorder. A number of authors, notably Alice Isen, have found relationships between positive affect and creativity. The speeded-up quality, productivity, ideational fluency, and verbosity all associated with manic and hypomanic states may facilitate creative output by increasing the number of new ideas and the amount of raw material a person has to work with. D. T. Campbell suggested a theory of creativity based on 'blind variation' and selective retention; in this model the generation of large numbers of ideas that can then be evaluated and edited, with some discarded and some selected to be retained, would facilitate creativity. Quantity allows later selection of items of high quality.

It is also important to note work finding associations between negative affect and creativity as well, although this research is somewhat puzzling at this point. While Schuldberg generally found negative correlations between creativity test scores and measures of both subclinical depressive symptoms and subclinical 'flat' affect, others have found so-called 'paradoxical' effects. These are situations where negative affect facilitates creativity, job performance, and other positive outcomes (including health-related variables).

In general, negative affect has gotten an undeserved 'bad rap' among psychologists, especially in the new field of positive psychology, and further work needs to be done on the positive effects of so-called negative emotions (and 'negative' cognitions).

There are also suggestions that being able to experience positive and negative emotions simultaneously is important in psychological health, and it may be that such 'bitter-sweet' mixed emotions play an important role in creativity. The 'mixed' episodes that can occur in bipolar I may emerge as especially important.

Manic cognition and speech

While much of the earlier work on creativity and madness focused on the disordered and sometimes psychotic cognitions of schizophrenia and their similarity in form (although perhaps lower quality) in relation to novel, productive, and creative ideas, there is now much more known about cognition in the mood disorders. Manic and hypomanic thinking generally involve interpersonal engagement with another person or audience, self-confidence, free flowing if not agitated sequences of ideas, and pressured and rapid thought and speech. One approach to distinguishing schizophrenic and manic or hypomanic cognition and language looks at measurements of formal thought disorder based on cognitive tests, ratings of language behavior in interviews and other procedures, and especially at verbalizations during the Rorschach inkblot procedure. Earlier research suggested that high levels of the thought disordered type of 'deviant verbalization' described by David Rapaport are specific to schizophrenia and related conditions. However, we now know that formal thought disorder on the Rorschach also occurs in people with manic, hypomanic, or depressed symptoms. Thought disorder specifically in people with bipolar diagnoses is characterized by combinatory responses ('fabulized' and incongruous combinations), cognitive sophistication and complexity, affectively-tinged content, and interpersonal engagement with the examiner. In contrast, people with schizophrenia tend to manifest more idiosyncratic or personal and unusual verbalizations, 'autistic' (highly personal to the point of being unshareable) thinking, completely individual logic, confusion, and interpersonal detachment or disconnection.

Specificity

There do seem to be different flavors of thought disorder associated with both schizophrenia and the affective disorders. This leads to the suggestion that there are differing types of both pathological and creative cognition and affect, varieties of functioning better suited to different sorts of creative endeavors, whether in literature, music, art versus philosophy versus military leadership or attainment in business. This work suggests the existence of separate domains and types of creativity. In addition, it will be useful to explore both between and within-person variations in style. This approach fits well with the original work of Guilford, and with the work of Howard Gardner, Robert Sternberg, and others who argue for and measure multiple components of creativity and other forms of intelligence.

More Complicated Models

Creativity and Health

This brings us to the subtlety and complexity of the relationships among health, creativity, and psychopathology, and to a reconsideration of the question of the connections between genius

and madness. A number of more complicated models have been suggested for linking creativity and psychopathology. Ruth Richards, in a pioneering 1981 paper, explored various different possible forms for these relationships, including the possibility of creativity causing psychopathology, psychopathology causing creativity, and a number of interesting and more complex combinations, such as a common factor causing both.

Two factor models, originally put forward by Frank Barron, posit additional health or resilience factors which, in combination with features of psychopathology, lead to creativity or to health as opposed to debilitating mental disorder. One 'pathology' factor may be access to 'primary process' experience or 'disordered' cognition, mentioned above. The second factor may be 'ego strength,' something Barron attempted to measure with his own 'ego strength' scale on the old version of the Minnesota Multiphasic Personality Inventory (MMPI). Ego strength is described as a personality characteristic that allows dealing with adversity, managing external stressors and internal distress, and bouncing back from setbacks. Barron found that creative individuals, specifically highly creative writers, tended to be very similar to people with diagnoses of schizophrenia and other mental disorders in terms of their scores on a number of clinical scales of the MMPI. However, the highly creative writers also had high scores on ego strength, a trait presumably allowing them to manage, deal with, communicate, share, and utilize unusual experiences productively, rather than being overwhelmed by them. There are also suggestions that creativity may be a key component of psychological health itself, even related to physical health. Creativity may be a marker or component of health and well-being.

Creativity and Psychopathology: Nonlinear and Dynamic

It is useful to consider creativity and psychopathology not only as existing along continua (as opposed to being dichotomous and categorical), but also as fluctuating and unfolding over time; they are dynamic, not static. People may well phase in and out of creative zones and also phase in and out of states that are more or less psychopathological. Future research and theoretical work on the relationship between genius and madness will benefit from focusing on both as dynamic processes within individuals, in flux at all times rather than representing life's endpoints. It is also important to consider the nonlinear causal relationships linking many different traits, characteristics, and behaviors, with positive or not so positive outcomes in people's lives: more of a good thing – be it wheat germ or cheerfulness – is not always better. Nonlinear relationships generally connect attributes and behaviors that may be viewed as healthy, unhealthy, or pathological with positive outcomes of attainment, achievement, or quality of life.

A dynamically changing system that contains nonlinearities is also capable of chaotic behavior, something artist, psychologist, and theorist Tobi Zaussner and others have suggested as an attribute of both creativity and well-lived life. Notably, the experiences of bipolar disorder also change with time and have specific phases, and some authors believe that the disorder includes chaotic variations in mood, although this assertion is currently controversial.

It is also very important to reiterate that it may be during the more moderate, regulated, and less extreme phases of mood

disorders that an individual is most creative or productive, something explored in the work of Jamison, Richards, and others. It is crucial not to over-idealize – and this is a failure of the philosophy and aesthetics of romanticism – extremely disturbed and painful psychological states because they are presumed to be associated with creativity.

Implications for Treatment

A number of potent and effective pharmacological treatments are available for the mood disorders, as well as empirically-supported psychotherapeutic treatments, notably cognitive behavioral therapy (CBT) and interpersonal psychotherapy (IPT) for depression. For depressive disorders a combination of medication and psychotherapy is likely to have the best results, although many people use one or the other. For bipolar disorders psychological treatment is often combined with or secondary to medication management if the client is willing to utilize pharmacotherapy. A variety of empirically supported psychological treatments are available for the bipolar disorders, including psychoeducational interventions to enhance medication compliance, CBT, marital and family therapy (including Miklowitz and colleagues' family focused treatment), as well as interpersonal and social rhythm therapy.

Some productive and creative individuals suffering from mood disorders may be reluctant to engage in treatment using either medications or psychotherapy, fearing that it may interfere with or decrease creativity or productivity, or that a greater degree of happiness or satisfaction may be incompatible with art. Research is unclear and opinion somewhat divided on the relationship between quality and quantity of creative output and treatment, but there are strong hints that support the substantial value of thoughtful treatment. First, there are a number of creative individuals who have reported favorably – in the scientific literature and elsewhere – on the positive effects of pharmacological treatment on their creativity, especially in reducing severe manic or depressed episodes. There is other research documenting a general satisfaction with treatment for bipolar disorder. I also want to argue that at least partial and episodic happiness is not incompatible with creativity and that – if undertaken with serious attention to the creative process on the part of both client and therapist – both pharmacological and psychological treatment can increase, rather than interfere with, good creative work. Support for this comes from Jamison's work that suggests that creativity is associated with periods between extreme swings of mood and from Richards' and colleagues' work on the inverted-U. There is additional work on the creative potential inherent in psychotherapy itself.

Andreasen argues for careful treatment of the creative individual with a mood disorder, paying attention not to over-treat (and hence produce excessive damping down of mood that may interfere with the creative process and encourage noncompliance with treatment), and avoiding undertreatment that allows breakthroughs of mood extremes that can hamper creativity and severely interfere with day to day functioning. Torrey and Knable make suggestions regarding dosage and other issues in pharmacological treatment. Richards argues that treatment may help the person experience more moderate intensities of mood and cognitive symptoms, staying in the

zones of experience associated, in much research, with higher creative output. Of particular concern is the risk of suicide. It is critically important not to minimize the risk and pain associated with these disorders when discussing their possible connections to creativity, nor to idealize the experience of mental disorder to the point of losing the creative person.

Conclusion: Creativity, Disorder, Health, and Human Nature

Considering the overlap and intertwinement, as well as the possible causal links, among forms of creativity and psychopathology deepens our perspective on deviance and nonnormative behavior and can lead to questioning the notion of 'normality' itself. 'Unusual' thoughts, feelings, perceptions, experiences, spiritual activity, and behaviors can either be socially devalued and viewed as problems and illnesses, or they can be valued and viewed as socially desirable. They are also strikingly widespread. It can sometimes be difficult to tell the difference between valued and nonvalued characteristics and behaviors just on the basis of the behaviors themselves. They sometimes overlap and mix, just as illness and health can mix, for example in people with chronic physical illnesses.

Ongoing debates regarding the relative importance of characteristics of mood disorders, schizophrenia, or other mental and physical disorders in creativity also suggest that there is a false dichotomy between cognition and affect, that our thoughts and evaluations of situations influence our feelings and that our feelings influence our supposedly 'objective' thoughts; there is generally no such thing as 'dispassionate' or 'cold' cognition.

In addition, we need to become more sophisticated in distinguishing among various types of clinical and sub-clinical psychological experiences and among different forms of creativity and achievement. This is an important area of ongoing research. Many experiences similar to ones considered pathological in a mainstream culture, or experiences that in fact imply a diagnosable syndrome, are quite common and widespread across individuals, in other cultures across the world, and over the life span. This is another reason to shift away from viewing mental disorders as disease categories and toward considering human experience as falling along continua, with intensities along different trait dimensions. This also points toward human existence as including fluctuation and variability.

In this view human nature and the human condition are dynamic, fluctuating, nonlinear, and inclusive of mixed characteristics and experiences. Some traits are considered socially desirable and positive, some negative, but all are mixed together in the living of everyday life, and in creative activity as well. This also suggests a reevaluation of which human characteristics may be helpful and which unhelpful, over the course of human history, when (and in what context) they are more or less useful to us, and at what intensities. The currently developing field of positive psychology, which emphasizes human strengths, capabilities, and assets, will benefit from continuing to scrutinize the very notions of positive and negative, particularly in the contexts of deviance, originality, and health.

There can be a little bit of madness in all of us, for better and for worse. It is important neither to overlook nor to glorify the pain and suffering that can be caused by severe mental

illness. But, it is also important not to ignore the positive contributions that disorder makes to human diversity. In addition, although very few of us become famous or are geniuses, recognized or unrecognized, everyday creativity plays an important role in nearly everyone's life, helping with solutions to everyday problems and in enriching the quality of normal life in relationships, work, recreation, hobbies, avocations, creative contemplation, and aesthetic appreciation.

Glossary

Attention deficit hyperactivity disorder

(ADHD) Symptoms include heightened activity, inattentiveness, and impulsivity.

Creative achievement The process of original thinking that results in actual creative outcome.

Creative potential Possessing the capability to generate ideas that are novel and appropriate, but not yet doing so.

Mentee A person who is being mentored, a protégé.

Mentor A teacher, guide, or sponsor who serves as an example and can be trusted and relied upon.

Definition of Mentor

According to Greek methodology, Mentor was a guardian and a teacher of Telemachus, guiding him throughout his life's adventures. Today, the word 'mentor' refers to an advisor or a guide who can be trusted and relied upon. A mentor serves as an example to a mentee. Most mentees admire their mentors, and wish to follow in their footsteps. Synonyms for mentor are guide, sponsor, or teacher. Mentoring is usually an intentional, committed, and nurturing relationship between two persons, with the focus on both professional and personal development. Mentors give moral, and sometimes financial, support to their mentees, and help mentees discover their talents and realize their dreams.

Mentors and Creativity

Needs for Mentoring Creative Individuals

Exceptionally creative students have unusual personalities, which may lead them to experience social and personal difficulties. Exceptionally creative children's thoughts are more divergent, seeing connections where others do not. They may encompass both feminine and masculine characteristics equally. Exceptionally creative students tend to be rebellious and nonconformists, ready to express their creative ideas to peers and adults. At the same time, they may be more sensitive, reactive, and experience deeper and larger range of feelings. Therefore, if their unusual ideas are ignored or ridiculed, they may become disturbed and withdraw, leading them to be more cautious next time they have a creative idea or an unusual question. Eventually, ridicule may discourage their desire to pursue their interests, and result in mediocre knowledge and achievement.

Research shows that teachers' judgments of their favorite students and creativity are negatively correlated. That is, teachers do not like students who possess creative characteristics, seeing them as disruptive and bothersome. Rather, they prefer students who conform to teachers' rules and orders without questioning teachers' authority. If asked for preferences between highly intelligent and highly creative students, teachers choose the students with higher IQ who are more studious, think logically, and are more responsible. This is

not surprising, since these types of students are easier to manage in the classroom, which makes teachers' jobs easier. Finally, teachers' preference for conformity and order is so strong that they may even mistake creative behavior for behavior associated with attention deficit hyperactivity disorder (ADHD).

However, a highly creative student will not succumb to the teacher's desire for conformity. In fact, pressure to conform may even drive him/her to express a higher degree of nonconformity (remember, creative children are rebellious), exploring ideas and concepts of interest.

Teachers are not the only ones who influence creative children's attitudes and behavior. Parents are just as likely to play a significant role in impacting their children's creativity. Parents would also prefer their children to be quiet and behave, and may punish them when a child's behavior is inconvenient to them for some reason. But creative behaviors are often perceived just as such: inconvenient and difficult to manage. Constant questioning and wild ideas can be annoying. Creative behavior may even be interpreted as aggressive or hostile. All this makes parents, and society in general, uncomfortable. Stifling creativity in a highly creative child may lead to lack of enthusiasm, nonadaptive behavior, and ultimately to underachievement.

Both typical masculine and typical feminine characteristics are essential to creativity, and creative students tend to be more androgynous. Rather than fitting into society's gender role expectations, creative children diverge from these roles, and exhibit sensitivity as well as independence. In some circumstances, however, expectancy for stereotypical gender roles and peer pressure might influence creative students to conform in order to fit in. This may impact their emotional well-being, and can cause their creativity and academic achievement to plummet.

Creative students often find themselves as part of a minority group – they are different from others, and are either unnoticed, or teased by their peers. They can turn into loners, reluctant to express their original ideas. It is possible that they become completely isolated from their siblings, peers, parents, and/or teachers. A supportive adult can help a highly creative student to accept being different from others, to be comfortable with their independence, and to stand up against group pressure.

Benefits to Mentees

A study by Christine Bennetts in 2002 found that creative people such as poets, painters, actors, sculptors, writers, musicians, and dancers are aware of their abilities at a very early age, and cannot separate the concept of 'self' with the concept of creativity. Therefore failure by others to recognize the importance of their creativity is seen as denying their 'self.' Mentors play a valuable role in recognizing and accepting creative people's abilities. They push their mentees towards new opportunities, and serve as role models of what it is like to live as a creative individual. Mentors develop a critical aesthetic sense in their mentees by challenging them intellectually in reasoned debate, and acting as exemplars in the field. Mentors can also provide an invaluable model of living and working for those creative people who choose to follow an unusual career path.

Mentor guidance reinforces and enhances the potential for new creative works, and serves as a guide for creative development, self-actualization, intellectual accomplishment, and individual independence and autonomy. It has been observed that there is a meaningful mentor-mentee relationship behind many creative achievements. Mark Twain, for instance, was mentored by the writer Bret Harte, while Sally K. Ride, the first American woman in space, was mentored by Arthur Walker, a Stanford University physics professor.

In 2006, Cropley pointed out new creative ideas can be unappreciated or even ridiculed. Mentors provide examples of how to communicate creative ideas in ways that the society can accept. They offer new perspectives, a safe space where creative ideas can emerge without punishment, offer a positive social perspective on themselves, and help to communicate ideas to others. Mentors help creative people gain courage to pursue their own individual paths, while testing the limits of the acceptable. They learn that their creativity does not make them an outcast, and this knowledge can instill feeling of self-confidence.

Mentees often follow in the footsteps of their mentors, acquiring similar characteristics and leading similar lifestyles. This does not affect mentees' creativity, however. Indeed, many Nobel laureates had Nobel winners as their mentors. For example, George J. Stigler, a Nobel Prize economist, was a mentor to Gary S. Becker, a Nobel Prize economist as well. These mentors provided intensive intellectual and research guidance, increasing mentees' potential for success and creative productivity. It is not necessary, however, that mentees agree with their mentors' philosophy. Rather, they develop their own standards by comparing their own principles with those of their mentors. Mentors are encouraged to help students find their own niche, their own love of a discipline, and not try to turn them into disciples who will directly follow in their footsteps.

Benefits of having a mentorship relationship abound. These include, but are not limited to: creativity enhancement, career advancement, an increase in knowledge and skills, development of known and undiscovered talents, development of a personal ethic, and establishment of friendship. Mentors may also display unconditional belief in the mentee; express ideas freely; and uphold high expectations. These benefits can enhance self-esteem, self-concept, and self-confidence.

Often the process of mentoring is more of an indirect teaching, akin to modeling the courage to express and pursue

creative ideas. Some mentors do not explicitly teach a certain academic skill, but rather attempt to push the mentee to discover his/her own creative talents. Sometimes mentors even help mentees discover talents that they were not aware of or simply never had the chance to use. Outstanding mentors tend to be nonjudgmental and flexible in their interactions with their mentees. Mutual respect is descriptive of a mentor-mentee relationship, where one listens to the other with admiration, and values the other's thoughts and ideas.

Creative unusual ideas require risk-taking, and are often met with ridicule. A safe and supportive environment is essential, therefore, for creative ideas to emerge. Mentors teach their mentees on how to evaluate their creative work and deal with rejection. They respect and support their mentees, while providing support for experimenting with ideas and risk-taking. Errors and mistakes can be made safely within the relationship without fear of being judged as inadequate. Mentors provide valuable experiences to their mentees, such as enriching their career and providing support for their future career goals. Mentees feel comfortable in their uniqueness while with mentors, and this comfort may translate into other relationships. Mentors also provide opportunities for meaningful experiences and share with their mentees joy of creative achievement. In addition, mentors can sometimes provide material support, such as books, computers, laboratory facilities or trips to conferences, concerts, theater, and museums. They may also offer support in getting scholarships, awards or jobs.

Great mentors serve as a channel for guidance and wisdom, always moving out of the way of the growing competence of the mentee, not expecting imitation, but serving as a vehicle for growth in a direction best suited to the mentee.

Benefits to Mentors

Benefits to mentors may not be as tangible as for mentees, but they are powerful nevertheless. Mentors develop long-lasting meaningful friendships with their mentees, leading to a greater quality of life. They experience lasting satisfaction of contribution, which may result in increased confidence and a sense of well-being. Through their mentees, mentors become exposed to fresh new energy and curiosity, and to a new way of looking at things. With the help of mentees, mentors may become energized themselves, revitalizing their own career and receiving creative stimulation. The process of learning and achieving, as well as creativity, are enhanced for both people in the mentoring relationship. In addition, mentees often collaborate with mentors, leading mentors to higher productivity and future success.

Implications for Mentor and Adult Leadership for Creativity in Education

Some mentorship relationships happen spontaneously, and others are created. Matching students and mentors requires sensitivity to personal differences in style of working and personality. Parents and teachers are encouraged to seek experts as mentors for the students with whom they work, or to serve as mentors themselves.

In 2004, Davis identified goals for creativity training: raising creativity consciousness and teaching creative attitudes;

improving students' understanding of creativity; strengthening creative abilities through exercise; teaching creative thinking techniques; and involving students in creative activities. In addition, it is important to minimize the use of assessments in making social comparisons while fostering creativity. When students focus on self-improvement, they are more likely to take risks, seek out challenge, and persevere in the face of difficulty. Conversely, students will feel inhibited in expressing their creative ideas if they are being evaluated or monitored. Pressure caused by evaluation can cause anxiety that distracts from the creative task. However, this does not mean that challenges should be completely removed from academics. Meaningful challenges are necessary for development, especially if they take place in a secure environment and are personally relevant.

In 2002, Torrance found that the top 120 talented American people in six professions all had mentors who introduced them to the joys and challenges of their domain while allowing them the freedom to cultivate their personal style. Mentors don't need to be famous or powerful figures. Highly creative school teachers or college faculty members help creative students by allowing a wide choice of topics, welcoming unorthodox views, interacting with their students outside of class, and conducting classes in a more informal manner. Parents and teachers who are supportive give their students the freedom to pursue their interests and encourage the development of questioning, experimentation, and research. Teachers who make a difference help students fall in love with a subject so intensely that it becomes the center of the students' future career image. Torrance also found that future career image and passion are the best predictors of future creative achievement. Additionally, Torrance found that mentors are most helpful in achieving creative individuals' potential. Torrance's 'Manifesto for Children' reflects 7-, 12-, 22-, and 40-year longitudinal studies, and show the importance of a child pursuing his or her own interests. The manifesto is as follows:

1. Don't be afraid to fall in love with something and pursue it with intensity.
2. Know, understand, practice, exploit, take pride in, and enjoy your greatest strengths.
3. Learn to free yourself from the expectations of others and to walk away from the games they impose on you – Free yourself to play your own game.
4. Find a great teacher or mentor who will help you.
5. Don't waste energy trying to be well-rounded.
6. Do what you love and can do well.
7. Learn the skills of interdependence.

Torrance also suggested that the goal of guidance is not to promote individuality and creativity, but to encourage a healthy balance of individuality, creativity, and conformity. Excessive conformity and excessive nonconformity hinder creativity, but a balance between creativity and conformity can enhance one another.

Mentoring Programs

Major Components of Mentoring

Individuals who have mentors are more satisfied with their jobs and with their careers in general, and also receive

promotions and compensations more frequently. Successful mentoring has been described by Crisp and Cruz, in 2009, as consisting of four major parts: supporting a mentee psychologically and emotionally, setting goals and choosing a career path, advancing academic subject knowledge in a chosen field, and being a role model.

Supporting a mentee psychologically and emotionally

Psychological and emotional support involves actively listening to the mentee with encouragement and understanding, addressing his/her uncertainties and fears, and providing support in building self-confidence. It also includes paying attention to mentee's ideas, thoughts, and questions, and establishing trust and personal connection. It is important to be have a genuine interest in a mentee's achievement and success.

Setting goals and choosing a career path

Support in setting goals and choosing a career path involves discussing and providing advice to a mentee regarding his/her chosen career path. It is important that a mentee's strengths and weaknesses are assessed and are taken into consideration prior to setting academic and career goals. A successful mentor asks specific questions in order to provide the best possible advice. It is also important to provide detailed advice and explanations of which goals are worth pursuing, and which ones are best to avoid in helping a mentee develop their career.

Advancing academic subject knowledge

Advancing academic subject knowledge in a chosen field involves tutoring the mentee in both academic and life-learning skills. Evaluating, and challenging the mentee academically is important in helping acquire necessary skills and knowledge. It also includes providing a mentee with visibility, nominating him/her for awards and promotions, and discussing mentee's accomplishments. In some cases, taking the blame for a mentee and shielding him or her from negative publicity may be necessary.

Being a role model

A mentee needs to have a chance to observe the mentor in interactions with other professionals in the field. Being a role model involves serving as a guide and as an exemplar to the mentee, discussing not only the mentor's successes and achievements, but also how mistakes and failures were handled. In addition, it is important to understand how a mentor handles professional and personal demands. Such sharing will enrich the relationship.

Elements of Successful School-Based Mentoring Programs

Several keys to successful school-based mentoring programs as shown by Randolph and Johnson in 2008 are as follows:

1. Expectations for mentors' overall time commitment and contact frequency between mentors and mentees are specified. Most of the programs require mentors to commit to weekly contact for at least one school year.

2. Training for mentors is provided before they enter into relationships with mentees. Some type of monitoring is also conducted after relationships start.
3. A framework is followed, which predetermines structured activities between mentors and mentees, and address the specific goals of the program.
4. Support for mentors is included, such as screening and training before the match, and support and supervision after the match. Post-match monitoring procedures are provided, with ongoing training to monitor the relationships between mentors and mentees. Either a mentor support group, or individual supervision to mentors can be employed.
5. Some programs do not have any formal expectations for parental involvement, and coordinators act as liaisons with parents or between parents and mentors. Other programs promote formal parental involvement by hosting parent activities during the school year, and mentors are invited to attend these meetings in order for parents and mentors to meet each other. However, in 2002, Millar found that there are programs which discourage contact between parents and mentors. In any case, it is important for a mentor to provide a mentee with a different, but noncompetitive perspective from parents.

The studies above examined the effect of mentoring on attitudinal and behavioral outcomes that ranged from school connectedness or academic engagement to involvement in bullying and fighting. Although most of the programs included tutoring as a part of the mentoring activities, only a few programs examined the effects of mentoring on academic performance. In several studies, the effects on outcomes in multiple domains were examined. The primary benefit for students participating in the mentoring programs was increased connectedness at school, in the family, and in the community. Evidence of mentorship on prosocial peer relationships and on graduate point average was inconclusive. The effects of the mentorship may be dependent, however, on the quality and length of the mentoring relationship, as discussed by Randolph and Johnson. For example, in 1999 Lee and Cramond found that only students mentored for longer than one year have significantly higher aspirations than those who mentored for a shorter period.

Main Process Considerations for Mentoring Programs in Education

There are also eleven key themes that should be considered for successful mentoring processes as shown by Ewing et al. in 2008:

1. **Pairing process.** This is the greatest challenge. Several pre-program meetings with meals are helpful to allow an informal opportunity for the potential mentors and mentees to get to know one another. Paring with a mentor from a mentee's discipline or areas of interest is preferred in some cases. In other cases, paring with a mentor from another discipline or areas of interest is best as it provides the mentee with a different perspective. Thus, making the list of potential mentors with detailed information about each mentor and about each mentee should be available

in order to facilitate pairing. However, mentees must take ownership and control of the pairing process while pairing is facilitated by the program.

2. **Entry participation barriers – recognition and time.** Time constraints of the mentors should be recognized. Support from senior mentors who have less time constraints is helpful. Any mentors, regardless of junior or senior level, should be recognized or rewarded for his or her participation.
3. **Ongoing participation barrier – time.** Flexibility to schedule meetings should be considered and less than five hours a month on mentoring activities is recommended.
4. **Participation incentives – rewards.** Participation incentives and rewards, such as receiving funding for participating in the mentoring process, is encouraged. Although mentors are not usually motivated by external recognition or money, it can seal commitment from the mentor and mentee and prevent them from drifting away.
5. **Cultural compatibility.** When people attempt to get to know one another, there may be many barriers, including age, personality, ethnic or cultural background, etc. Thus, it is important that a mentee has some common ground with a mentor. In 2002, Millar showed that mentors need the facility to celebrate the individuality of disadvantaged or withdrawn students.
6. **Gender.** A mentor's and mentee's preference should be taken into consideration.
7. **Goals.** From the beginning, general and specific goals should be discussed, documented, and shared with other mentors and mentees in order to evaluate progress. Examples of goals include improving time management, balancing different priorities, building an academic or career identity, overcoming fears and other negative emotions in making progress, and being able to refuse to take on additional work.
8. **Intended and unintended outcomes.** Comparing the goals set by individuals in the program to the outcomes achieved is important. Additional positive outcomes not specifically stated as goals may include emotional support, developing broader formal or informal networks, increased sense of direction, taking more time for reflection, etc. Achievement of goals and attainment of concrete and specific outcomes can help shape mentees' future goals.
9. **Nature of relationships.** Some relationships and meetings can be informal, whereas others may have set agendas, action items, and meeting notes. Relationships can provide important personal and individual support for mentees. For some mentees, simply having another senior person to listen and offer support can be rewarding. For others, they can develop strategic goals and processes with the help of their mentors.
10. **Structure of program.** Formal whole-group meetings can add information and ideas to the mentoring process besides a mentee's regular meetings with a mentor.
11. **Mentoring agreement.** It is important to set an agreement between a mentor and a mentee as a means of regulating and monitoring progress. There needs to be structure to the mentoring process. An agreement can help mentors and mentees set aside time in order to meet and take mentoring more seriously.

Mentors and Mentees' Commitment for Successful Mentoring Programs

Commitment to the mentoring relationship plays a significant role for both mentors' and mentees' satisfaction, as discussed by Poteat and colleagues in 2009. The nature of the satisfaction is similar – the higher the personal commitment, the greater the satisfaction. In addition, commitment leads not only to a greater satisfaction with the mentoring relationship, but it also can lead to the greater effectiveness of the mentoring program and future mentee's success.

Mentors are usually busy people, and mentoring takes time and energy. Therefore, if mentors see a high commitment on the mentee's part, they will be more likely to invest themselves further. Mentee's commitment may enhance mentor's ego justifying the time and energy placed into the relationship. Thus it is best that counselors and educators help their students develop and exhibit commitment to their mentors.

Summary and Conclusions

Early writings concerning the importance of mentoring in creative achievement were based upon analyses of biographies and autobiographies of high achieving, notable creative people, case studies, or psychometric studies of eminent scientists. Since then, a number of empirical studies emerged including a 40-year-longitudinal study examining the effects of mentors on creativity of their students. Results from Millar in 2002 indicated having a mentor related significantly to improvement of all the measures of creative achievement both in high school and in post high school years.

Creative individuals need a mentor to realize their full potential. Research has shown that eminent creators, including the Nobel Prize winners, have had at least a formal or informal mentor. Mentoring has long been valued in the literature and in practice. It has even become a national priority, as evidenced by hundreds of formal programs and institutional practices that include a mentoring component.

In one mentor program for at-risk middle school students, overall failure rate of students in the program declined from 28% to 12% over a period of three years. This indicates that at-risk creative students also can benefit from having a personal mentor. The psychological dangers are severe if creative needs

are strong and suppression is severe or prolonged. The stifling of creativity cuts at the very roots of satisfaction in living and may ultimately create overwhelming tension and breakdown. Such students experience difficulties with feelings of social stress and estrangement. The power of peer pressure and conformity coupled with a student's wavering sense of being predictable can easily lead to denial of even an already recognized ability. We cannot afford to neglect creative individuals who need a mentor.

Glossary

Epistemic cognition Includes the individual's knowledge about the limits of knowing, the certainty of knowing, and the criteria for knowing. It further includes the ability to identify and choose between the forms of solution appropriate for different problem types.

Feeling-of-warmth (FOW) judgments Method for studying problem solving. Subjects are asked to indicate how near they believe they are to the solution.

Metacognition Knowledge and cognition about cognitive phenomena.

Monitoring process Includes knowledge about oneself and others involved in the problem solving process, knowledge about problems, and metacognitive experiences.

Strategy A general plan of action in which the sequence of solution activities is laid down.

Thinking aloud methodology Respondents are asked to verbalize their thoughts as they work on a problem. The method is used for studying processes involved in problem solving and thinking.

Tip-of-the-tongue states (TOTs) Refers to the experience of feeling certain that one knows a word, but being unable to retrieve it.

Definitions of Metacognition

The term metacognition was introduced by John Flavell in the early 1970s, based on the term metamemory previously conceived by the same author. Metacognition is viewed as learners' knowledge of their own cognition, defining it as knowledge and cognition about cognitive phenomena. Metacognition is often referred to in the literature as thinking about one's own thinking, or as cognitions about cognitions. It is usually related to learners' knowledge, awareness, and control of the processes by which they learn, and the metacognitive learner is thought to be characterized by the ability to recognize, evaluate, and – where needed – to reconstruct existing ideas.

Metacognition consists of two components: knowledge and control. Metacognitive knowledge pertains to one's knowledge about how one's cognition operates ('I know that I do not memorize names well'), whereas metacognitive control pertains to how one controls one's cognitive operations ('To facilitate remembering I will try some mnemonic technique'). Some authors have conceptualized metacognition as operating at two levels: the objective level and the meta-level. The objective level carries out cognitive operations, whereas the meta-level controls activities that occur at the objective level. Terms also used in the literature to describe metacognition are: self-appraisal and self-management of cognition, metalearning, deutero-learning, and mindfulness. The number of definitions, terms, and analyses of what metacognition stands for has been the cause for some confusion in the literature.

In an attempt to clarify some of the obscurity covering what metacognition stands for, Flavell proposed a taxonomic categorization of the components of metacognition. In doing so, he distinguished between (a) metacognitive knowledge and (b) metacognitive experience. Metacognitive knowledge is that part of one's knowledge that refers to cognitive matters.

It comprises knowledge of person variables (knowledge concerning what human beings are like as cognitive organisms), task variables (referring to knowledge about how the specific information encountered affects and constrains the way in which one deals with it) and strategy variables (knowledge about cognitive strategies or procedures for achieving various goals). Metacognitive experience, by contrast, comprises conscious experiences that can be either cognitive or affective and are pertinent to an ongoing cognitive situation or endeavor.

The definition is extremely broad. In most cases, however, metacognition refers more narrowly to monitoring one's own cognitive processes and the influences on them while one focuses on a specific task. The monitoring process includes three parts:

- knowledge about oneself and others involved in the problem solving process,
- knowledge about problems, and
- metacognitive experiences which lead to the re-evaluation of strategies.

Some researchers have noted that the definition of metacognition overlooks the distinction between what are called executive one and executive two strategies. Executive one strategies refer to knowledge about the particular task, whereas executive two strategies refer to knowledge of whether a particular strategy is appropriate for being applied in a problem solving situation. An even more precise distinction can be made between on the one hand knowledge about one's own cognitive processes and when to apply them, and on the other, knowledge about knowledge and the validity of truth claims in general. A critical difference exists between knowing that a specific strategy is appropriate for solving a problem, and knowing that for some problems we can never determine the absolute truth or correctness of a solution. This second aspect

of metacognition relates to the meta level of monitoring and was given the name epistemic cognition. It is important in creative problem solving, where no single and correct solution exists, and where the criteria for evaluating a possible solution are limited. Creative problems are solved on three levels of cognitive processing. On the first level, individuals enter into problems by reading and perceiving them. On the second level, metacognitive processes are involved in monitoring the first level of cognition. These processes mainly include knowledge about problems, strategies that may be used to solve specific problems, knowledge of when and how a strategy should be applied, and the evaluation of these processes. The third level is epistemic cognition. It includes the individual's knowledge about the limits of knowing, the certainty of knowing and the criteria for knowing. It further includes the ability to identify and choose between the forms of solutions appropriate for different problem types. The ability to see the difference between problems which have only one correct solution, and problems which have no absolutely correct solution, but only better or worse ones, is an important developmental characteristic of the late adolescent and adult years.

A more operationalized classification of metacognition has been proposed by researchers involved in a psychometric approach in studying problem solving. These approaches distinguish between several metacomponents, such as selection of performance components for task solution, selection of one or more representations upon which these components are to act, selection of a strategy for combining the components, decision about whether to maintain a given strategy, selection of a speed-accuracy trade-off, and solution monitoring – the keeping track of progress being made toward a solution. Loosely speaking, metacomponents are responsible for figuring out how to do a particular task or set of tasks, and then making sure that the task or set of tasks is done correctly. Most of these metacomponents refer to level one and level two cognitive processes.

Metacognitive Research

Research on metacognition has its roots in two distinct areas of research: developmental psychology and cognitive psychology. Metacognitive research in the area of developmental psychology can be traced back to the theory proposed by Jean Piaget and Lev Vygotsky. However, metacognitive research in a pure form did not emerge until the 1970s, when Flavell and colleagues investigated children's knowledge of their own cognitions. They were interested in finding out if the improvement in children's memory abilities was a function of greater conscious understanding of the rules that govern memory and cognition. Thus, the studies trace the development of metacognitive thinking, that is, the ability to reflect on one's own cognitive processes.

In the area of cognitive psychology, work on metacognition was initiated by the investigation on feeling of knowing experiences (FOKs). First, people were given a recall test, of either newly learned information or general knowledge. For example, participants might have been asked, "What is the capital city of the Bahamas?" (Nassau). If the participant was unsuccessful at recall, the participant was asked to make a feeling-of-knowing

judgment, predicting the answer would be recognized in a multiple-choice format. Finally, the participant received the recognition test. It was shown that feeling-of-knowing judgments did indeed predict the likelihood of correct recognition for general knowledge materials, an observation replicated many times. However, in mainstream cognitive psychology, metacognition still lingered at the fringes. Indeed, at most conferences, metacognition researchers presented their papers in memory sessions not metacognition sessions. In the twenty-first century metacognition has emerged as an important subfield of cognitive psychology. Perhaps in part, the emergence of metacognition into the mainstream reflects the greater focus of cognitive psychologists on the experiential aspects of memory.

Research in metacognition has covered mainly three components: (a) knowledge about strategies (knowledge about when, where, and why different strategies should be used); (b) strategy use (the actual use of metacognitive strategies); and (c) cognitive monitoring (an acquisition procedure needed for evaluating and changing strategy use and for determining the limits of the knowledge). Among the conclusions reached by metacognitive research to date are that: (a) knowing about knowing develops; (b) both children and adults often fail to monitor cognitions; and (c) some strategies are difficult to learn and easy to abandon.

The fact that the link between metacognition and thinking skills, which encouraged application of the former to improve the latter has resulted in a number of researchers focusing on groups with learning difficulties. The view that metacognitive processes of self-monitoring and self-regulation are fundamental determinants of competent functioning in the real world has resulted in several research studies relating metacognitive dysfunction to schizophrenia.

Others, on the contrary, focused on the importance of metacognition for general aptitude and giftedness. Several researchers have reported significant differences in metacognitive strategy usage between intellectually gifted and average students.

Methods and Techniques Used in Analyzing Metacognition

The central problem related to metacognition research is its estimation in the individual's cognitive process while solving a problem or learning. This is a practical obstacle caused by the fact that metacognition is an inner awareness or process rather than an overt behavior, and because individuals themselves are often not aware of these processes. In employing interviews for educational purposes, for instance, there is difficulty in judging whether a pupil who takes some time before replying to a question is unsure and unconfident about his/her response, or whether that silent interval is a sign of one's effort to reflect back on his/her learning and retrieve the answer in a metacognitive manner.

The most frequently used approach is thinking aloud methodology, where the respondents are asked to verbalize their thoughts as they work on a problem. This method was used by many early investigators. It gained popularity in problem solving studies during the 1960s. Use of the method in

information processing research led to its utilization in many related areas of psychological research. The thinking aloud method requires no more than that the subjects during their thinking activity provide an account of what they are doing. The subjects thus report problem solving behaviors, rather than mental states. The latter being the characteristic of introspection and retrospection which require the subjects to analyze the composition of thought processes. The comparison of introspective and thinking aloud methodology revealed several characteristics being in favor of the thinking aloud methodology. The thinking aloud protocols are more complete and contain more information than the introspective protocols. A second characteristic is that the thinking aloud protocols are more present oriented, have a more elliptical form, and contain more indefinite referents.

Although there is evidence to suggest that the instruction to think aloud does not significantly alter the sequence of the cognitive process, the method has its limitations: verbal protocols include only the events and operations of which the subject is aware at the time; additionally, they are sensitive only to sequential operations. Another source of error could be the analysis of thinking aloud protocols with different taxonomies. No matter how carefully designed, the chosen scheme for both data collection and data analysis will not only influence what the investigator observes, but will to some degree determine the regularities and laws which might be identified. It seems that these methodological shortcomings affect above all research into metacognition. Metacognitive processes occur infrequently in thinking aloud protocols (about 1% of all statements can be identified as metacognitive).

Recently, a different method for investigating the individual's metacognitions during problem solving has been introduced. The technique requires the subjects to give judgments repeatedly about how close they feel to the solution of problems – called feeling-of-warmth (FOW) judgments – in the course of the problem solving. These judgments are called 'warmth' judgments, after the searching game in which one person hides an object and then directs others to where the object is by telling them that they are getting warmer – closer to the object, or colder – farther away. Subjects are asked to indicate how near they believe they are to the solution. The 'feeling of warmth' procedure was used to examine the subjective phenomenology of different problems. It could be shown that the patterns-of-warmth ratings differed for insight and non-insight problems. Non-insight problems showed a more incremental pattern in the course of their solving than did insight problems. The conclusion drawn from these findings was that insight problems were solved by some nonanalytic, sudden process, in contrast to an analytic process of reducing the difference between the initial and goal state, which characterized the solution of non-insight problems. Some researchers opposed this conclusion as being rather vague and speculative. The finding that subjects cannot predict their performance on insight problems does not logically necessitate that solutions to such problems occur as a sudden flash of illumination.

A similar technique for studying metacognition requires subjects to make assessments about the likelihood that they know the answer to a question, or will be able to solve a problem (feeling-of-knowing judgments – FKJ).

These judgments are based on episodic memory which, for its optimal function, requires a subsidiary monitoring and control system that assesses the familiarity of incoming events, and adjusts attention. Cognitive energy is assigned to events on the basis of novelty – devoting little energy to old and already well-known events, and much attention to novel events. It is assumed that the values of novelty assessed by such a monitoring-control system are feelings that are available to consciousness, and that they may be used for making feeling-of-knowing judgments. Many researchers have stressed the importance of such a judging system for creativity, especially for problem finding. Identifying differences between a schema and the environment is also important for the process of conceptualization.

In order to gain a deeper insight into metacognition, the tip-of-the-tongue states (TOTs refer to the experience of feeling certain that one knows a word, but being unable to retrieve it) were also studied. In the metacognitive view, TOTs are viewed as an imperfect monitor of ongoing cognitive processes. That is, TOTs are subjective experiences that allow rememberers to monitor and control their retrieval processes when lexical retrieval breaks down. However, as mentioned earlier, it is difficult to observe these processes, and defining them with FOW ratings and TOTs is a circular endeavor.

To overcome the mentioned methodological problems related to FOW, TOT, and thinking aloud methodology some researchers have suggested the use of moderating variables. Activation parameters like heart rate and blood pressure, electroencephalograms (EEG) and even functional magnetic resonance (fMRI) techniques were used. The typical reaction to mental work or active coping is tachycardia and a redistribution of blood flow from skin and viscera to skeletal muscles. In contrast, passive coping is associated with an unchanged or perhaps lowered cardiac output. The characteristic of EEG patterns in a relaxed mental state is a higher amplitude in the alpha band (regular 7–14 Hz wave pattern). Some speculations exist that the so-called late components in event related potentials (an ERP is a complex EEG wave form that is related in time to a specific sensory event), like the transient wave in the range of 200–300 ms, and even the slow wave that develops 500–1000 ms after stimulus onset, are related to an orienting response. This response has been described as the consequence of a comparison between a sequence of neural events representing the incoming stimulus and stored neuronal models of past events. The explanation is similar to the assumptions that are based on FKJ, which can be observed at the behavioral level. The fMRI is an imaging tool that measures the amount of blood traveling to various regions of the brain as a means of assessing the amount of neural activity in those areas. MRI produces a picture of any structure showing differences in tissue density. It is based on the principle that hydrogen atoms behave like spinning bar magnets in the presence of a magnetic field. When the magnetic field is turned off and a pulse of radiation is beamed across the atoms, they emit detectable radio waves that are characteristic of their density and their chemical environment. MRI can be used to assess changes in blood oxygenation, which is an fMRI. Some recent research data indicate that a network of brain areas is more activated in the insight solutions when compared with the search solutions during the initial moments of problem solving. Especially right prefrontal

activation, along with anterior cingulate activation, may be important for metacognitive components of insight solutions, including attention and monitoring of the solution. These are important first steps in the study of insight from which hopefully future research can build.

Metacognition and Problem Solving

Concepts such as executive control and monitoring are important for problem solving in order to manage problem complexity and to evaluate progress towards goals, yet not many empirical studies have been made on the influence of metacognition on problem solving, and they have also failed to give undivided support to the hypothesis.

Several lines of research are consistent with the notion that incompetent individuals lack the metacognitive skills necessary for accurate self-assessment. Work on the nature of expertise, for instance, has revealed that novices possess poorer metacognitive skills than do experts. In physics, novices are less accurate than experts in judging the difficulty of physics problems. Some of the strategic misfunctions of college students engaged in mathematical problem solving were described as failures of goal setting, monitoring, and the evaluation of plans, which is the essence of metacognitive proficiency. The majority of students so engaged embark on a course of action that can be described as: read a problem, pick a direction, and then work on it until you run out of time. Experts, by contrast, have metacognitive knowledge that leads them to ask themselves, and to answer, three kinds of questions:

- What (precisely) are you doing?
- What is the reason for doing it? and
- How will the result be used later in the solution?

In chess, novices are less calibrated than experts about how many times they need to see a given chessboard position before they are able to reproduce it correctly. In tennis, novices are less likely than experts to successfully gauge whether specific play attempts were successful. On the other hand, experts in physics, for instance, give fewer metacognitive statements than novices, the explanation being a more automatic process among the experts.

Because some controversy exists around the relation between metacognition and general ability, it has also been investigated whether high levels of metacognitive knowledge about problem solving could compensate for overall aptitude. There are three, mutually exclusive models for describing the relation between intellectual ability and metacognitive skillfulness. The first model regards metacognitive skillfulness as a manifestation of intellectual ability. In a second, contrasting model, intellectual ability and metacognitive skillfulness are regarded as entirely independent. Finally, according to the mixed model, metacognitive skillfulness is related to intellectual ability to a certain extent, but it also has a surplus value on top of intellectual ability. However, research has shown that highly metacognitive students outperformed less metacognitive students in problem-solving, regardless of their overall aptitude level. In fact, high-metacognitive/low aptitude children performed significantly better than low-metacognitive children with higher overall aptitude scores. This indicates that metacognitive

knowledge contributes to achievement above and beyond the contributions of knowledge and general ability.

Although the findings are mixed concerning the influence that metacognition has on problem solving, the results support the relevance of metacognitive theories for modeling intelligence and high-level reasoning. The careful monitoring of cognitive activities allows humans to control not only the search for a problem solution but also the search for an effective problem-solving strategy. The difference is that problem-focused attention of subjects improves local problem solving behavior, whereas metacognitive attention allows subjects to be flexible globally and thus have a greater chance of finding a more complex and effective problem solving strategy.

Metacognition and Giftedness

In recent decades research in the gifted literature has shifted from a focus on who the gifted are to how the gifted think. Studies have tried to relate metacognition and giftedness. The findings differ considerably. It was reported that students who were high achievers were better able to describe their learning strategies. On the other hand, no superior metacognitive knowledge in gifted grade four students could be found. It was concluded that gifted students might possess some metacognitive knowledge, but they would not necessarily utilize it appropriately.

The results of several experiments utilizing FOW rating have shown that able problem solvers differed in their FOW ratings when solving different problem types. These differences were less pronounced for average problem solvers. For low problem solvers no such differences were obtained. These findings suggest that able problem solvers have a higher ability to estimate their closeness to the solution and they use it to decide on the next steps in the cognitive activity.

A second characteristic of gifted individuals is their ability to better classify problems according to the way in which these problems are solved. Thus, able problem solvers, because of their higher abilities in monitoring their own cognitive processes, are more successful in classifying problems according to the solution approach than are poorer problem solvers.

That high performers have a greater knowledge about cognitive phenomena was shown also by the comparison between the classification explanations given by high and low performers. The explanations given by able problem solvers were more abstract, and reflected knowledge about the cognitive strategies which were involved in the solution process. By contrast, the explanations of poorer problem solvers were more oriented toward concrete features of the problems solved (e.g., the modality of the problem, whether the problem was difficult, etc.). Similar differences were reported for procedural knowledge among experts and novices in different domains. The procedural knowledge of novices appears to be clustered around concrete phenomena. In contrast, the procedural knowledge of experts is organized around higher-order principles.

Support for the above conclusions comes also from EEG research. Gifted individuals, while solving different tasks, used processes which displayed a similar complexity of neural mass activity, by contrast, average individuals displayed a greater

diversity in the complexity of neural mass activity. The differences were extremely pronounced over the right hemisphere. The problems used did not greatly differ. All of them could be classified as well-defined, having one correct solution. Hence, there was no need for the strategy change displayed by the average individuals. It seems, further, that average individuals involved brain areas irrelevant for good task performance. Average individuals displayed the greatest complexity of neural mass activity over the right frontal and central areas for arithmetic tasks, and lower complexity for the analogy tasks. From a theoretical viewpoint the arithmetic tasks are solved in a more stepwise manner, in contrast to analogy tasks which require a more holistic approach. Research findings indicated that the right hemisphere specializes in holistic perception, and is primarily a synthesist, dealing with information input. The speaking, left hemisphere, by contrast, seems to operate in a more logical, analytic, stepwise fashion. The pattern of EEG measure displayed by gifted individuals resembled this difference.

It can be concluded that metacognition is an important factor in problem solving performance. Able problem solvers have higher abilities of estimating their closeness to the solution and they use them for deciding on the next steps in the cognitive activity. Capable students know much more about general cognitive strategies – how and when to apply them – than do less capable individuals. Poor problem solvers are also less efficient in monitoring their own cognitive process during problem solving than are able problem solvers. Poor students not only do not realize that they did not understand, in fact, they more frequently think that they had understood. Poorer college students are the ones who complain that they really knew the material but that they failed the examination. This may indicate that students who do badly on tests are also poor at monitoring their comprehension and at predicting their future memory for material.

Metacognition, Epistemic Cognition, and Creativity

What metacognitive processes might distinguish creative from less creative individuals? To answer this question one must first understand the creative process. Probably one of the oldest models describes creative thinking in four stages – preparation, incubation, illumination, and verification. Preparation includes the whole process of intellectual education. During this stage individuals are laying the foundations of their later creative acts by acquiring the knowledge and skills of their field. In this preparation stage metacognition and epistemic cognition may have a central role. Epistemic cognition refers to the individual's knowledge about the limits of knowing, the certainty of knowing, and the criteria for knowing. Loosely speaking, individuals must know that some things can be known and others cannot, or that they can be known only probabilistically, and that one knows the answer to a question if it can be conclusively verified scientifically. Creative individuals must also know if their knowledge is full, rich and flexible enough to allow for creative restructurings. Furthermore, creative individuals must understand that problems do not always have one solution, that cognitive strategies are sometimes limited and even reasoning correctly about a problem does not necessarily

lead to an absolutely correct solution. Epistemic cognition is important for solving ill-structured problems which require creativity. If a subject is not aware of the above mentioned limitations, he or she will approach an ill-defined problem as if it were a puzzle. Average students approach creative problems in a similar way to that in which they solve the well-defined problems. By contrast, the thinking aloud protocols of gifted students reveal statements which indicate epistemic cognition. They evaluate creative problems as being one of the problems for which no absolutely correct solution exists, where the solution requires a lot of thinking which would not necessarily produce a correct solution, and where there are no firm criteria that could be used to verify the answer scientifically.

During the incubation stage the problem is not consciously pursued. Incubation is characterized by the free working of the unconscious and partly conscious processes of the mind. One can only speculate about the work done during this phase – apparently the knowledge acquired in the preparation phase is being restructured into new knowledge. Metacognition in the incubation stage is unconscious or not present at all. Attempts to guide and control creativity too early seemed doomed to failure as described in several biographies of artists and scientists. Recently support for this anecdotic description was found by a functional magnetic resonance imaging (fMRI) study examining the possible neurological underpinnings of the highly creative and spontaneous activity known as improvisation. It was found that when the musicians improvise, their brains turn off areas linked to self-censoring and inhibition, and turn on those that let self-expression flow. A large region of the brain involved in monitoring one's performance is shut down, while a small region involved in organizing self-initiated thoughts and behaviors is highly activated. It is suggested that this and several related patterns are likely to be key indicators of a brain that is engaged in highly creative thought.

Illumination is the final flush or click, it is the culmination of the incubation stage; it is inspiration, revelation, and insight; it is the Eureka and Aha experience in the creative process. What has been unconscious becomes fully conscious, and requires metacognition, one must know that the idea or product is a creative one, and decide upon the strategies to verify and evaluate the solution.

Can Metacognition Be Trained?

A second approach to study the importance of metacognition for creative problem solving is to study the trainability of meta-processes. In this way it is confirmed that these processes exist and that they are important for problem solving. Comparing training approaches aiming at different processes, like flexible knowledge, contextual knowledge, intuition and similar, has revealed that the greatest improvement in problem solving was achieved when students were instructed in the domain of metacognition. Numerous classroom studies have shown that explicitly teaching metacognitive strategies in the context of a specific domain (e.g., physics or mathematics) can improve learning outcomes. Strategies taught in these studies integrate metacognitive activities with cognitive and seek to make the steps of analyzing, planning, assessing, and reflection habitual

in the learner. Studies have also shown that learning is more effective when learners explain worked out solutions to themselves – known as the self-explanation effect. More recently, computer tutors focusing on teaching metacognitive skills have shown positive effects on learning behaviors.

The greatest improvements were observed when metacognitive instructions were aimed at the solution of well-defined problems, less effective were instructions which aimed at enhancing creative problem solving and analogical reasoning. This seems understandable, as much more is known about the domain of well-defined problems than is known about ill-defined problems.

Instructions used in metacognitive training usually aim at one or more of the following elements of metacognition:

- Knowledge about problems. Students are taught to distinguish among problem types. They are introduced to the main difficulties individuals are confronted with when solving a problem. Some suggestions are provided about how to avoid perceptual and response set, and how to increase the capacity of working memory by making chunks more abstract, or by changing the modality of representation of the problem statement.
- Knowledge about strategies. Students are introduced to strategies like modeling, subgoaling, working backward, making inferences, goal discovery, and analogies.
- Knowledge of when and how the strategies should be applied is provided.
- Knowledge aimed at monitoring one's own cognitive processes during problem solving. Self-regulation is a skill which is independent of subject-domains, that is, once a learner masters the skill, he can apply it across domains and even in domains where he has little prior background knowledge. So, the skill is important for improving a

learner's competence. Some learners develop the skill by themselves; but some learners do not. The former are intelligent novices who can plan how to solve a problem, apply their knowledge to authentic tasks, and monitor and regulate their problem solving process; the latter may have difficulty in learning, especially if it is difficult for them to apply their knowledge to authentic tasks, and to monitor and regulate their thinking process. So, it is necessary to help a learner develop his/her self-regulation skill to allow him/her to become an intelligent novice.

This article is a revision of the previous edition article by Raymond W Gibbs Jr, volume 2, pp. 209–221, © 1999, Elsevier Inc.

Glossary

Conceptual metaphor A mental mapping in which knowledge from one domain of experience (the target) is understood in terms of information from a different and usually more structured, domain.

Poetic metaphor A linguistic expression that instantiates in some creative novel manner, some metaphorical mapping between diverse domains of experience.

Speaking and understanding The psychological processes of designing utterances for particular

audiences and inferring what speakers intended to communicate.

Teaching creativity Facilitating people's engagement in thinking about topics in new ways, often through trying to metaphorically relate ideas from diverse domains of experience.

Verbal metaphor A linguistic expression that usually reflects some preexisting conceptual metaphor.

Metaphors for Creative Thought

Metaphor is apt to flourish when people talk about creativity. Consider how several authors describe their creative processes when writing fiction. For example, the novelist John Gardner once characterized his creative process of composing fiction in the following manner,

Sometimes what happens is that you poke your pick into a piece of respectable earth and silver shows up in an iron-ore vein and God knows where you're heading. You follow it and you have to review everything in the light of the silver. (Tomlinson, 2005: 54)

A different variation on this theme of writing as mining is seen in a statement from the novelist James Dickey about revision:

I work . . . on the principle of refining low-grade ore. I assume that the first fifty ways that I try it are going to be wrong. I do it by a process of elimination. No matter how backbreaking the shoveling is and running it through the sluices and whatever you have to do to refine low-grade ore. You have the dubious consolation that what you get out of it is just as much real gold as it would be if you were just going around picking up nuggets off the ground. It's just that it takes so damn much labor to get it. (Tomlinson, 2005: 55)

Not surprisingly, poets also reflect on their creativity in metaphorical ways. Consider the final verse of a poem titled 'Digging' by Seamus Heaney.

The cold smell of potato mould, the squelch and slop
Of soggy peat, the curt cuts on an edge
Through living root awaken in my head.
But I've no space to follow men like them.
Between my finger and my thumb
The squat pen rests.
I'll dig with it.

Heaney expresses the metaphorical idea that writing poetry is like digging, specifically like digging of turf and potatoes. We may understand several metaphoric thoughts about

creative writing from this excerpt, including creativity, like digging, is an activity that involves hard work; creativity, like digging, involves intense, concentration; creativity, like digging, is an activity with a long tradition within the community; and that creativity, like digging, requires a great deal of self-absorption.

Each of these statements and poetic examples use metaphor to describe the elusive nature of creative thought and action. Metaphor is traditionally defined as a rhetorical device in which a speaker or writer describes one domain of knowledge (the target) in terms of a different domain (the source), as in "Creative writing is mining for gold." Studies show that people employ metaphor thought processes, like this, in a wide variety of domains, including both scientific and everyday problem-solving domains. For example, scientists characterize electricity as a fluid, atoms as floating objects, or minds as machines which enhances their knowledge of, and sensitivity to, the metaphoricality of complex physical and biological phenomena, and become productive metaphors in generating new scientific research and thinking.

Creativity, more generally, is understood in terms of three central metaphors. First, *thinking is perceiving* (e.g., "I see what you mean") refers to how information is sensed, communicated and evaluated. Second, *thinking is moving* (e.g., "If I can get around this obstacle, we will reach the solution soon," "I was following what you were doing until you lost me at that point") describes the sequencing of mental actions, states, employed to arrive at certain goals. Third, *thinking is object manipulation* (e.g., "If we can just find this last piece, we will figure out it fits into the complete product") describes how we find and evaluate ideas and fit them together to form more cohesive wholes. Together, these three metaphors explain why creativity implies different things to different people, and why some approaches to creativity appear radically different from others, especially with people who are asked to describe their own creative processes. Yet this collection of metaphors shows how creative processes are not just the poetic language used to describe creativity, but may be fundamental to creative thought itself.

Conceptual Metaphors

Speaking metaphorically is not something that only great writers and scientists do, because metaphor pervades ordinary speech and writing. Many scholars now contend that the ubiquity of metaphor in language demonstrates the fundamental importance of metaphor in thought, called 'conceptual metaphors.' The primary source of evidence for conceptual metaphors comes from the systematic analysis of conventional expressions in different languages. Consider the following ways that English speakers sometimes talk about their romantic relationships.

"We're headed in opposite directions"

"We're spinning our wheels"

"Our relationship is at a crossroads"

"Our marriage was on the rocks"

Cognitive linguistic analyses argue that these individual expressions are not clichéd, expressing literal meaning, but reflect different aspects of the enduring conceptual metaphor *love relationship is a journey*. Each linguistic expression refers to a different entailment that arises from the mapping of familiar, often embodied, understanding of journeys onto the more abstract idea of a love relationship (e.g., difficulties in the relationship are conceived of as obstacles on the physical journey). Moreover, many individual concepts can be understood in terms of multiple, sometimes contradictory, conceptual metaphors. Thus, a love relationship can also be understood as a natural force as exhibited by the following conventional expressions.

"She swept me off my feet"

"Waves of passion overcame him"

"We were engulfed by love"

"She was deeply immersed in love"

People's ability to think of abstract ideas and experiences in alternative, metaphorical ways suggests more reasons why there may be different creative approaches to many of life's problems.

Part of the foundation for metaphoric thought and language is seen in 'primary metaphors' which refers to metaphorical mappings arising from positive correlations in people's bodily experience. Consider some of these and the linguistic expressions that reflect these primary metaphors.

important is big (e.g., "Tomorrow is a big day")

more is up (e.g., "Prices are high")

similarity is closeness (e.g., "Those colors aren't the same, but they're close")

organization is physical structure (e.g., "How do theories fit together?")

change is motion (e.g., "My health has gone from bad to worse")

purposes are destinations (e.g., "He'll be successful, but isn't there yet")

causes are physical forces (e.g., "They pushed the bill through Congress")

understanding is grasping (e.g., "I've never been able to grasp complex math")

Note how in each case, the target domain (e.g., things that are important) is typically closely associated, or correlated, in people's experience of the source domain (e.g., things that are big).

Different sets of primary metaphors underlie different conceptual metaphors. For example, the conceptual metaphor *theories are buildings* (e.g., "The theory lacks a good foundation" and "The theory collapsed") is motivated by two underlying primary metaphors, *persistence is remaining erect* and *organization is structure*.

In general, conceptual metaphors have embodied foundations, with these metaphors forming a vast number of people's conceptions of abstract ideas from numerous, diverse domains (e.g., time, causation, spatial orientation, political and mathematical ideas, emotions, the self, concepts about cognition, morality), which are found across languages and cultures. Embodied metaphor also provides the grounding for novel, poetic metaphors. For example, Turkish, similar to many other languages, conceives of life as movement along a path where birth is conceptualized as arrival, life is a journey initiated by the arrival, and death is the departure that ends the journey. Life is broadly conceptualized as a region bounded by two doors, one leading to life and the other to death, which gives rise to the following conceptual mappings:

Source domain	Target domain
Space bound by the two doors	Life
Being within the confines of a bounded space	Being alive
Physical threshold for change of location (e.g., doorway)	Threshold for change of state
Crossing a physical threshold into a space between two doors	Being born
Crossing a physical boundary to exit a space between two doors	Dying
A moving entity	Human body

The conceptual metaphor *life is a journey* is comprised of this system of relationships where a source domain (people's experiences of journeys) is used to better understand some aspects of a dissimilar target domain (life). Creative linguistic instantiations of some of these mappings can be seen in the following excerpts from two Turkish poems (Ozcaliskan, 2003: 285 and 286):

"Dunyaya ilk geldigim anda
Yurudum ayn zamanda
Iki kapt /t bir handa
Gidiyorum gunduz gece"
("The first moment I came into the world
I walked at the same time
In a caravanserai with two doors
I am going day and night")

"Otesi yok sehre ulasunca kaderin yolu
Pisman bir el kapayacak kapisun omrunun"
("When the road of fate reaches the city of no beyond
A regretful hand will close the door of your life")

Creative poets may have special abilities to craft metaphorical messages in spectacular ways but many of their poetic creations are grounded in widespread conventional metaphors that have roots in enduring aspects of bodily experience, ones that are perhaps universal.

Understanding Metaphorical Language

The empirical demonstration that metaphor pervades both ordinary and creative speech and writing is at odds with the

traditional view of metaphor as a deviant form of language or thought. Going back to the ancient Greeks, many scholars have assumed that literal language best reflects ordinary, rational thoughts, and that people must recognize the deviant nature of metaphorical utterances before determining their figurative meanings. For example, consider one instance of extended creative metaphor use, this time in the context of a newspaper article discussing the State of California's budget crisis in 2009 ('San Francisco Chronicle' June 1, 2009: B6):

Forget the idea of the budget ax chopping away at the deadwood of Sacramento (i.e., the State's capital where the Governor and legislature work and govern) – the next couple of weeks are going to be more like a raging forest fire, as programs and workers' wages go up in fiscal flames. . . . State worker unions and the disabled were out in force Thursday, clogging the Capitol and lobbying lawmakers in the hopes of blocking Gov. Arnold Schwarzenegger from striking the match.

How do people interpret the metaphorical meaning of utterances like "Forget the idea of the budget ax chopping away at the deadwood of Sacramento?" On the surface, this expression make no literal sense and one may suppose that readers have to recognize this literal incongruity before going forward and interpreting the intended, figurative meaning. This explanation, which echoes the traditional view of metaphor as deviant language, suggests that metaphorical language should always be more difficult to interpret than roughly equivalent literal speech.

But the results of many psycholinguistic experiments have shown this idea to be false. These studies investigated the amount of time it took people to read and interpret literal or metaphorical expressions in appropriate discourse contexts. Listeners/readers can often understand the figurative interpretations of not only metaphor, including novel metaphorical expressions, but also irony/sarcasm, idioms, proverbs, and indirect speech acts, without having to first analyze and then reject their literal meanings when these are seen in realistic social contexts. People can read metaphorical utterances as quickly as literal uses of the same expressions in different contexts or equivalent nonmetaphorical expressions. Even without a defective literal meaning to trigger a search for alternative figurative meanings, metaphors (e.g., "Surgeons are butchers" to take one famous example), can be automatically interpreted. Of course, people, such as literary critics, can slowly ponder the potential meanings of a creative metaphor, and speculate on which metaphorical meanings are most appropriate and perhaps author intended. But this more deliberate reading of metaphors should not be mistaken as demonstrating that metaphors always demand extra cognitive work to be readily understood.

Part of the reason why metaphors, even creative ones, are often easy to understand is because people appear to mentally simulate the actions described in metaphorical sentences, even when these actions are physically impossible to perform. For example, people's mental imagery for metaphorical phrases, such as "tear apart the argument," exhibit significant embodied qualities of the actions referred to by these phrases (e.g., people conceive of the 'argument' as a physical object that when torn apart no longer persists). Similarly, people's speeded comprehension of metaphorical phrases like "grasp the concept" are facilitated when they first make, or imagine making, in this

case, a grasping movement. Real and imaginative bodily processes appear to enhance the construction of simulation activities to speed up metaphor processing, an idea that is completely contrary to the traditional notion that bodily processes and physical meanings are to be ignored or rejected in understanding verbal metaphors.

Experimental findings like these emphasize that people may be creating partial, but not necessarily complete, embodied simulations of speakers' metaphorical messages that involve moment-by-moment "what must it be like" processes, such as grasping, that make use of ongoing tactile-kinesthetic experiences. One implication of this research is that people do not just access passively encoded conceptual metaphors from long-term memory during online metaphor understanding, but simulate what these actions may be like to create detailed understandings of speakers' metaphorical messages. Embodied simulations may be part of many higher-level creative activities such as problem-solving, decision-making, and novel language use.

Constraints on Metaphorical Creativity

Is metaphoric creativity unlimited or does it emerge from certain personal (including bodily) and cultural constraints? The study of metaphoric variation offers some challenges to prominent theories of creative metaphoric use. Consider the following examples of newspaper headlines used to talk about the outcome of sporting events, in this case, American college football games: "Cougars drown Beavers," "Cowboys corral Buffaloes," "Clemson cooks Rice," and "Army torpedoes Navy" (Kovecses, 2009). The nicknames of the college teams (e.g., 'Cougars' are the mascot for Washington State University, 'Beavers' are the mascot for Oregon State University, 'Buffaloes' the mascot for University of Colorado, etc.) are paired with verbs that metaphorically refer to defeat. Thus, beavers live in water and can be defeated when drowned, cowboys corral cattle, and therefore would defeat an opponent like buffaloes by corralling them, rice is considered 'done' or defeated when cooked, and a Navy ship is defeated when torpedoed. Clever headline writers take advantage of people's ability to know what literal actions can be metaphorically used to refer to the idea of defeating, and do so in humorous ways, inviting readers to chuckle at the puns.

These sports headlines illustrate how people's knowledge of, and personal experiences with, different concrete and abstract concepts is put to work in the process of creating new metaphorical ways of speaking. Creating new metaphors is shaped by two processes: people's differential experiences in the world, and people's differential access to certain cognitive processes. For example, people pay attention to their bodies differently depending on the physical environment and the social context. The immediate situation in which communicative action takes place is a more exact constraint that people take into account as they aim to be coherent in what they say. Consider the following newspaper headline from 'The Wall Street Journal Europe' (2003): "The Americanization of Japan's car industry shifts into higher gear." Why does this expression make sense and, again, seem particularly apt when talking about Japan's auto industry? The headline reflects the common conceptual metaphors that *progress is motion forward*, such that

in this context, we readily infer that Japan's car industry is making good progress, or is advancing. But we draw this inference from understanding the link between Japan's car industry and the idea that the forward movement of a car is accomplished through the shift into higher gears. Even though Japan's car industry is an abstract entity that physically cannot move forward, we can understand it as a metaphorical object that can move, and when it does so by shifting into higher gear, like the cars made by the industry, the expression seems coherent and apt.

The physical environment also shapes people's differential experience of their bodies and the world around them, and this too influences the creation of metaphors in talking about abstract ideas. For example, consider some metaphoric expressions used in talk about the economy like "healthy economy," "economic recovery," "sickly firm," "a financial injection," "arthritic economy," and so on. These expressions may arise from people's experiences of their bodies in particular environments in the form of the *economy is health* metaphor. One possibility is that people use more health metaphors in talking about the economy during times of the year when they were more likely to be ill, such as when experiencing common ailments of colds, the flu, pneumonia, and bronchitis. In fact, one 10-year analysis of *The Economist* showed that the use of health metaphors in talking about the economy was far more evident during the winter months of December to March, which is when people most often experience illness, compared to any other time period. Once again, the physical setting in which talk occurs, and what is most salient to people's bodily experience in those contexts, shapes the selection of metaphorical source domains when creatively describing abstract target domains such as the economy.

Another aspect of bodily constraints on metaphoric creativity is seen as an examination of synesthetic metaphors. These poetic metaphors are especially vivid because they express cross-sensory mappings that are constrained by a cognitive principle whereby mappings go from lower sensory modes to higher ones (e.g., touch > taste > smell > sound > sight). One analysis of synesthetic metaphors showed several instances of these preferred patterns in the work of the Chinese writer Mo Yan. For example, the following expression demonstrates the synesthetic transfer from touch (i.e., the source domain) to smell (i.e., the target domain): "The house was full of bubbling hot stench, like a dead chicken or duck being scaled by boiling water." This sentence conveys the idea of a horrible smell being something that is 'hot' to the touch. Another metaphor expresses a synesthetic mapping from touch to sound, "... the music was light and bright, exquisite and emotive, stroking people's faces, like a gentle breeze in warm and flowery March." The word 'music' referring to sound is understood in terms of an extended simile of a 'breeze' that can be felt, as if 'stroking faces.' A different sentence illustrates a touch to sight (color) synesthetic transfer: "For a minute it was murky in the house and then a damp, light yellow sunlight squeezed itself inside through the crack of the door." This statement evokes an image of the 'light yellow sunlight' as something that can be felt as 'damp,' creating 'a mixed sensation amid the seemingly semantic conflict between' touch and color (Yu, 2007: 25). Finally, consider an instance of a sound to sight mapping: "The sound of the water coming from the river was getting

brighter and brighter, as if it had shape as well as color, and not only audible, but also visible." In this case, we understand the sound in visual terms, something the writer explicitly notes, which is perhaps the most common type of synesthetic metaphor.

These examples of poetic metaphor beautifully articulate how systematic patterns of cross-sensory mappings have great aesthetic appeal, which is surely one of the important rhetorical functions of some metaphors, especially when seen in literary contexts. Moreover, this examination of synesthetic metaphors demonstrates how the vividness of some creative metaphors is not purely visual, static, or 'mental,' because many vivid metaphors involves knowledge from many modalities, as well as kinesthetic experiences more generally. Furthermore, this study of synesthetic metaphors shows how bodily experience, and the relative prominence of different sensory modalities in our experience, constrains the creation of specific literary metaphors.

This analysis of creative metaphors also suggests that many metaphors arise not from source-to-target domain parallelism, but from extensive, contextually-driven source domain inferences that are both local and personal. Consider the following excerpt from the Nick Hornsby novel *'High fidelity'* (1995: 12).

I tried not to run down Phil too much – I felt bad enough as it was what with screwing his girlfriend and all. But it became unavoidable because when Jackie expressed doubts about him, I had to nurture those doubts as if they were tiny, sickly kittens, until eventually they became sturdy, healthy grievances with their own cat-flaps which allowed them to wander in and out of our conversation at will.

How do we understand the creative use of metaphor in this example, where 'grievances' were first conceived of as 'sickly kittens,' and soon became 'healthy' with their 'own cat-flaps'? Consider the case of 'cat-flaps,' which generally conveys the idea that the grievances about the boyfriend could freely enter the conversation as a kitten may enter and leave a house at will through the cat-flap. There does not seem to be a single source-to-target domain mapping between cat-flaps and the idea of freely talking about the boyfriend's problems. Instead, cat-flaps contribute to the further development of the source domain of grievances as kittens, or cat-like, and provides a richer scenario for thinking about the grievances as kittens, with their own free will.

Even if people initially attempt to establish clear source-to-target domain mappings for interpreting creative metaphors, people may fail to draw these inferences, and still extract additional information from the source domain (i.e., all things related to kittens and their behaviors) to create contextually relevant interpretations of the metaphors. But more importantly, the ubiquity of nonparallelism in metaphor, both conventional and novel, also suggests that understanding metaphoric language is not a matter of finding some independent meaning for each and every bit of target domain meaning. Whenever a metaphoric view of some topic is provided, as in the Hornsby passage, only some of the word choices may have direct relations to the target domain, with others acting to fill out, often in creative ways, our understanding of the source domain.

Context opportunistically selects which aspect of a source-domain scenario ends up being mapped or transferred to the target domain, and thereby when metaphorical sentence or parts of sentences end up with target-domain meanings of their own, leaving other related metaphorical chunks merely to contribute toward building the source scenario. (Barnden, 2009: 92–93)

Much of the creativity in metaphoric language arises from turning familiar, established metaphoric ideas and expressions and twisting them to create something new, but with an echo to the past. For example, the metaphorical proverb “Different strokes for different folks” originated in the 1950s reflects the cultural ideal of people’s need for mutual acceptance. Creative forms of this proverb over the years include “Different spokes for different folks” (from a book on bicycles), “Different smokes for different folks” (from a cartoon showing a picture of a businessman smoking a cigar and a hippie smoking a marijuana cigarette), “Different slopes for different folks” (from an Air Canada ad promoting ski vacations in Canada), and “Different Volks for different folks” (from a Volkswagon ad highlighting that it sells cars other than the Beetle). In each case, people appear to recognize the allusion to the original proverb, and find humor in the slight twist on that old piece of wisdom so blatantly being used for entertainment, commercial purposes.

Literary authors have also created novel versions of familiar proverbs to represent unusual (e.g., ironic, satirical, absurdist) perspectives on life’s enduring themes. Consider the following examples for the literary text ‘Proverbs from Purgatory’ (Schwartz, 2002; itself an allusion to Blake’s ‘Proverbs from Hell’):

A bird in the hand makes waste.
It’s like killing one bird with two stones.
Two heads are better than none.
A friend in need is worth two in the bush.
A stitch in time is only skin deep.
Too many cooks spoil the child.
I’ll have him eating out of my lap.
Let’s burn that bridge when we get to it.
A friend in need opens a can of worms.
Don’t cross your chickens before they hatch.
He’s just a chip of the old tooth

These twisted proverbs blend together parts of familiar metaphorical expressions to creatively convey new insights on old ‘pearls of wisdom.’ Each phrase expresses a satirical view, or the dark side, of common metaphorical themes that play such an important role in shaping people’s beliefs and actions. Thus, “A stitch in time is only skin deep” provides a rather profound alternative view of the worthy reminder that “A stitch in time saves nine” (i.e., even our most conservative actions taken to protect us from future harm may not guarantee that we always remain safe).

One important proposal suggests a metaphor, and all other forms of figurative language, may be ‘optimally innovative’ or optimally creative if it provokes a novel response, that:

differs not only quantitatively but primarily qualitatively from the salient response(s) associated with the stimulus and, at the same time, allow for the automatic recoverability of a salient response related to that stimulus so that both responses make sense (i.e., the similarity and difference between them can be accessible. (Giora, 2002: 180)

For example, the phrase “a peace of paper,” referring to a peace proposal, is seen as more being optimally innovative because it automatically generates a salient meaning (i.e., ‘a piece of paper’) that can be compared in some accessible manner to the novel meaning (e.g., both ‘peace’ and ‘piece’ are pronounced the same). Studies show that people find phrases like “a peace of paper” more pleasurable than familiar phrases (e.g., “a piece of paper”), variant phrases (e.g., “a single piece of paper”), and pure innovations (e.g., “a pill of pepper”). Similarly, novel metaphors (e.g., “a geometrical abstract painting” referring to one’s eyes), whose intended meanings differed significantly from their salient interpretations, are more pleasing than literal interpretations of these phrases, while novel metaphors are more pleasing than more familiar metaphors (e.g., “big eyes” referring to having a big appetite). In the end, highly novel and creative language will be less attractive, and less appreciated, than are optimally innovative metaphors that are creative extensions which allow for the recovery of the familiar.

Enhancing Creativity Through Metaphor

We enjoy the creative products of writers who twist and turn metaphors for new purposes. But these talents can also be taught. Art critics, for example, often use metaphor extensively in their writings, and some art educators have explicitly trained students to use metaphorical language to enhance their critical interpretation and appreciations of artworks. For instance, one project asked a group of students to write about small sections of Willem De Kooning’s famous 1952–1956 painting ‘Woman 1,’ by imagining themselves as colors going from the bottle or tube to the surface of the canvas. Some of their descriptions include (Rentz, 2003: 11):

I emerge from beneath, glowing through thin layers as a beacon of burning luminous, burning, light.

My life was safe, nice, safely contained within a glass jar. I could see and enjoy life. I could watch creation and think about concepts. My colour kept me warm and sensuous – the lid is off – the palate descends. Pain – anguish. I’m splattered over the surface, scrubbed, pushed, rubbed out. I feel thin, less than myself. Now I’m being overlaid – red and black are added to me?

I am the red oil paint squeezed from the tube. I have been tinted, scrambled, scrubbed, and dragged sometimes unwillingly and other times with an abandon, that just pushed other colours into submission. I become a bra strap, rouge roughly smudged onto a gaudy face, a tart, a mother’s womb, and a tinted pink pair of socks. I feel used like my subject.

These metaphorical understandings of DeKooning’s painting demonstrate how much of people’s appreciation of artworks is tied to the imaginative projection of themselves into the elements of artworks. There is very likely a symbiosis between how artists, of all kinds, create artifacts by thinking of themselves as the paint, music, clay moving toward more abstract artistic ideals, and audiences’ understanding of artworks imagining themselves, through embodied simulation, as part of the elements and actions perceived in artworks.

Indeed, the claim that people can creatively use metaphor to discover and express important ideas is increasingly seen in educational studies of students’ leaning of complex math and physics concepts through different embodied activities that bear

both concrete and metaphoric relations to the concepts being acquired. Studies of scientists' metaphoric gestures (e.g., mathematicians using their clenched fists to represent different 'sets') is consistent with the idea that embodied action is critical to the learning and continued development of abstract ideas that are often fundamentally structured in terms of embodied conceptual metaphors (e.g., *arithmetic is motion*, as is "Count up to 20 without skipping any numbers").

Finally, marketing scholars have explored several methods for engaging people's creative metaphorical understandings of consumer products to enable small firms, not-for-profits, and social enterprises solve a wide number of marketing and advertising problems. For example, the 'Zaltman Metaphor Elicitation Technique' (ZMET) is a qualitative methodology that uses in-depth interviews to probe people's thoughts and impressions of advertising. Informants are asked to bring images, in this case of advertising, that interests them, and to describe how each picture related to his or her impression of advertising (i.e., story telling). Later on, informants described their impressions of advertising using the different senses of sight, sound, touch, smell, taste, as well as emotional feelings that arose from these impressions. Informants then imagined a short movie that described their thoughts and feelings about advertising. Finally, the informants created a composite of their thoughts and feelings about advertising. This was done by first having informants select specific images from the various pictures that they wanted to include in the summary image. A graphic artist then scanned these images into a computer, and worked collaboratively with the informant to create a summary image.

The purpose of this procedure is to increase the likelihood of uncovering important facets of people's unconscious understandings of certain advertisements. Following data collection, all of the verbal protocols were analyzed to determine the metaphors that structured people's knowledge and impressions of advertising. First, researchers search through the protocols for instances of metaphoric words, phrases, and expressions. Next, these verbal metaphors were compiled and analyzed to identify a set of thematic categories that indicated something about people's overall impressions of advertising. The next step linked the thematic categories to specific conceptual metaphors. Finally, a smaller set of deep metaphors were identified that represented a higher-level of abstraction from conceptual metaphors.

This analysis revealed that there were three deep metaphors (resource, force, and the essence) that structured people's broad interpretations of advertising. Under these three deep metaphors were several groups of specific conceptual metaphors. The deep metaphor of resource, for example, was organized in terms of five conceptual metaphors: advertising as hostess, teacher, counselor, enabler, and magician. For instance, the hostess metaphor is associated with the thematic category of advertising serving to introduce how products and services have different benefits and values, as seen in one informant's comment in reference to an ad for motor oil, "in an ad I read that need certain oil in the summer and certain oil in the winter. I feel good . . . knowing that I am going to using the right product at the right time." Advertising as a counselor goes beyond the hostess metaphor to suggest emotional and cognitive benefits with a product or service, as seen

in the comment "advertising helps me to know which products will and will not reflect the sort of person I am." The magician metaphor describes advertising's ability to make people think differently, beyond the ad content, as seen in the comment that ads "stimulate your imagination" or "suggests avenues, opens doors of thought," or "evokes memories of happy things."

The deep metaphor of advertising as a force refers to advertising's powerful presence in contemporary culture, with conceptual metaphors (i.e., omnipresent being, a noisy neighbor, a broken record, a con-man, and seducer) mostly expressing negative views about advertising. For instance, informants commented that ads are things "you just can't away from" (omnipresent being), or are like "a horse sticking his nose through the fence" (nosy neighbor), that "are on again, and again, and again . . . pretty soon you tend to tune out" (broken record), or can "set a trap for me" to "get you to do what they want" (con-man), and "encourage me to buy things that I do not need" (seducer).

The final deep metaphor evident in this analysis was of advertising as an essence, providing idealized images of people and products. The main conceptual metaphor at work here is advertising is an evil therapist, as seen in the comment that ads "create within the individual feelings of anxiety, need, longing, desire, hunger, loss, helplessness, and anger that can only be relieved through the consumption of the product or service" being offered.

In general, ZMET elicited a wide range of metaphors, suggesting how people's understandings of ads are deeply organized around different patterns of metaphorical thought. The beauty of the technique is that it systematically prompts people to creatively think and say more about what they conceptualize of particular knowledge in metaphorical ways.

Glossary

Fresco A painting technique in which pigment is applied to wet plaster, which reacts with the pigment to seal it and prevent it from flaking off. Fresco compositions were planned in advance with the use of detailed full-scale charcoal drawings, whose main outlines were pricked and transferred to the wet plaster. Once the plaster was applied, rapid execution was essential. Artists had to reliably assess how much they could paint in a single session and constantly sprinkle water on the unpainted plaster to keep it damp and receptive to the pigment. Since most frescoes are architecturally situated, they often demand compensation for unusual vantage points and far viewing distances – complications that are absent from easel painting. Michelangelo's frescoes on the Sistine Chapel *Ceiling* and the *Last Judgment* on the Chapel's altar wall are widely regarded as the high point of this medium.

Humanism A worldview or perspective that attaches importance to human dignity, concerns, and capabilities, particularly emphasizing rationality. Humanism contrasts with the supernatural or appeals to authority and was a major stimulus to the Italian Renaissance. By Michelangelo's time, humanist scholars were honored as major intellectual figures. The tension between the humanistic reverence of

pagan antiquity and Catholic religious orthodoxy was a major factor in Michelangelo's character and art.

Nonfinito An Italian word meaning 'unfinished.' In the literature on Michelangelo, this term is used to denote the rough-hewn appearance of many of his sculptures. Sometimes this quality derives from Michelangelo having been prevented from working further due to circumstances; otherwise, scholars are divided as to whether the *nonfinito* quality represents deliberate satisfaction or unresolvable dissatisfaction with a work.

Ontogenetic heterochrony An embryological term describing how large differences in the morphology of organisms can arise from small changes in the timing of developmental events. Artistic novelty can emerge from a similar mechanism, by which traditional methods for art-making are modified. Many artists have used heterochronies as part of their creative process, with Michelangelo among the earliest and most effective exponents.

Pietà An artistic motif in which Mary, the mother of Jesus, holds the dead body of Christ. Michelangelo made at least three life-size marble Pietàs, including his last two sculptures. His earliest rendition, completed at age 25 for the Vatican, remains the most famous Pietà, a unique fusion of Gothic and Classical sensibilities.

Introduction

Michelangelo Buonarroti (6 March 1475 – 18 February 1564) was an enormously productive and influential Italian sculptor, painter, architect, and poet, and one of the supreme creative personalities of all time. His career and temperament have strongly influenced Western popular and scientific conceptions of genius (and religious conceptions of divinity), and he is widely regarded as the single greatest figure in all of Western art. The subject of numerous biographies and critical studies, even in his own lifetime, Michelangelo informs the study of creativity in many ways, but perhaps mainly in understanding the nature of the creative process.

This article is divided into two main sections. The first outlines Michelangelo's life, career, and works. His continual productivity and the sheer scale of his achievements necessitate emphasizing only certain themes (his most important works, the technical demands of his media, and his exploration of the creative process), while downplaying others (e.g., his politics, sexual orientation, possible psychopathology, personal relationships, etc.). The second section addresses how Michelangelo informs the study of creativity, with a special focus on understanding his creative processes and more general implications for process models of creativity.

Life, Career, and Works

Michelangelo's Early Life and Works in Florence

On 6 March 1475, Michelangelo Buonarroti was born in the Apennine village of Caprese. His father, a proud but impoverished aristocrat, governed Caprese for the city of Florence, to which the family relocated less than a month after Michelangelo's birth. He grew up in Florence and showed an early and intense desire to become an artist, despite his family's aristocratic aversion to manual labor – which, at the time, absolutely included painting and sculpting.

In the late fifteenth century, Florence was probably the single best city in Europe for an aspiring artist to launch a career. It was a political and economic powerhouse; it had a first-rate cultural and literary tradition, being the birthplace of Dante and Boccaccio; it also boasted much of the best painting, sculpture, and architecture anywhere. A very short list would include: several major fresco cycles by Giotto and Masaccio (arguably the two most important European painters of the previous 200 years); frescoes and panel paintings by a host of other great artists, including the young Leonardo da Vinci; Ghiberti's relief sculptures on the North and East sets of Baptistery doors (Michelangelo dubbed the East doors the 'Gates of Paradise'); many of the finest statues by Donatello (probably Michelangelo's greatest sculptural predecessor); and

the famous dome atop Santa Maria di Fiore, the largest since antiquity, designed, like many of Florence's finest buildings, by Filippo Brunelleschi. Brunelleschi also shared in the invention of linear perspective with Leonbattista Alberti. Michelangelo grew up surrounded by these works, and these manifestations of genius would all play substantial roles in his career.

Perhaps even more astonishing than this sheer cultural density is the fact that, except for Giotto's frescoes, all of these revolutionary artistic masterworks had been created within one lifetime of Michelangelo's birth. They represented the first major wave of what we now call the Renaissance, which was in full swing by the late 1400s. By then, painters, sculptors, and architects had solved many of the major problems of realistic depiction – for instance, lifelike proportions of figures, shading techniques to give the illusion of three-dimensional form, and a consistent perspective space. Other depictive problems – such as a complete mastery of the details of human anatomy, convincing emotional expressions of the face and body, and transient natural and atmospheric phenomena – had been partially worked out. Such progress was made possible by many factors: a rediscovery of ancient knowledge, an influx of wealth from Florence's commercial hegemony, strong civic pride that deliberately sought to create lasting monuments to greatness, the emergence of humanism, and, more pragmatically, the development of a strong craft tradition in the arts. In this tradition, artistic knowledge was actively sought and promulgated through an apprenticeship system, in an effort to surpass the achievements of earlier generations.

In 1488, aged 13, Michelangelo became a part of that system when he prevailed upon his father and uncle (his mother had died seven years earlier) to let him be apprenticed to Domenico del Ghirlandaio, a leading Florentine painter. Unusually, Michelangelo drew a salary rather than having to pay for his indenture, suggesting he had already attained considerable skill – not surprising, in light of what followed. At this time, Michelangelo explored various artistic media, showing his technical versatility and hinting at his future greatness. Ghirlandaio introduced Michelangelo to fresco, probably the single most demanding painting medium; several figures in Ghirlandaio's frescoes in the Cappella Maggiore of the Church of Santa Maria Novella are traditionally ascribed to Michelangelo. His early pen-and-ink copies of works by Giotto and Masaccio have a naturalness and sense of three-dimensional form exceeding even these great predecessors. Also recently attributed to the 13-year-old Michelangelo is a tempera and oil painting copy of an engraving of *The Torment of St. Anthony* by Martin Schongauer, which, if authentic, reveals yet another potential stylistic direction.

Sculpting in marble soon became his greatest passion; indeed, despite his wide-ranging achievements, Michelangelo always considered himself foremost a sculptor – in his view, the loftiest type of art. After only a year in Ghirlandaio's painting workshop, Michelangelo had the opportunity to study in an art school in the house of Lorenzo de' Medici ('Il Magnifico'), the richest man in Florence and its virtual ruler. Presumably Michelangelo had already modeled forms in clay; in the Medici gardens, he had access to ancient marble sculptures and studied with Bertoldo di Giovanni, who had in his youth assisted the elderly Donatello. Legend credits the young Michelangelo with

a faun's head in marble that caught Lorenzo's attention, earning him a place among the superstar humanist scholars in Lorenzo's court. Exposure to Neo-Platonic ideas is supposed to have influenced the content of Michelangelo's art; certainly they provided a set of mental concepts which would have been unusual in an artist of that time and likely contributed to Michelangelo's sense of the intellectual potential of art-making. He stayed in Lorenzo's household for several years.

In that time, Michelangelo created his earliest two extant marble sculptures. The first, *The Madonna of the Stairs*, is a shallow relief in which the back and arm of the infant Jesus already show the developed musculature of his later style. This anatomical emphasis is developed dramatically in *The Battle of the Centaurs*, a deep relief with numerous active figures. This work of the 17-year-old Michelangelo has been characterized as perhaps the most advanced figural composition of the Renaissance up to that time; it far surpasses any model he would have had in the Medici gardens. Besides anatomical concerns, both works show a variety of textures and finish, likewise characteristics of his later style. Michelangelo's formidable personality also became obvious in this time; in the Brancacci Chapel, amidst Masaccio's greatest frescoes, he criticized drawings by his fellow student Pietro Torrigiani so bitterly that Torrigiani punched him in the face, breaking his nose and permanently disfiguring him.

Lorenzo died on 9 April 1492, aged 43, and was succeeded by his incompetent son Piero, whose only commission for Michelangelo was for a statue in snow. Michelangelo returned to his father's house for a time. Lorenzo's death coincided with the rise of the charismatic Dominican preacher Girolamo Savonarola, whose fire-and-brimstone sermons on the vanity of worldly wealth made him enormously influential. After the French invaded Florence in 1494, ousting the Medici, Savonarola emerged as virtual dictator of the city, until public opinion turned; he was burnt at the stake on 23 May 1498. Despite his Medici connections, Michelangelo had considerable sympathy for Savonarola's message, attentively reading his writings and listening to his sermons. The tension between the ultra-humanistic and the ultra-religious was a constant throughout Michelangelo's life and informed the intense emotionality and iconographic richness of his works. The same tension is evident in Michelangelo's anatomical explorations around this time; reportedly he carved a wooden *Crucifix* in exchange for permission to dissect corpses in the Hospital of Santo Spirito – a practice strongly discouraged by the Church.

Michelangelo in His Twenties: Early Major Works in Rome and Florence

Given the volatility of Florentine politics, Michelangelo traveled for much of this period: to Venice in 1494, Bologna in 1494–95, and most decisively to Rome in 1496. There he executed his first life-size figure, a very pagan standing *Bacchus* (1496–97). In 1498, he accepted a French cardinal's commission for a large marble *Pietà* for the Vatican, promising that it would be the most beautiful work in marble in all of Rome – and delivering on that promise in 1500. In this work, Michelangelo demonstrated unprecedented technical mastery on several criteria: anatomical detail, emotional expressiveness, and the overall conception of the work. The uniformly

high degree of polish and detail is unusual for Michelangelo. Much discussed at its unveiling, in part because of Mary's very youthful face, it is the only sculpture that he ever signed. At one fell swoop, the Vatican *Pietà* put the 25-year-old Michelangelo in the front rank of living artists; his next major work would solidify his reputation as probably the greatest sculptor of all time.

Having returned to Florence, which had just been declared a Republic, Michelangelo received a long-desired commission on 16 August 1501 to carve a colossal statue of the Biblical *David*. The gigantic marble block he had been given had previously been worked on and somewhat compromised by another sculptor and had lain outside the Florence Cathedral since the 1460s. Michelangelo began carving the *David* in the early morning of 13 September 1501, less than a month after getting the commission; the completed statue was unveiled on 8 September 1504. A committee decided to place it just outside the Palazzo Vecchio, the governmental seat of Florence.

The *David* may be the most famous statue in the world. Its renown derives from a number of factors. It is enormous – 5.17 m tall (about 17 ft), without the pedestal. *David* is completely nude – one of the first such statues since antiquity. It depicts an unusual moment in the Biblical story – *David* tense and defiant prior to the fight with Goliath, instead of afterwards, as in most other depictions. Despite unprecedented anatomical detail and precision, its proportions are idiosyncratic – the head and hands are far too large, partly a consequence of the original intent for the statue to occupy a position high up on the Duomo, overlooking the city. Less obviously, the *David* presented daunting technical challenges, requiring an unusual pivoting of the figure inside the block (to circumvent earlier chiselling) and careful planning of the distribution of the figure's weight (throughout all stages of the carving process) to avoid collapse. All told, the *David* reinforced the 29-year-old Michelangelo's unique and total mastery of all technical and conceptual aspects of marble sculpture and his ability to succeed on the grandest scale.

In the three years of the *David*, Michelangelo also undertook several lesser sculptural projects, and painted the circular *Doni Madonna*, his only mature panel painting. It features a foregrounded Holy Family and five athletic male nudes prominently occupying the entire background, with the infant John the Baptist linking the two groups. In 1503, he also accepted a commission for statues of the Twelve Apostles, though he only began only one – the barely roughed in *St. Matthew*.

Shortly after completing the *David*, the city commissioned a fresco depicting *The Battle of Cascina* on one of the inside walls of the Palazzo Vecchio. On an adjacent wall, Leonardo da Vinci had been asked to paint *The Battle of Anghiari*. Leonardo was a generation older than Michelangelo, the greatest painter in Florence, and one of the most creative persons in history. Leonardo conceived his painting as a cavalry engagement, allowing him to depict a range of visual effects and human and equine forms; Michelangelo played to his own strength in depicting male anatomy, depicting soldiers bathing just as the battle alarm was sounded. This was a unique opportunity – the simultaneous commission of two of history's greatest artists, both at their peaks (Leonardo had just finished the *Mona Lisa*), for large murals in the same room. Sadly, neither fresco appears to have been completed; both likely reached the

'cartoon' stage of full-scale working drawings, and Leonardo probably did some painting. These drawings garnered enormous contemporary fame, serving as instructive models for many artists; over time, they were dismembered by admirers. Today, only some preparatory sketches and copies by other artists exist – though there is a tantalizing recent suggestion that the remains of the frescoes are preserved behind a wall erected by Giorgio Vasari, the Renaissance artist biographer who painted the frescoes now inside the Palazzo. Final completion of the frescoes was compromised by Leonardo's chronic indecisiveness and Michelangelo being called to Rome by the new Pope, Julius II, who would now play a crucial role in his career.

Michelangelo and Pope Julius II

With his own mighty force of personality and generous patronage, Pope Julius II (1443–1513) was a key figure in the development of the Roman High Renaissance, which would displace Florence from preeminence. He first brought Michelangelo to Rome in 1505 to design his tomb, which was to be placed in the Old Church of St. Peter's. Of the several designs Michelangelo had submitted, Julius chose one calling for a three-story freestanding structure with at least 24 statues. Michelangelo spent the next year quarrying marble and began carving. Work on the tomb was suddenly interrupted in 1506, when Julius commissioned Donato Bramante to build an enormous new Basilica of St. Peter's in the Vatican. Michelangelo, offended at the suspension of his commission, returned to Florence in a huff. Living up to his reputation as the 'warrior' Pope, Julius then executed a military capture of Bologna and forced the outflanked Florentines to send him Michelangelo, whereupon he commissioned a monumental bronze portrait statue of himself. Despite his distaste for bronze, Michelangelo made the statue; it was vengefully melted down several years later, when papal forces lost Bologna.

Scarcely back in Florence, in the spring of 1508 Michelangelo was again called to Rome, ordered by Julius to paint the ceiling of the Sistine Chapel, adjacent to the construction site of the new St. Peter's. The Chapel was of considerable ecclesiastical importance: there the sequestered College of Cardinals elected new Popes. At the time, the ceiling, approximately 5000 square feet in area and 70 ft above the floor, was simply gold stars on a blue background. Michelangelo was to paint the figures of the Twelve Apostles. He scoffed at the commission, claiming he was a sculptor, not a painter. Indeed, his experience executing fresco was limited to his apprentice days more than 20 years earlier. However, the challenges of the site – a lofty viewing distance replete with unusual perspectives, further complicated by the curved surface of the barrel vault – echoed many considerations of the projected *Julius Tomb*.

Despite initial reluctance, Michelangelo complied, but rejected the Twelve Apostles as a suitable subject. Probably with the aid of a theological adviser, a far more ambitious program was devised, consisting of more than 300 figures organized into nine central illustrations of scenes from Genesis, flanked by Old Testament Prophets and pagan Sibyls, plus Christ's ancestors; interwoven across the surface would be twenty nude male youths and painted architectural elements. Michelangelo made several hundred preliminary drawings – some of which

are among the finest of all time – and imported artists from Florence to assist with the execution. Work began on the part of the *Ceiling* away from the main altar, with the chronologically later scenes from Genesis, depicting the story of Noah. After a short while he dispensed with the help, and thereafter worked largely on his own.

Executed between July 1508 and October 1512, when Michelangelo was in his mid-30s, the Sistine Chapel *Ceiling* marks a high point of human creative achievement. Often executed with remarkable speed – the figure of Adam in the famed *Creation of Adam* was completed in just three days, the entire panel of *God Separating Light from Darkness* in one – the *Ceiling* figures can be said to have anticipated (and essentially solved) virtually all of the issues in the depiction of the human body that would occupy the best artists in Europe for the next century. Given the undertaking's unprecedented scale, Michelangelo learned as he went, and his approach to painting evolved: an early scene of Noah had to be completely repainted when the plaster did not set properly; later-done figures occupy larger areas, to facilitate viewing from a distance, and show increasing compositional boldness and dynamism – culminating in the massive figure of *Jonah* above the altar wall. Michelangelo also appears to have relied progressively less on preparatory cartoons, executing some later figures with unprecedented freedom.

Shortly after the completion of the *Ceiling*, Julius II died, on 21 February 1513. Michelangelo returned to the *Julius Tomb*, recasting the overall design and working on several statues for it, including the famed *Moses* and two *Slaves* now in the Louvre. Work would again be interrupted when Michelangelo was summoned back to Florence in 1516. The so-called 'tragedy of the tomb' would span 40 years and involve five or six different designs for the mausoleum, interleaved between other projects, and repeated negotiations about the details with Julius's heirs. Its final incarnation, no longer a freestanding structure, would not be finished until 1545, when it was installed in San Pietro in Vincoli in Rome.

Michelangelo After Forty

Back in Florence, Michelangelo was given several major commissions by Julius's successor, Pope Leo X, a son of Lorenzo de' Medici. The first was for the façade of the great Church of San Lorenzo. This occupied him for several years; a wooden model of his design exists, but in the end it came to nothing – to this day, San Lorenzo's façade is bare. In 1519, Leo commissioned Michelangelo to design the *Medici Chapel* (or New Sacristy) and then the Laurentian Library (for which he provided a magnificent staircase), both in the San Lorenzo complex.

The grandest of these projects, arguably Michelangelo's greatest achievement, simultaneously unified and multi-media, was the *Medici Chapel*, which he worked on for over a decade. Initially intended to house four tombs for Medici family members, in the end the only monuments are those of Giuliano and Lorenzo di Piero de' Medici (respectively, a son and grandson of Lorenzo 'Il Magnifico'). For once, Michelangelo had complete control of the entire project, designing the monuments, statuary, and architectural elements – though work was not completed until after he had left Florence for good in 1534. After significant

changes to the design, the final installation consists of two tombs on opposite walls, each with a statue representing the deceased and flanked by two reclining figures, statues of Madonna and saints on another wall, and an altar on the remaining wall. The four heroic reclining tomb figures, *Day*, *Night*, *Dawn*, and *Evening*, break new ground in the process of marble sculpting, with bold varieties of texture. The Medici 'portraits' were controversial, as they bore no apparent resemblance to their subjects – though this seems not to have bothered Michelangelo.

While Michelangelo was still working on the *Medici Chapel*, in 1530, Florence was besieged by papal and imperial forces. After its capture, an assassination order was put out on the 55-year-old Michelangelo because he had been in charge of fortifications for the city. Fearing for his life, he hid in a cellar under the chapel for six weeks; there he created some magnificent charcoal drawings on the walls, which were rediscovered in 1975. Michelangelo was reprieved only after the intercession of Pope Clement VII and made several trips to Rome in the early 1530s. He was in Rome when Clement died in 1534, and, fearing his pardon would be rescinded, never returned to Florence, living in Rome throughout his remaining 30 years.

Michelangelo was appointed Supreme Architect, Painter, and Sculptor to the Vatican in 1535. His first task was a fresco of *The Last Judgment*, to be painted on the altar wall of the Sistine Chapel – over 1700 square feet. Painted between 1536 and 1541, it is his most terrifying work, packed with almost 400 figures. In the lower left, the dead rise; the blessed occupy the upper register; the damned, the lower right. In the center, a musclebound, beardless Christ raises his hand in a gesture of damnation, surrounded by saints with their iconographic symbols. Among the most interesting passages is the dangling flayed skin of the martyred St. Bartholomew, which features a tragic self-portrait of the aging artist. By now, Michelangelo's anatomical exaggerations inflate the figures beyond any semblance of optical realism; their relative size also reflects their theological status, rather than obeying any unified visual perspective. The almost total nudity of the figures offended many viewers' sensibilities; in the wake of the Counter-Reformation, strategically placed drapery was added by Michelangelo's pupil, Daniele da Volterra.

Shortly after *The Last Judgment*, Michelangelo painted his final two frescoes, *The Conversion of Paul* (1542–45) and *The Crucifixion of Peter* (1546–50), in the Pauline Chapel, next to the Sistine Chapel. Smaller than their Sistine predecessors (each is about 400 square feet), they continue the anatomical distortions of *The Last Judgment*. Rarely seen, as the Pauline remains the Pope's private chapel, critical opinion is divided as to their quality.

After these frescoes, Michelangelo's main occupation was supervising the ongoing construction of St. Peter's, though he seems to have no formal training in architecture. His most visible contribution to the Basilica is the grand Dome, echoing Brunelleschi's in Florence, and in the end slightly modified from his plans. Many of Michelangelo's most moving drawings also date from this period. Throughout the 1530s, he produced a number of exquisitely polished figurative compositions on mythological themes; in his final years, aside from architectural designs, his drawings focused on scenes depicting the death of Christ, attaining an unsurpassed depth of expression.

Sadly, near the end of his life, Michelangelo apparently destroyed a large number of drawings he found unsatisfactory.

Amidst his late frescoes, architecture, and drawings, Michelangelo's sculptural output declined markedly. Barring two minor figures for the *Julius Tomb* and a small wood *Crucifix*, he produced only three significant statues in his last 30 years. One was an imposing bust of *Brutus* (1540). Another was a multi-figure *Pietà* (c. 1550–55), featuring a self-portrait as Joseph of Arimathea. During its creation, imperfections in the marble led Michelangelo to smash and subsequently abandon the group, though he permitted it to be reassembled. Last of all was the *Rondanini Pietà* (c. 1552–64), on which he is said to have worked just 6 days before his death.

Michelangelo died in Rome on 18 February 1564, probably of pneumonia, with the Dome of St. Peter's still only partly complete. His body was transported to Florence, and he is buried in the Church of Santa Croce, in the neighborhood where he spent his childhood. Inside the church, he lies near a monument designed by Vasari, his admiring biographer. His funeral was one of great pomp – an unprecedented honor for a visual artist, but fitting for the artist who, more than any other, lays claim to being the greatest of all.

Michelangelo and Creativity

General Aspects of Michelangelo's Creativity

As with all eminent creators, Michelangelo's superhuman achievements were made possible by many simultaneously interacting factors. The preceding biographical sketch has emphasized Michelangelo's rich knowledge base and mastery of the technical demands of his media – both of which contributed to his unusual exploration of the creative process, a theme which is further taken up below. Before discussing this in more depth, however, several other factors contributing to Michelangelo's creativity should be noted.

For starters, it is hard to think of anyone in history who had a significantly stronger motivation to create than Michelangelo. He aspired to artistic greatness as early as age 13, when he defied his family to be apprenticed to Ghirlandaio. As an adult, despite phenomenal success, he lived only for his art, largely forsaking friendships and basic comforts, sleeping in his boots, rarely washing, eating moderately, and taking on project after project that would require all of his energy. The *David*, the major frescoes, *Julius II Tomb*, *Medici Chapel*, and architectural work on St. Peter's each took multiple years of intensive and often lonely effort. Coupled with his high standards and strong opinions, Michelangelo's irascible, melancholy temperament isolated him even further. However, he continued to create even under the worst conditions, for example, while in hiding after the siege of Florence in 1530.

Besides motivation, Michelangelo also had phenomenal intelligence, particularly in visual and kinesthetic modes. In his youth, he apparently won a contest to make the worst drawing of a human figure (interestingly, not an easy feat for an expert), by vividly recalling some graffiti he had seen and copying the mental image. Kinesthetically, his dexterous draftsmanship speaks for itself; even in his seventies, he could carve marble with unmatched vigor and precision. Interestingly, his verbal intelligence was also very strong: he had allegedly memorized

virtually all of Dante's 14 000-plus-line *Divine Comedy*, and his own sonnets and madrigals rank among the very best Italian poetry of his time, earning a place in the Western literary canon.

More generally, tensions between opposing tendencies are manifest throughout Michelangelo's work, and they certainly energized his creativity. Perhaps most salient is the incompatibility of the paganism of classical antiquity versus Catholicism. This friction permeated the entire Renaissance, and in Michelangelo's case, it can also be cast in terms of his own likely homosexuality versus fear of damnation. Another tension, which his own career helped remedy, was the gulf between the lay perception of artists as manual laborers and his own view of art-making as a lofty, intellectual enterprise. Another, partly the result of his historical position, is the tension between the technical mastery of visual realism and the expressiveness that could be achieved by over-emphasizing some visual features – for Michelangelo, usually anatomical mass and movement, which grew in exaggeration during his career.

In all of these tensions, a comparison can be made between Michelangelo and his great rival Leonardo da Vinci (1452–1519). Leonardo's interest for students of creativity is mainly in his 'Renaissance man' diversity, contributing to a dozen domains in the arts and sciences. Michelangelo's diversity was less far-ranging but still extraordinary. He excelled in virtually all of the artistic media of his age, poetry, and engineering – having designed his own scaffold for the Sistine *Ceiling*, the fortifications during the siege of Florence in 1530, and the great Dome of St. Peter's. Curiously, however, within the domain of art, Michelangelo had perhaps the narrowest subject matter focus of any great artist. All of his work celebrates the human figure, particularly the heroic male nude; background elements, like the landscapes on the Sistine *Ceiling*, are absolutely perfunctory. In contrast, Leonardo pioneered improvements in the expressiveness of faces and moving human bodies, and introduced unprecedented nuances of light and shadow and atmospheric perspective in landscape. Both Leonardo and Michelangelo also made extraordinary innovations to the process of art-making, which greatly inform the nature of the creative process, and to which we now turn.

Michelangelo and the Creative Process

Art historians have always noted the important differences between Michelangelo's artworks and those of his predecessors and contemporaries – in terms of Michelangelo's dynamic power, his virtuosity of foreshortening and modeling, mastery of anatomical detail and musculature, the often overt emotionality of his figures and faces, and generally noble, heroic conception of humanity. While these are key aspects of Michelangelo's mature style, they are primarily features of his final products. Though fewer direct claims about his creative process have been made, such a process-oriented perspective probably better informs the basic nature of creativity than a reliance merely on final products.

The creative process is a major topic in contemporary creativity research. Virtually all scholars agree that it is highly complex and involves numerous subprocesses: generating and elaborating ideas, combining and expanding concepts, devising metaphors and analogies, evaluating a work-in-progress, etc. Because of this daunting complexity, researchers

usually heuristically divide the process of creation into several discrete but iterative stages or emphasize interactive component mechanisms. However, both approaches deprive the creative process of systematic structure, which might lead to a more profitable mode of understanding its rich dynamics.

Some guidance on this issue, particularly in the context of understanding Michelangelo, may be had by conceptualizing the creative process in more domain-specific terms, considering the technical requirements of the media in which he worked, how these constrained his activity, and how he violated traditional constraints. In Michelangelo's time, art-making techniques involving specialized knowledge of different media, perspective, and anatomy, were well articulated and passed along through workshop practice. Thus, the standard way of creating a work in a traditional medium can be understood, as can departures from the standard.

Looking at Michelangelo's work in this way reveals Michelangelo's radically different approach to art-making, compared to his contemporaries. The degree and variety of finish and textures, in unexpected ways, is unprecedented. Interestingly, few subsequent sculptors seem to have picked up on this, at least till Rodin, almost 400 years later. Likewise, while Michelangelo's '*nonfinito*' is a recurrent theme in the art historical literature, few conclusions have been drawn about how to understand it; scholars are divided as to whether the *nonfinito* quality represents satisfaction or dissatisfaction with a work.

However, one can recontextualize Michelangelo's *nonfinito* in terms of his active manipulation of the process of creation itself, a striking but underappreciated artistic innovation. This manipulation primarily involves introducing changes of sequence and timing into the basic methods of art-making, analogous to the embryological process of 'ontogenetic heterochrony,' by which small changes in the timing of developmental events can lead to large differences in final morphology. To illustrate this point, take Michelangelo's oft-quoted statement about sculpture essentially involving carving away excess marble to reveal a preexisting statue from a marble block. This remark is sometimes interpreted in a way that suggests Michelangelo had a completely preconceived idea of the final product and that he merely needed to remove extraneous parts of the block. The process of removing marble does require careful planning of the distribution of weight as a statue is carved, to avoid collapse; however, many degrees of freedom remain. Ongoing removal may reveal possibilities that can give new directions to a work, which may have little relation to one's initial conception. Indeed, Michelangelo sometimes radically altered a statue as he worked, and this tendency increased with age. For instance, his very last sculpture, the *Rondanini Pietà*, seems at one point to have been nearly completed; then the torso and head of Christ (its most important parts) were hacked away, leaving his right arm separated from the rest of the body and merging the head of Christ into the physical space of Mary's shoulder.

Other kinds of heterochronies, or changes in timing, are evident at other times of his career. He added unprecedented finish and detail to his early *David* and Vatican *Pietà*, extending the final stages of polishing beyond any of his predecessors' methods. In contrast, his subsequent *Prisoners* and *St. Matthew* are largely unfinished – perhaps for extrinsic reasons, though to great expressive effect. Other works, particularly those of the

time of the *Medici Chapel*, mix *finito* and *nonfinito*, even in adjacent passages. Perhaps most strikingly, the body of the *Day* statue in the *Medici Chapel* has a polished body but very rough-hewn face, a complete reversal of the usual degree of relative finish. Along these lines, Michelangelo's departure from traditional, planning-intensive modes of fresco painting have been noted above.

Conclusion

Michelangelo's awesome achievements in the visual arts represent a daunting case study of creative genius. In such a long, varied, and productive career, any single research approach must fall far short of fully explicating Michelangelo's depth and richness. Among the many possible perspectives, this article has emphasized a consideration of his expert technical knowledge base and active manipulation of the creative process as ways in which the titanic contradictions and tensions of his life and times were realized into transcendent works of art. Variations in the very process of creation have not really been addressed by creativity researchers, but the topic likely represents a fruitful avenue for future research. Half a millennium after he lived, Michelangelo remains in many ways ahead of his time, and a careful scholarly study of his artistic methods will no doubt continue to inform the nature of creativity in new and powerful ways.

Glossary

Causation The doctrine that events are linked by cause-and-effect relationships; a category of perception that structures our understanding of the world as a chain of causes and effects.

Construction of knowledge The process of forming beliefs, theories, and models of the world that shape our perceptions of the world.

Discovery The act or process of articulating some new fact about the world that is true independently of the presence or mind of the observer.

Induction The process by which singular statements or statements about singular events are used to lend support to universal statements, or statements that are true for all events of a particular type.

Mindfulness A state of active cognitive and emotional engagement with lived experience, leading to the creation of new categories for structuring our understanding of the world.

Mindlessness A state of passive acceptance of concepts and observations, usually involving the categorization of new perceptions in entrenched categories that are not responsive to new experiences.

This article introduces and elaborates the idea of a mindful state of being, and applies this idea toward a new understanding of the processes of creation and discovery. A mindful consideration of the world involves the conscious and continuous challenge of the categories and values we use to structure our experience, understand observations, and generate reasons for our actions, and the reconstruction of new categories, values, and concepts to replace old ones. We will show that the processes of creating new patterns of thought and breaking down old patterns are essential features of both processes of artistic ‘creation’ and processes of scientific ‘discovery.’ The sharp line that is so often drawn between the ways in which the artist and the scientist approach and relate to the world needs to be reconsidered. Recognizing the elements of artistic creation present in what we now call the process of discovery leads to a new and useful reframing of the work of the scientist, as well as a new perspective of the relevance of the work of the artist in the evolution of knowledge.

The article is structured in four parts. The first section introduces the concept of mindfulness and discusses its role in the way we use concepts to refer to objects, people, and events. It examines the implications of mindful consideration for the meaning, universality, and coherence of those concepts. The second section explores paths to mindfulness, in part by tracing the roots of the concept to the line of philosophical inquiry into the nature of our knowledge of the external world which began with the works of Hume and Kant. The third section reviews the phenomenology of mindful and mindless states, by reviewing the experimental record of mindfulness research, and establishing the relations in which mindfulness enters as a dependent and independent variable. The last section argues that mindful involvement with a phenomenon is a property of processes of creation and discovery alike, and that the line used to distinguish these processes from one another sets forth a misleading distinction. The benefits of seeing discovery as a creative process – rather than a process of passive observation of a ‘new’ phenomenon – are discussed.

Prelude

If the barber shaves all and only those who do not shave themselves, then who shaves the barber? It cannot be the barber himself, because then *he* would be shaving himself, and he is *only* supposed to shave those who do not shave themselves. Nor can it be someone else, since the barber shaves *all* those who do not shave themselves. By the law of the excluded middle, either the barber shaves himself or he does not (assuming that he is shaven to begin with). Since either statement seems to be excluded by the premises of the problem, we are left in a bind. The logician that we call on our cellular phone tells us the example represents a paradox – a problem whose solution process starts from true premises and reaches false or untenable conclusions by procedurally impeccable steps of reasoning.

To ‘solve’ the paradox, which we can do by claiming that there is no such barber, requires us to step ‘outside’ of the premises as stated and to question the assumptions inherent in the problem statement – to ask whether or not these assumptions are true or unique. To do so, we must resist the temptation to believe that what is said is more relevant or useful than what is left unsaid, as well as the temptation to mechanically apply the laws of logic in a repeated – but futile – search for an answer. Overcoming these temptations represents the step that takes us from a mindless to a mindful involvement with our experience.

Mindless and Mindful States

Mindfulness involves the creation of new categories for organizing our awareness of the world. A precondition for the unfolding of this process is an awareness that the concepts which we currently hold to be coherent are only tentatively and therefore temporarily so. Just like the idea of phlogiston – which was held by seventeenth century chemists to be the

substance given off by a burning object – turned out to be incoherent in view of subsequent stoichiometric analyses of oxidation, so the ideas we currently hold about the foundations of physics and chemistry, and the inferences we draw from these for biology and the social sciences, may turn out to have a far looser grasp on reality than we now think is the case. The predictive imperfection of physical laws may turn out to be related to the nature of the mental objects which we use to formulate those laws. If concepts are tools with which the mind picks up and handles objects, people, and events rather than direct consequences of the availability of and involvement with certain sensory experiences, then there is no reason to think that these tools are not perfectible – that they cannot be continuously and perpetually improved upon. Improvement of these concepts is a continuous process in which the destruction of old ways of thinking and relating to the world must precede – or at least accompany – the creation of new concepts and ideas. Implicit in this process is an awareness that the categories we are currently using are fallible and potentially incoherent, and that their usage is potentially self-defeating, in the sense that using them leads us to undertake actions which diminish our well-being – by our own definition of it.

Seeing the height of a car as predetermined by constraints outside of our control deprives us of the possibility to navigate through a tunnel whose ceiling is too low for its passage – which we could have accomplished by letting the air out of the car's tires. Seeing a problem as an exercise in the application of the laws of logic prevents us from solving it by challenging its underlying assumptions. Seeing a lamppost as just a lamppost deprives us of a safe place to which we can chain our bicycle. Seeing a piece of chalk as a mere writing implement deprives us of a means to soak up the ink we have spilled on a manuscript. Seeing a dog as a domesticated animal subject to the commands of her owner prevents us from picking up the small child when a Rottweiler is charging with a bizarre look on his face. Seeing a screwdriver, a screw, and a pair of pliers found in the back of the car as a trio of implements with no apparent connection to each other deprives us of an elegant way to open a wine bottle while on a picnic to which we have forgotten the corkscrew. Seeing a wire coat hanger as just a wire coat hanger deprives us of a means of getting into the car in which we have locked our keys. Seeing a can of shaving cream as a mere bathroom implement deprives us of a quick and effective method of removing a fresh red wine stain from a beige carpet. Seeing the instructions for an assignment as given and undiscussable prevents us from proposing – perhaps successfully – to write an essay on a subject which we feel passionate about. Seeing a policeman as the robotic representative of an objectively formulated and immutable body of laws deprives us of the possibility to negotiate a lower penalty for our unwitting infraction. Seeing a cigarette lighter as something we light cigarettes with deprives us of the possibility of using the organic compound in its reservoir to set aflame some damp wood on a cold night. Seeing the apple in our lunch bag as a piece of food deprives us of a projectile with which we could have dislodged the badminton butterfly stuck in a tree.

A mindful state involves the active drawing of distinctions between different raw sense data, and therefore the active creation of categories with which we structure our experience. It involves an openness to new information about the world,

especially to information which refutes inherent hypotheses and causal models, and which provides test cases for our concepts and ideas. It also involves an awareness of different perspectives or interpretations of the world – usually corresponding to different minds which 'see' in different ways. By contrast, a mindless approach to experience involves a cognitive commitment to inherited categories and causal models of the world, which may be invested with properties like truth and absolute certainty. Necessarily, when we are in a mindless state, we are likely to discount new information, and especially information which challenges or does not fit neatly into the hierarchy of concepts and values we use to understand the world – or to 'force fit' the new information into the inherited categories, by coding it, or committing to one understanding of it. Alternative ways of 'seeing' the world are threatening to our mindsets, since they directly challenge the conceptual framework used to categorize observations. Jon Elster's distinction between active and passive negation neatly applies here: a commitment to a rigid mindset represents a passive negation of an alternative point of view, which the subject implicitly – or passively – denies by virtue of not being aware of it. The transformation of passive negation into active negation is already a passage to a more conscious state – which acknowledges the existence and perhaps the threat of the alternative point of view, albeit in a negative sense. Active negation represents, relative to passive negation, an awakening to a more mindful state.

In the section that follows, we shall examine the characteristics which distinguish a mindful from a mindless state by discussing the nature and value of categories, with respect to their universality, verisimilitude, and communicability. We will seek to show that mindfulness and mindlessness are useful concepts for describing the evolution of concepts and categories, and can be used to predict the nature of the knowledge of the world which obtains at the end of an unfolding process of cognitive evolution.

On the Nature and Evolution of Categories

When speaking or thinking of our experiences and observations, we inevitably represent real objects, people, and phenomena by words or propositions which act as placeholders for these experiences in our minds. We refer to a person who periodically places some pieces of paper in our mailbox as the mailman; to a person who periodically brushes her teeth for at least 20 minutes while rolling her eyes at a mirror as an obsessive-compulsive; to a vast set of interactions between many people in which some end up with money and others end up with goods and services as a market; to a collection of events involving measurements of kinetic and potential energy in a small region of space as an electron; and to a beautifully shaped collection of viscera, bones, nerves, and muscles which is seemingly capable of thought and feeling as a self or a person. The names that we give our observations are the categories that we shall use to organize our experiences.

Categories have greater or lesser universality, depending on the sharpness of the criteria that we use for deciding whether or not an experienced object or event is an instantiation of a categorical class. Whether we consider the events of August 1991 in the former Soviet Union a coup d'état or a debacle,

for instance, depends on whether or not we define a coup d'état by the intent of the protagonists or by the ultimate outcomes of their actions. Whether or not we consider a group of people who are sleeping in the same house a family depends on the properties of the relationships between them – genetic relatedness, mating behaviors, psychological closeness – which we choose to ascribe to members of a family.

We discover, by examining the levels of universality at which a category can be applied, that our commitment to various categories is contingent on the criteria that we use to include an observation or experience in a category. At one end of the spectrum, all observed behaviors may be examples of a particular category. Some economists, for example, find instantiations of the maximization of personal utility in all observed human behaviors. By definition, if someone undertakes an action, it is in virtue of some interest or intention which she has had prior to taking it. The action therefore is taken to further the actor's interest – and therefore it is an example of self-interest-maximization. At the other end of the spectrum, there are 'categories' which contain a single element – the event or person or object from which they draw their substance. Barring time travel, there is only one initial charge of the French infantry at the battle of Waterloo.

It is only by maintaining a skeptical attitude toward the categories which we are currently using that we can retain the capability to improve upon them, and to make our own ways of expression more truth-like or verisimilar in nature. For example, once the momentum associated with a moving mass has been 'defined' as the mass of the object times its velocity, we cannot speak of the 'momentum' of a mass traveling at relativistically significant velocities, since the classical definition of momentum does not include a correction for the mass of the particle as a function of its velocity. Once we have settled upon an understanding of a person's actions as instantiations of the axioms of rational choice, we cannot accommodate phenomena such as weakness of will or susceptibility to biased perceptions and judgments. The first essential feature of a commitment to a flexible and renewable – rather than immutable – set of categories is openness to new information, or the willingness to continuously test existing categories using data to which they purport to be relevant. Just as under a microscope of increasing power solid cells visible to the naked eye give way to intricate structures which in turn give way to more structures, so testing available categories by increasingly nuanced situations to which they are applicable will often reveal that the categories in question give way to fresh – and perhaps predictively more competent – ways of looking at the same information. For example, categorizing a person in terms of his or her personality profile will give way to new understandings of that person once we debrief her on the workings of her mind while she was answering the questions of a personality inventory. At risk, of course, are the categories used to identify various personalities, which may become meaningless or incoherent upon dialogue or reflection.

The universality of the categories we have devised creates the illusion that our thoughts are more communicable through language than is actually the case.

People believe that others understand the same meaning that they have intended for a given word or concept, and that others use words the same way in which they use the

same words. Deborah Tannen's work has documented important differences in the interpretation of the same situations by men and women. A woman's allusive references to the shortcomings of a project, when sandwiched between laudatory remarks, may be taken by a man to be wholehearted endorsement of the project, contrary to the expectations of the woman interlocutor. When many blind men give their separate accounts of a single elephant after feeling different parts of the animal, their accounts may give the semblance of the presence of many different animals. When clear-sighted people speak of the feelings and the thoughts that the sight of the same elephant arouses in them, they may be misled into thinking that they are experiencing the same feelings by the fact that they are looking at the same elephant and uttering the same words. It is therefore possible for them to find 'corroboration' for the validity of the concepts they are using by confounding the phonetic similarity of their words with a similarity or identity of the experiences and thoughts on which those words are based. An awareness of more than one possible perspective or interpretation of the world involves, therefore, a minimally presumptuous approach to the expressions of others. Our understanding of what someone meant when she said something must remain open to refutation by her subsequent expressions and actions. A mindful interpretation of others' expressions involves a continuous search for the meaning of their sentences, rather than an early commitment to a particular image, or 'psychological profile' of that person, and is therefore closely related to a commitment to listening as part of the ethics of a conversation. By contrast, mindless interpretations of others' expressions involve a cognitive commitment to a particular set of motives or circumstances or properties which we impute to a speaker, and which is dispositive of any meaning that she gives her words. For example, we might say that it is in someone's best interest to take a particular view of the world, given her socioeconomic background (wealthy, well educated, never prospectively homeless). This 'interpretation' thus provides an excuse for thinking of ways to rebut her arguments, even while she is still talking, instead of listening for new nuances or ways to interpretation.

The Phenomenology of Mindful and Mindless States

Experimental research by Ellen Langer and her colleagues has documented the precursors and effects of mindless states as well as the conditions that make possible a mindful approach to the world. This section reviews her experimental results by considering mindfulness and mindlessness in turn as dependent and independent variables. In this way, the precursors and benefits of mindful approaches, and the precursors and drawbacks associated with mindless states, can be considered side by side.

The Consequences and Precursors of Mindlessness

Mindless behavior can often be distinguished by its consequences and effects, which means that it is often available to scrutiny only retrospectively. Locking ourselves out of a car or throwing socks in the garbage can instead of the laundry basket jolts us awake. William James once told a story of starting to get

ready for a dinner and ending up climbing into bed. Two routines that began the same became confused and he mindlessly followed the more familiar one. The phenomenon of mentally locking ourselves into routines and scripted behaviors is – by introspection – pervasive, and seems to have been so at least since the time of Henry David Thoreau, who despaired of the possibility of meeting someone who was truly ‘awake.’

Langer argues from experimental and anecdotal evidence that mindless behavior can be induced by a commitment to a particular role or label given to a person by himself or by others. In a study that pretested the ability of participants to solve simple arithmetic problems, and then assigned participants to roles of ‘boss’ and ‘assistant’ for an impromptu set of interactions, the post-tested ability of the participants labeled ‘assistants’ was significantly less than on the pretest. The label ‘assistant’ undermined the participants’ view of their abilities, which impacted performance.

Mindless behavior can also be induced by a commitment to a mindset, perhaps one that generated some good results in the past. Abraham and Edith Hirsch Luchins led participants of an experiment to the discovery of an optimal solution to an arithmetic problem, and then changed the problem so that the initial solution was no longer optimal, but could nevertheless be adjusted to give the required answer. They found that participants were reluctant to ‘let go’ of the initial solution to the problem, even when that solution became nonoptimal. Janice R. Kelly and Joseph E. McGrath asked participants to solve two problems, the first under a significant time constraint and the second under no time constraint. They found that the time pressure experienced by the participants during the first problem carried over to the second problem. It seemed as if the participants had committed themselves to the requirements of the first task.

Mindsets that people use to prejudice a particular state of being or activity can influence their enjoyment of that activity. Labeling an amusing task – playing with the form and content of cartoons – as either ‘work’ or ‘play’ influences the self-reported enjoyment of the process of performing the task. Those to whom it was suggested that the activity was a form of play were more likely to report enjoying the activity than were those to whom it was suggested that the activity was a piece of work.

Cognitive commitments were also shown to influence people’s performance on tasks designed to measure presence or awareness. Participants in an experiment were given a description of an imaginary perceptible disorder in which it was implied that they may be suffering from it without knowing it. Some participants were given information which suggested that it was likely that they were affected by the disorder, and others were given information which suggested that it was unlikely that they were suffering from the disorder. Participants who were led to believe that they were probably not subject to the disorder were more often subject to the (simulated) symptoms than were those who thought that they might have the disorder: people in the former group performed more poorly on a task of aural perception than did people in the latter group.

The Phenomenology of Mindful Awareness: Some Experimental Results

The most remarkable regularity that emerges from the experimental record is that people are sensitive and open to

‘awakenings’ which challenge them to question their own assumptions and to break down their precognitions. As Langer points out, mindlessness is very different from Freud’s conception of willful-notknowing, which involves the will to actively repress or banish a particular thought. Langer’s experiments point to some of the possibilities for opening up inherited categories and mindsets to new information and fresh perspectives. These range from mere promptings to avoid labels, to the conditionalization of propositions and hypotheses about the world.

It has been shown that the label given to a person sharply influences the evaluation of that person even by trained therapists. Participants in an experiment were asked to provide evaluations of a man whose interview was presented to them on videotape. Half the therapists were told that the man is a job applicant, whereas the other half were told that the man is a patient. Those therapists who had been trained on the use of labels saw the man as well adjusted, regardless of the label that he was given by the experimenter. Those therapists who had received no such forewarning were strongly influenced by the label they were given at the beginning of the experiment: they found the ‘patient’ to have serious psychological problems.

The direct exposure of a person to a concrete problem – as opposed to the exposure to a problem after a period of training in the use of a particular solution – was also found to increase the likelihood that the problem solver will arrive at several possible ways of solving the problem, relative to a person that has received training. College students asked to use a set of building blocks to build a bridge over an imaginary river, and who had no prior exposure to the use of the blocks, came up with a greater number of possible solutions than did students who were shown examples of how the blocks could be used.

The use of conditionalization of concepts and causal relations was also found to lead to a more mindful consideration of the information received. Students to whom a model of urban development was presented in a conditional way (i.e., in which concepts were presented using the construction ‘A could be B,’ rather than the construction ‘A is B’ or ‘A is a model for B’) were more successful in making use of the information presented to them than were students who were presented with the information in absolute terms (i.e., using either constructions like ‘A is B’ or constructions like ‘A is a possible model for B’).

In another study, students were given different versions of a typical examination given to stockbrokers. Some versions presented the information in deterministic and closed-ended terms. Other versions presented the information as a set of stylized facts, whose statistical nature was apparent. The students who were presented with the versions of the ‘facts’ that were more open to criticism or to revision generated more creative answers – and reported enjoying reading the material to a greater degree – than did the students who were presented with the deterministically framed information. The implication is that the presentation of models of the world in ways that indistinguishably conflate objects with their representations – which underlies the vast majority of undergraduate curricula in the natural and social sciences – is self-defeating if the purpose of such a presentation is to encourage the creative application of the models to real-world situations.

Empirical investigations have also revealed some effects of mindful consideration on the attitude and motivation of people

toward certain activities, other people, or states of being. People asked to engage in an activity which they initially thought of as unpleasant – such as listening to rap music – were more likely to find the activity pleasurable after performing it if they had been asked to notice several novel aspects of the activity than if they were not given instructions before engaging in it. These findings suggest that the myth of well-defined preferences which do not change over time – a staple of normative and positive economic theory for the past 50 years – may be the outcome of a self-fulfilling prophecy, which breaks down when people engage in the activities mindfully.

Mindful Health

A quick review of some recent health findings suggests that when we create new categories and give up limiting mindsets, the control we have over our health is enormous. Mind/body dualism created the problem of the search for mediating mechanisms. How do we get from the nonmaterial mind to the material body? If we give up this dualism and put the mind and body back together, the problem goes away. Langer and her students did just that in several studies with dramatic results. Essentially they 'put the mind' in different places and took physical measures to see if the body registered the difference. For example, eye charts have progressively smaller letters, thereby creating the expectation that soon we will not be able to see. Reversing these charts so the letters become progressively larger, led subjects to be able to see what they previously could not see. In another investigation chambermaids were questioned about their exercise. Despite the fact that they exercise all day long, they did not see themselves as getting exercise and consequently they were relatively unhealthy. They were told that their work was exercise. A month later, they reported no changes in how hard they worked, what they ate, or how much they exercised outside of work. All that changed was their mindset: work for them now was exercise. They lost weight, showed a decrease in body/mass, and waist/hip ratio and a drop in blood pressure. Placebos and spontaneous remissions may be explained the same way. Archival research found similar results. When the mind felt old, the body did as well. For example, balding is a cue for old age. Men who bald prematurely, also have premature prostate problems. Clothing serves as an age-related cue: those who wear uniforms and thus have fewer age-related cues stay 'younger' longer than those without uniforms. For example, Korean taxi drivers who wear uniforms live longer than Korean taxi drivers who do not wear uniforms. Many studies confirm the idea that if the mind is cued to be healthy, the effects are measurable and often dramatic. Many seemingly unavoidable damages to our body can be reversed or ameliorated by the conscious application of the mind.

Mindful Approaches to the World: Some Links to the Philosophy of Knowledge

The 'paradox' of mindfulness is that if the attainment of a mindful state could be enacted by following a prescription, an algorithm, or a program, then that state would cease to be

mindful. Analogously to self contradictory impulses like 'be spontaneous' or 'try to forget her,' the injunction 'be mindful by following these simple rules' is self-defeating, for it is precisely in the escape from rigid rules and rule-based behavior that the essential characteristic of a mindful state lies. The path to mindfulness must itself be created, and therefore is itself the outcome of a mindful state. As noted previously, a precondition for the unfolding processes of cognitive creation and destruction is a skeptical or at least modest appraisal of the current concepts and ideas which we use to understand the world. Occasions for learning to be modest are to be found even in our daily experience. As Rupert Riedl has shown, a visit to the house of a new friend can throw doubt on intuitions about causes and effects which are so evident that they seem necessary or inescapable:

It is late in the day and the shadows have fallen. The house we enter is unknown to us, but the situation is familiar. It is too dark in the entrance hall to read the name plates. Where is the light switch? There – three buttons. It's probably the top one. We push it and immediately jump back: for as long as the finger was on the switch, a bell shrilled through the whole house (and then the fluorescent light flickers on as well). Embarrassing! It must have been the doorbell (or did we also cause the light to come on?) A door opens behind us. Have we roused the tenants too? But no! It is the front door. "Excuse me" says the person coming in, "I thought the door was already locked." Did he then cause the bell to ring and did we turn the light on after all? Apparently. But why do we expect to be the cause of an unexpected coincidence, namely, the simultaneous occurrence of the touching of the switch and the sound of the bell?

Riedl has similarly shown that seemingly unimpeachable intuitions and expectations about causes that underlie our most indignant moral sentiments may turn out to be lamentably erroneous:

People are getting on a streetcar in Vienna. Among the passengers is a working class woman with her young son. The boy has an enormous bandage wrapped around his head. (How dreadful! What happened to him?) People give up their seats to the afflicted pair. The bandaging is not a professional job, it was obviously done at home and in a hurry; they must be on their way to the hospital (people secretly search the child's face for an explanation, and the bandage for traces of blood). The little boy whines and fusses (signs of sympathy from everyone). The mother seems unconcerned (how inappropriate!); she even shows signs of impatience (that is amazing). The little one begins to fidget; his mother pushes him back in his seat. The passengers' attitude changes from discrete observation to manifest concern. (The mother's behavior is disgraceful!) The boy cries and tries to climb the bench on which they are sitting. His mother pulls him back so roughly that even the bandage is beginning to shake. (The poor child! This is terrible!) The passengers' mood turns to open confrontation. The mother is criticized, but for her part rejects all interference. Now she is criticized again, and more openly. Thereupon she tells them to mind their own business and questions the competence of all those who criticized her. (That is too much! An outrage to human decency.) Emotions run high, and things get noisy and turbulent. The child is bawling; his mother, red-faced and furious, declares she is going to show us what is the matter and begins (to everybody's horror) tearing off the whole bandage. What appears is a metal chamber pot that the little Don Quixote has pushed so tightly on his head that it is stuck; they are on their way to get help from the nearest plumber. People get off the streetcar in great embarrassment.

It is possible, and desirable, to go further and to seek an explanation of the very nature of causation, rather than merely

challenge various proposed causal links. Philosopher David Hume criticized our knowledge of causal relations by first arguing that we are rationally justified in believing that one event (a B event) will follow another event (an A event) if we are justified in believing that nature is uniform – that the laws of nature are invariant across time. We are justified in believing that nature is uniform either by a priori reasoning (of the type, ‘axioms of real axis mean that $(2\ 1\ 2) \bmod 10\ 5\ 4$ could not possibly be false’) or by our own experience. A priori reasoning fails because we can imagine a set of axioms which imply that nature is not uniform (one axiom could be, ‘nature is not uniform, although it seemed that way up to time 5 T’).

We are left to our experience, which means that we are justified in believing that nature is uniform only if we are justified in believing that our past observations of uniformity imply that nature will be uniform in the future. But we are justified in believing this statement only if we are justified in believing that nature is uniform. So we are justified in believing that nature is uniform only if we are *already* justified in believing that nature is uniform, which we are not. Hume characterizes causation as a habitual construction of the mind.

Mindless approaches to choice involve the acceptance of inherited categories, either from one’s own experience, or from other minds. These categories can be of the type, ‘an A event is of the type that causes a B event,’ given some inductive evidence for this relationship. This inductive evidence can be very scarce: a chance observation, the opinion of a person which the mind has labeled as an expert, and so forth. Therefore a mindless approach to choice is equivalent to the mechanical acceptance of a view of causation which Hume has criticized.

Another aspect of mindless approaches to choice which can be understood from a Humean perspective has to do with propositions of the form, ‘an A event in the world will cause a B event in the mind.’ This sort of causal reasoning can lead to inferences of the sort, ‘being with person *x* has made me feel bad. I will feel bad next time I am with person *x*. Therefore being with person *x* is undesirable.’ Here ‘T’ is using inductive evidence to predict her own affective response to a stimulus which she has experienced before. This is a form of mindlessness. One cannot ‘know’ how one will feel, but can only suppose that one will feel in a certain way. By developing a cognitive commitment to that ‘guess,’ one may be precluding the possibility of feeling in a different way (or taking a different action).

Now let us turn to mindful approaches to choice. How do we draw distinctions anew? By referring to properties of objects, events, and phenomena. How do we know of these properties, and how do we know that these properties will ‘hold’ in the future? By a mechanism akin to induction. We use spatiotemporal boundaries to categorize events, and we assume a Euclidean geometry of space, coupled with a Newtonian conception of time (flowing equably from an absolute past to an absolute future). How do we know that such a mechanism for categorization will work in the future? Because it has worked well in the past. What are the logical grounds for our belief in this regularity? Again, our experience. We reach the same sort of circularity which was reached by Hume in the case of causation, which requires some antecedent justification for the concept of causation not to be found in the elements or the temporal sequence of the elements of a presumed causal chain.

The idea of causation is also useful to an understanding of the nature of categories, and to their limitations and boundaries. Quite often, what makes the properties of objects or people what they are, and therefore what makes objects or people what they are, is their causal powers. The causal powers of a piece of chalk, for example, can be used to distinguish between properties that seem essential (like solubility in water and white color) and properties that seem inessential (like being in the left pocket of a person’s skirt, or being 300 miles south of a Ford Pinto – these properties can be altered by changing anything about the objects that they describe, for example, by shaking the skirt or moving the Pinto).

The category in which we place a person or an object has something to do with what we believe its properties to be – otherwise we would treat categories as mere conventions and would stop seeking to ‘make sense’ to one another in a more than conventional sense. Queries about causation will therefore also be queries about categories, to the extent that we use the causal powers of an object to draw the boundaries of a category to which that object belongs. If we challenge the notion that causation is ‘objective,’ or that it reflects a property of reality that is independent of our minds, then we will simultaneously challenge the notion that the categories which we are currently using to organize our experience are objective, and accept the role of the mind in determining what we refer to as real. In as far as the history of people’s presence in the world is also a history of people’s ideas about the world and therefore of the relationship between their minds and their experiences, we are interested in mindfulness as a way of looking at the evolution of ideas. Mindless approaches to experience map onto dogmatic perspectives, whose exponents seek to ‘prove,’ verify, or justify their theories by means of repeated confrontations of the theory and data sets that emerge from preplanned programs of empirical investigation. Mindfulness, on the other hand, does not entail a single approach to the evolution of consciousness or awareness of the world. A commitment to any particular epistemological program entails a commitment to a particular set of categories, and to a discursive form of referring to those categories. Such a commitment therefore runs contrary to an unconstrained way of knowing the world, and to a fallibilist approach to knowledge.

We shall consider, in what follows, the two most well-known approaches to the historical evolution of concepts: Karl Popper’s description of the evolution of ‘objective’ knowledge by a repeated process of trial and error carried out by many (like-minded, fallibilist) people over a long period of time, and Georg Wilhelm Friedrich Hegel’s description of the evolution of consciousness through a dialectic process, by which ideas are refuted or negated, and expanded and turned upon themselves by confrontations with their antitheses and transformations into syntheses. These descriptions of the passage of the mind through the world are illuminating, but not unique or necessary. We will argue that they *describe* possible mindful approaches to the world – in the sense that they incorporate openness to new information and alternative points of view and leave open the creation of new categories – but do not *define* or otherwise constrain such approaches. Furthermore, neither has a built-in mechanism for excluding a mechanical, automated, or mindless application of its form to the problem of reconciling our cognitions with our experiences. We shall

explore – in order to illustrate this antinecessitarian point – some alternative descriptions of the evolution of ideas in time.

Popper and the Discourse of Trial and Error

Popper wanted to portray the evolution of human thought as a sequence of trials and errors, which leads to a ‘growth’ of the knowledge we have of the world. The ‘scientific method,’ which his *Logik der Forschung* is credited with making explicit, is a process by which a person faced with a concrete problem offers, tentatively, a theory by way of a solution to that problem.

He then proceeds to criticize that theory, most importantly from an empirical standpoint, by comparing the predictions and empirical statements of that theory with empirical observations of the phenomenon one is trying to predict, influence, or control. A theory withstands or does not withstand such criticism according to whether or not the empirical statements it generates are *logically* contradicted by the empirical statements generated by the experience of the person in question.

The logical law of the excluded middle – by which a statement is either true or false, but not both, nor neither – is therefore the engine of progress in the history of knowledge, in Popper’s model. Theories that have withstood the most vigorous criticism of this sort are accepted only provisionally. Their ultimate truth or falsity remains forever an open question.

The only apparent constraint which the scientific method places on the scientist is that of adherence to a particular form of criticism – that of empirical testing – which requires that theories be expressed in a falsifiable form, or a form which makes them refutable by empirical observations. The scientist is free to use any association of thoughts and ideas, any conceivable ontology, and any means of generating empirical statements from these thoughts, in order to arrive at the empirical statements required by Popper. Furthermore, one of the desiderata which the scientific method seems to strive for is that of openness to new information, which it accomplishes by requiring that theories be put through the most rigorous empirical tests, and accepted only provisionally when they have passed these tests.

It must be observed, however, that the application of the scientific method critically depends on the application of the law of the excluded middle in order to adjudicate between alternative hypotheses. The disappearance of this ‘engine of natural selection’ among competing theories is what makes the dialectic, to Popper’s mind, unappealing as a description of the evolution of knowledge. He argues that the simultaneous acceptance of thesis and antithesis via their incorporation into the synthesis, in the case in which they contradict one another, amounts to the acceptance of *any* proposition whatsoever, by a straight application of the laws of logic. This criticism, however, is based on the assumptions that the collective, shared consciousness of the world which is generated by the application of the scientific method is in fact an objective knowledge of the world – a knowledge whose truth-likeness is not dependent on the interpretative acts and thoughts of a person possessing it, and that the progress of objective knowledge is ‘powered’ by the application of the law of the excluded middle for the purpose of criticizing theories. The first assumption is required because Popper

makes knowledge itself – rather than the consciousness of the knower – the subject of his criticism.

Describing knowledge as an objective, independent entity requires us to create a rule separating actuality from mere possibility, whereas saying that only states of consciousness – combining knowledge with the will to know – exist does not entail the rejection of contradictions on the grounds that they can generate any statement, unless we also assume that there exists the will to apply the laws of logic to that end. One must *want* to generate the universe of all possible statements from a contradiction in order for this universe to come into being. Accepting either of these assumptions is the outcome of an act of will – their acceptance is not required by any sort of precognition or ascertainably true precondition.

That such an acceptance of the assumptions underlying the scientific method *must* be the outcome of an act of will – rather than the inevitable consequence of the aim of arriving at truth-like descriptions of the world – is supported by the proof that Popper’s definition of verisimilitude cannot be used to discriminate between two false theories so as to judge one theory to be more truth-like than another theory. In conjunction with Popper’s fallibilist doctrine – which states that all theories are sooner or later shown to be false – the result entails that there is no ‘progress’ in scientific knowledge – at least not to the extent that progress is defined by the evolution of more truth-like theories out of less truth-like theories.

Hegel and the Dialectic Process

The dialectic evolution of thought is based on the interplay of three concepts. The thesis is an idea or a proposition that emerges or is put forth; the antithesis is a refutation or negation of the thesis. It springs forth against the thesis, seeking to deny its substance. The synthesis represents the merging together of the thesis and the antithesis, perhaps with the aim of recognizing the merits and limitations of both. The synthesis then itself becomes a thesis, and the process begins anew. Hegel introduces the idea of the dialectic by way of an example which suggests that he did not think of the thesis and the antithesis as propositions which may be connected by a logical relationship like mutual contradiction, and reminds us that he did not hold fast to the definition of truth as a correspondence between the content of a statement and the content of an observation.

The bud disappears in the bursting-forth of the blossom, and one might say that the former is refuted by the latter; similarly, when the fruit appears, the blossom is shown up in its turn as a false manifestation of the plant, and the fruit now emerges as the truth instead. These forms are not just distinguished from one another, they also supplant one another as mutually incompatible. Yet at the same time their fluid nature makes them moments of an organic unity in which they not only do not conflict, but in which each is as necessary as the other. . . .

Whereas the scientific method assigns a predominantly *critical* role to the mind, Hegel’s view assigns the mind a creative and generative role. Not only does consciousness of the world change over time, but the criteria for demarcation between illusion and consciousness also change. No such freedom is available to one who follows the scientific method, who must conform to a correspondence theory of truth and

to the law of the excluded middle in order to keep the engine of criticism running.

Two Alternative Views of the Evolution of Mind

The processes of dialectic reasoning and of trial and error are two of several possible approaches to the evolution of thought. The following two are put forth as examples based on loosening two of the constraints which logical structure places on the method of trial and error proposed by Popper. Because Hegel's broader conception of the evolution of consciousness by a process of turning-upon-itself can be seen to subsume both the idea of the dialectic and discursive alternatives to Aristotelian logic, the two examples can be interpreted as workings-out of that conception.

Necessity, possibility, and the openness of the past and present

If we were to replace the relation of necessity or entailment in logic with one of possibility or enablement, we would achieve a discourse which highlights the role of the processes of imagination and interpretation, rather than that of calculation. The reason for this is that the number of possibilities – or options for action or belief – that we can generate increases with the number of interpretations that we can give to our current psychological states. If an experience is categorized unconditionally, in a way which inhibits further, playful consideration of its meaning, penumbra, or resonance, and if the categories we use are, in our minds, linked by relationships of logical necessity, then the states that we are led to by a single experience will be determined or fixed by the working of the logical apparatus we have at our disposal. Increasing the number of interpretations that we are willing to give to a single experience therefore will also increase the number of possible options for action or the number of possible psychological states which we can take on following that experience.

The replacement of the logic of necessity with the logic of possibility can be accomplished by an exchange of the will to know, or determine or control the future for the will to play with our relationship to the present and the past. Popper argued persuasively, in the context of his numerous lucid presentations of the scientific method, that 'the future is open' in the sense that our subsequent experiences may at any time refute our current beliefs. Loosening the bolts of logical argumentation can lead to psychological states in which the past and present are also open to creative interpretation – at the cost of a decreased sharpness of the relationship of denial or refutation.

Participation, the interpretation of events, and the openness of ontology

If we replace the process of constataion or 'passive' observation that is supposed to provide the empirical tests of a theory with a process of participation or creative interpretation in the experience which we now describe as observation, then we will arrive at a 'story' about the evolution of knowledge that is markedly different from that embodied in Popper's account of the scientific method. The approach that emerges is based on the relationship between the observer's observation of an event and his conscious participation in his observation of

that phenomenon. For example, one could be observing an event, observing oneself observe that event, and observing the observation of the observation. The resulting state of mind can be reduced to a mere constative statement by the reductively minded scientist. However, such a reduction would prevent us from exploring the possibilities which the quality of reflexivity – or active participation in our own experiences – affords us. We could not, for example, gauge the effect of the observation on ourselves, or the effects of becoming conscious of that effect, and so forth.

A reductionist approach also truncates unnecessarily our representation of experience: if the essential properties of an object or person are connected to its causal powers, then the results of someone's experience of that object – her thoughts and actions, including the names she gives that object – are part of the causal powers of the object. Calling a facial expression a smile, for example, becomes part of the essential properties of that event – since a smile can be the cause of another smile or of a grimace.

Loosening the constraints we place on the link between experiences and statements about experiences leads us to an approach to descriptions which is reflexive as well as constative. In turn, this approach permits the incorporation of the process of interpretation and conscious participation of an event into the description of that event, and therefore makes the description open to revision after confrontation with additional information, or with the interpretations which others give to the same event. As in the case of the replacement of the logic of necessity with the logic of possibility, the replacement of descriptions closed to reflexive interpretation by descriptions open to reflexive interpretation must be the outcome of a will to replace a focus on predicting or expecting a particular future with a concern for an active participation in the present. The replacement of descriptions with reflexive interpretations leads to an ontology – a representation of what exists – that is itself open to evolution.

Mindfulness, Creation, and Discovery

We are accustomed to thinking about the process of artistic creation in sharply different terms from that of scientific discovery. On this view, the artist creates new forms and images from inherent or given elements, whereas the scientist breaks down his perceptions and observations into elemental components and systems, in order to understand them. Whereas 'reality' for the artist involves a component of active participation of her mind and is therefore created, enacted, or brought about by a conscious act of will, for the scientist 'reality' is an object of passive observation – of discovery through repeated observations and criticisms of those observations. In all instances, 'reality' stands independently of the will and imagination of the scientist, and his involvement in it is either passive or supposedly governed by the impersonal laws of rational discourse. Thus, just as reason and desire, or affect and cognition, are thought of as independent aspects of being, so the scientist's contemplation and analysis of reality is divorced from the artist's creation and interpretation of it.

We would like to show that this view is mistaken, by showing that the hypotheticodeductive method can be

understood as one possible instrument of interpretation, whose application leads to intelligible results by an act of will and imagination very similar to the artist's activity. Testing a hypothesis by comparing its content with that of empirical statements is a process whose outcome depends on the choice of hypothesis and the interpretation of an observation used to produce an empirical statement. Even simple empirical attributes like 'being red' are outcomes of an interpretation of a sense datum, rather than direct representations of that datum. Attempts to 'depersonalize' observations by substituting 'emitting radiation with a wavelength of $x \text{ nm}$ ' for 'being red' replace one act of interpreting a sense datum (i.e., interpreting a sensation by the proposition 'is red') by another (i.e., interpreting a visual perception by the proposition 'is equal to $x \text{ nm}$ ').

When by 'observation' we mean 'intelligible empirical statement,' there is no 'immediate' access to our experiences: the mind participates, to a greater or lesser extent, in the creation of an intelligible interpretation.

The process of generating hypotheses that can be tested against a set of empirical statements or theories which inspire new programs of empirical inquiry can also be interpreted as a creative process. We have, to begin with, considerable freedom to choose the elementary propositions – or axioms – which will lead to a set of mutually exclusive and collectively exhaustive hypotheses that can be tested against our 'intelligible empirical statements'. Events – in and of themselves – cannot refute or corroborate one another. It is only statements about events that can stand in such logical relationships *vis-à-vis* one another, and then only relative to a system of self-consistent axioms. If we were to admit contradictory axioms to stand side by side in a logical system, then we would have to accept any hypothesis as following with equal logical force from those axioms, and therefore would have to accept any hypothesis as being corroborated by any empirical statement.

To see this, consider how we might produce equally logically impeccable proofs of the statements, 'the president beat his wife' and 'the president did not beat his wife,' from the logically contradictory statements, 'today is Tuesday' and 'today is not Tuesday.'

First, from the premise 'today is Tuesday,' we can deduce the consequent, 'either the president beat his wife or today is Tuesday' (since $p \rightarrow p \wedge q$). Second, from the two premises 'today is not Tuesday' and 'the president beat his wife or today is Tuesday,' we can deduce the consequent, 'the president beat his wife' (since $\sim p \ \& \ (p \wedge q) \rightarrow q$). By an analogous process, we can prove the proposition, 'the president did not beat his wife,' or any other proposition that we choose.

It follows from this argument that the process of hypothesis testing only establishes the truth value of the tested propositions if the theory that generates the alternative hypotheses is self-consistent. If the theory contains a contradiction, then any hypothesis can be derived with equal logical force from it, and the test of a hypothesis will no longer provide an empirical test of the theory in question.

To illustrate the difference between creation and discovery, consider how we might describe the process of proving a hypothesis like 'there are no more than 220 prime numbers in the set of the first 1000 real numbers.' (A prime number is a whole number which is divisible only by one and itself.)

The aim of this example is to show that even cases of cognition that appear to sharply constrain the process of 'knowing' and to leave little room for the mindful will of the 'knower' can be thought of as creative processes, and leave room for the imagination of the 'problem solver' or 'innovator.'

The argument, as given by Gabriel Stolzenberg, may go as follows:

The number of primes that come up in the first 1000 natural numbers already 'exists', as a property of the system of whole numbers. Whatever this number is, it is only our imperfect computational powers and memory that is preventing us from knowing it at this instant. We can, given time and some computational resources, remedy this deficiency and produce an algorithm – like the sieve of Eratosthenes – which can produce the correct number of primes whose values lie between 0 and 1001. This calculation will then provide an answer to the problem – an answer which already 'exists', independently of our cognition of it. Therefore the act of producing that number is one of discovering the correct answer, just like we might discover an object hidden by a friend in a place known only to him in a crowded room.

This argument assumes that once we have constructed a logical structure, that structure has a series of properties which can be understood in a way which does not depend on the mind that is performing the process of understanding.

Stolzenberg further argues that the number of prime numbers lying between 0 and 1001 is a state of knowledge, not an objectively existing quantity. We create, by our counting of those numbers, or by applying a particular algorithm for generating the number of primes within a certain value range, a state of consciousness or a state of mind corresponding to the representation of a number. Once we have created that state of mind, we can easily communicate it, by means of a written or spoken word, to another mind, thus creating an inexpensive 'replica' of this state of mind. Without the will to create that state of mind – indeed, without the will which created the representation we know as the system of numbers – there would have been no 'matter of fact' about the proposition, 'there are at least 220 prime numbers lying between 0 and 1001.' The argument can be developed further, and in a way which highlights the advantages of seeing the proof of the proposition as a process of creation. Whereas the outcome of a process of discovery is a finite number or fact, perfectly matched to the demands of the demonstration or the question asked, the outcome of the process of creating a state of mind is a complex mental object which has many qualities. For example, part of the state of mind that is created by computing the number of primes that occur between 0 and 1001 may be the complexity of the algorithm used to calculate the number and the annoyance produced by the waste of time spent computing, or an appreciation for the aesthetic value of the algorithm. Part of that state of mind may also be a fresh insight into the distribution of primes in the natural number system, or an inspired guess at the proof of an 'unsolved' problem of number theory. If the problem solver reflects upon the state of mind that she has created as part of the process of answering a question put to her, she will be aware of these qualities and heed the temptations packed in each of them: to refine the algorithm used or to attempt to create a proof of an unsolved theory. By contrast, if the process is understood as one of discovery, then the quest of the mind is 'at an end' once it has reached an answer.

Concluding Comments

If one grain of sand does not suffice to change something from a heap of sand into a nonheap of sand, and if a 10 000-grain pile of sand is a heap, then a 9999-grain collection is also a heap. If we apply the process recursively 9999 times, we arrive at the conclusion that a grain of sand is a heap. If we start from the premise that a 1-grain collection of sand is not a heap and apply our little logical machine in reverse, we discover that a 10 000-grain collection is not a heap, which means that it is a heap and is not a heap simultaneously, from a logical point of view. But, since any statement follows from this contradiction, referring to 'heaps' presents a problem to those who want to test hypotheses about the properties of heaps.

Attempting to provide a logical justification 'from first principles' for categories formed by the mind on the basis of experience and expectation, and thus to 'ground' or even to constrain the process of forming categories, is a misguided enterprise: it is self-defeating by the standards of success of its own practitioners.

The transition from a view of experience as the chronic instantiation of the same 'forms' or categories to one which continuously creates new representations will most likely hinge on people's will to exchange the logic of necessity and the spirit of discovery for the discourse of possibility and the process of creation.

Claude Monet 1840–1926

P D Stokes, Barnard College, Columbia University, New York, NY, USA

© 2011 Elsevier Inc. All rights reserved.

Claude Monet (1840–1926) was a Painter whose works from major phases include: First – *La Grenouillere* (1869), *Regatta at Argenteuil* (1872); Second – *Wheatstacks* (1890), *Poplars* (1891), *Rouen Cathedral* (1894), Third – *Water Lilies/Grandes Decorations* (1920).

Monet did not independently invent Impressionism; however, he was the Impressionist who reinvented it, twice. The reinventions were both incremental and radical. Incremental in that they were based on gradual refining of Monet's goal criterion (show how light breaks up); radical, in that realizing the refinements eliminated the object as subject.

Monet's reinventiveness, in the face of (indeed flouting) success, raises two questions: why and how. Answers are suggested by work on habitual variability levels and constraint models of creativity. We begin at the beginning, when skills along with variability levels are acquired.

Apprenticeship: Learning and Learning to be Variable

Giftedness is the product of plasticity: the gifted child's brain responds more readily to particular aspects of the environment. From this responsiveness ensues early engagement, and accelerated pursuit of skill, in the domain of the gift. The key words here are early and accelerated. According to learned variability theory, learning *how* to do something (the skill) includes learning *how differently* to continue doing it (the variability level). Acceleration involves rapid progression from one aspect of skill acquisition to another. By precluding repetition, it promotes and rewards high variability at the time (early in exposure to a domain) when variability levels are established.

Once a level is established, a task demanding higher variability will produce anxiety, one requiring less will result in boredom. In either case, the individual is motivated to regain his habitual, therefore, comfortable level. Why Monet's radical reinventions? Habitual high variability is a possibility.

Consider. Monet's gifts were recognized early, rewarded often, and expanded rapidly. Text and exercise books margins were, the artist wrote in a letter, "garlanded ... and decorated ... with fantastical ornamentation." Profiles of his teachers, and prominent citizens of Le Havre, were caricatured: gigantic distorted heads atop tiny torsos and spindly legs. From caricature come two important aspects of Monet's work (on which we will later elaborate): elimination and exaggeration.

At the framer's shop where the young artist's caricatures were sold (i.e., recognized and rewarded), Monet met Eugene Boudin, a painter of small, airy, beach scenes. The year was 1858; it marked the start of Monet's painting apprenticeship. From Boudin, Monet learned how to paint (quickly, the product a colored sketch), what (nature), and where (outdoors, *en plein air*). Note the relationship of caricature and sketch:

both are reductions, selections. Note too, that Monet attributed Bodin's sketches to what he called 'instantaneity' or 'immediacy.' As we shall see, the immediate would morph into the moment, into a series of moments.

The remainder of Monet's apprenticeship took place in Paris, partly at the studio of Charles Gleyre (begun 1862); more importantly, in the company of three other Gleyre students (Auguste Renoir, Alfred Sisley, and Frederic Bazille) and outdoors, in Chailly (near the forest), Normandy (near the sea), and Paris (near the Seine). A pair of paintings done simultaneously by Monet and Renoir (*La Grenouillere*, 1869) introduced the early Impressionist style, and ended the apprenticeship.

Digression: Solution by Substitution

So far we have an answer to our first question about the repeated reinventions (why?): a high variability level acquired early in skill acquisition. Before continuing with the career, we discuss (briefly) the paired-constraint model used to answer the second (how?).

The model assumes that creativity is a problem, and that solution takes place in what is called a problem space. The space has three parts: an initial state (in painting, an existing style), a goal state (the new style), and between the two, a search space (to select elements of the new style – motifs, materials, etc.). The problem is solved incrementally, search is carried out step-by-step, in a series of substitutions. The substitutions involve paired constraints. One of each pair restricts (as in common usage) or precludes pursuit of a solution path in one part of the search space; while the other directs or promotes pursuit in another. As Monet's development will show, an initial substitution can generate a cascade of constraints that together constitute and define the new style.

Mastery: Inventing and Reinventing Impression

A key element in the invention of Impressionism – other than *plein air* painting – was the color wheel. Contemporary color wheels are crude by comparison to Chevreul's which broke the three primary and three secondary hues in 72 adjacent, but separate, segments showing complementary and contrasting colors. The latter (contrasting colors) were employed by Delacroix, whose diaries, recording their use, were read by Monet. A consequence of the wheel for early Impressionism was substituting contrasting colors for blacks and browns when painting shadows.

A lasting consequence was Monet's continually refined goal criterion: showing how light breaks up – on things, between things, and finally, by itself alone. The progression combines

goal criterion with Monet’s earlier strategy, derived from caricature and color sketch: eliminate and exaggerate.

Solution by Substitution I: How Does Light Break Up on Things?

Painting when Monet arrived in Paris depended on light–dark (i.e., value) contrasts to depict depth. Darks were muddy, browns and blacks. In an early Salon entry, *Woman in a Green Dress* (1866), Monet painted the floor brown, the background, an even darker brown-into-black. His model’s jacket is black trimmed with brown; the shadows under her brows, eye, and on her hand are also brown. Three years later, painting alongside Renoir, incremental changes appear: *La Grenouilliere* (1869) is a colored sketch; its subjects are simplified, its brush-strokes separate, but its shadows are still brown and black.

Regatta at Argenteuil (1872) shows how Monet realized his first goal. How does light break up on things? In clear, bright, clearly separated strokes of contrasting colors. The house at the far right of **Figure 1** (my much-simplified cartoon) is sketched in strokes of cadmium red and orange: in its reflection, the red and orange intermingle with the greens of tree and grass, and the blue of the sky. The cream colored sails are reflected in lozenges larger than those of house and tree. The shift in scale shows that they are closer, but both boat and house sit on the same surface – there is no depth of field between them.

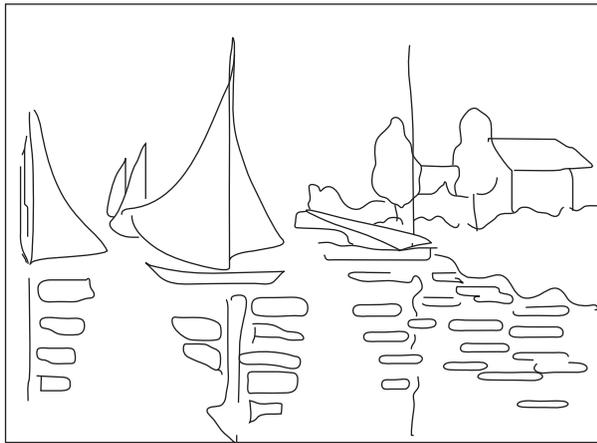

Figure 1 *Regatta at Argenteuil* (1872).

Table 1 Constraints for Phase 1

Category	Pairings
Subject	Preclude the object as subject → Promote the object as armature
Task	Preclude contrasts in value → Promote contrasts in hue
	Preclude sharp, precise edges → Promote soft, indistinct edges
	Preclude smooth finish → Promote mosaic of separate strokes
	Preclude depth → Promote surface

Table 1 presents the paired constraints that make this kind of painting possible. The constraints form a kind of cascade, one follows from, is necessitated by another. Given the goal, the subject is no longer the objects shown in the painting; they are now mere armatures on which light is to be broken. To do this requires substituting contrasts in hue for contrasts in value, which in turn precludes sharp edges. As indicated in **Figure 1**, objects with unmodeled surfaces and indistinct edges now merge and float to the surface.

Solution by Substitution II: How Does Light Break Up Between Things?

By 1891, Monet had become so sensitive to the slightest change in the light that he painted not one, but 23 versions of grainstacks. The titles tell the changes in time of day (*Grainstacks at the End of Summer, Morning Effect; Grainstacks in the Sunlight, Midday*), by time of year (*Grainstacks in the Winter; Grainstacks, White Frost Effect*). The same year also produced 24 versions of poplars; again at different times of day and in several seasons.

Monet was no longer painting light breaking up on things. His goal shifted along with his sensitivity. “The motif,” he told a reporter, “is secondary for me: what I want to paint is what there is between the motif and me.” The between was the envelope, ephemeral, every-changing. Boudin’s ‘immediacy’ (captured in the quick sketch) became Monet’s ‘moment’ (captured in a series of separate moments).

How does light break up between things? In *Poplars* (outlined in **Figure 2**), it breaks into the same hues, everywhere. The envelope is continuous, there are no local colors, only shared ones. The trees, their reflections, even the sky, share the same pinks and purples, greens and yellows. They are also equidistant from the viewer’s eye, interconnected, web-like, on the painting’s surface.

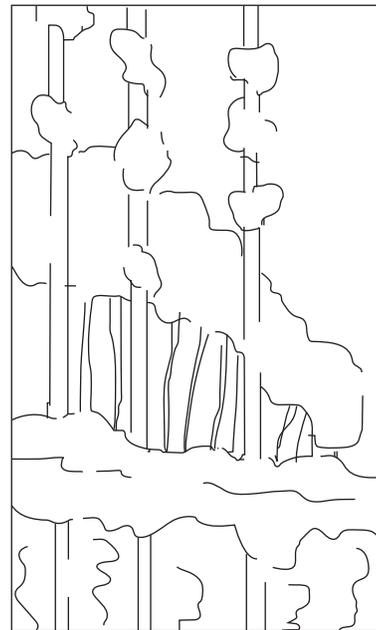

Figure 2 *Poplars* (1981).

Table 2 Constraints for Phase 2

Category	Pairings
Subject	Preclude the object as armature → Promote the ‘moment’
Task	Preclude change in motif → Promote variations of the same motif
	Preclude color of the object → Promote color of the ‘enveloppe’
	Preclude separation strokes → Promote interconnection, scumbling
	Preclude single point of view → Promote scattering of attention

The constraint pairs that accomplished this are shown in **Table 2**. Although the objects (grainstacks, poplars, later the façade of Rouen Cathedral) did not change, they were no longer the subject. Rather, their persistence allowed the painter to focus on the momentary, the every-changing light, quickly and summarily sketched in interconnected colors and brush-strokes that scatter our attention, purposefully diverting it from objects to atmosphere. Seen as a series, moment-to-moment, the paintings depict – in very slow motion – the passage of time.

Solution by Substitution III: How Does Light Break Up by Itself?

The large, late water garden paintings amplified everything Monet had done previously. Elimination and exaggeration are all. Instead of a series, the moment is extended in space. Indeed, as suggested by my sketch (**Figure 3**), it occupies all the space.

Objects (in Monet’s words, now ‘mere accessories’) loosen and lose their boundaries. Lily-pad fragments (ellipses in the figure) float on, and share hues (lavender, violet, teal) with the pond’s surface. Composition by shape is replaced with composition by color. Close-up, filling our field of vision, Monet’s color field redirects the eye (sans recognition) to the level of sensation. Light itself is breaking up, it is everything, and we are immersed in it.

Table 3 summarizes the final constraint cascade.

Applications and Summations

There are two things about Monet’s development that apply to all creativity of the domain-expanding kind.

One, early is important. Elimination and exaggeration are the essence of both the caricature and the quick sketch. The ‘immediacy’ of the later, became first, the ‘moment’ and finally, the immersion. Both strategy and goal were implicit in the initiation. High variability was sustained, and in turn, sustained the creativity.

Two, the radical is achieved gradually, incrementally. Each realization of Monet’s current goal led to its subsequent refinement. As the goal changed, so too the constraints that satisfied it. Importantly, it took time. Consider just the dates of the paintings we discussed: *Regatta*, 1872; *Poplars*, 1891; *Water Lilies*, 1920.

To demonstrate how early and incrementally combined in the career, we summarize, condensing steps that contributed to

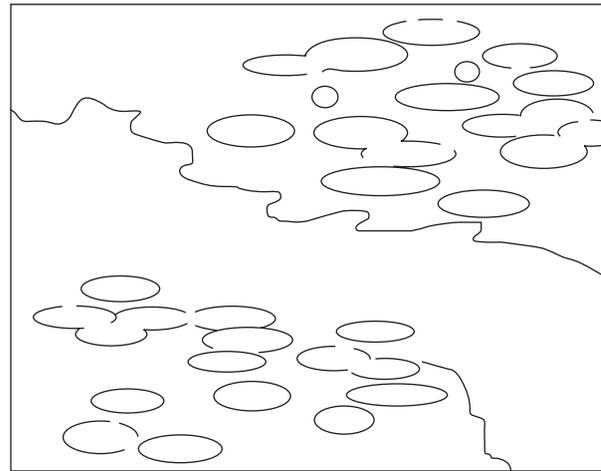

Figure 3 *Water Lilies* (1920).

Table 3 Constraints for Phase 3

Category	Pairings
Subject	Preclude series of moment → Promote extension of a single moment
Task	Preclude composition by shape → Promote composition by color
	Preclude boundaries → Promote color field
	Preclude recognition → Promote sensation
	Preclude attention → Promote immersion

the shift from the optically precise to the optically amorphous. Each step eliminated something and exaggerated its opposite.

- Obfuscating the object. In Phase 1, the object, broken into its constituent hues (eliminate the intact) was optically correct. In Phase 2, the object was camouflaged in the colors of the envelope (eliminate local color). By Phase 3, it was absorbed into the overall color field.
- Eliminating depth. In Phase 1, closely valued hues eliminated chiaroscuro, the dark–light contrasts that produced the illusion of three-dimensionality. Separate brush strokes floated to the surface. In Phase 2, the closely related values were common to all objects. Fore, middle and back grounds merged. In Phase 3, extreme close-ups eliminated everything but surface, of the pond and of the plane.

Concluding Questions

Was It Difficult?

This is a question I have asked before. Initially, my question was related to variability: more difficult constraints generate and maintain higher levels of variability. This time I am thinking about Csikszentmihalyi’s idea of flow. I do not think that it applies to creators like Monet, for whom it was very difficult, always, and never not.

Who said it was difficult? Monet himself, repeatedly, in letters from which we sample.

- In 1889, to his wife: “I’m back from work, a bad session, and I wiped out everything I did this morning; it wasn’t well realized or understood. It’s always like this to start with.”
- In 1890, to Gustave Geffrey: “I’m hard at it, working stubbornly on a series of difficult effects (grain stacks) . . . I’m getting so slow at my work that it makes me despair, but the further I get, the more I see that a lot of work has to be done in order to render what I’m looking for: the ‘instantaneity,’ the ‘envelope,’ above all, the same light spread over everything, and more than ever I’m disgusted by easy things that come in one go.”
- In 1893, to Alice: “Happy are the young people who believe it is easy.” And to Geffrey: “My stay here is advancing, which doesn’t mean that I’m near to finishing my Cathedral. Regretfully, I can only repeat that the further I get, the more difficult it is for me to convey what I feel and I tell myself that anyone who claims he’s finished a painting is terribly arrogant. To finish something means complete, perfect, and I’m forcing myself to work, but can’t make any progress; looking for something, groping my way forward, but coming up with nothing very special, except to reach the point when I’m exhausted by it all.”

Was It Flow?

Given the difficulty, it does not sound at all like flow, which is characterized as enjoyable. The enjoyment, moreover, is associated with clear goals, immediate feedback, and a balance between challenges and skills. While Monet did articulate his goals (e.g., paint the envelope), they were not clear in the sense of Csikszentmihalyi’s musician knowing “which notes to play next.” At best, Monet’s purposefully ill-defined problems may have become well-structured, in part, and temporarily. This is how Simon described ill-structured problems like designing a

house. During the solution process, the problem is broken down into subproblems which are well-structured and thus solvable, in part. The immediate feedback was, more often than not, negative. Finally, reread the last Monet quote: ‘groping’ does not sound like a skills-challenge match.

Ceaseless refashioning and refining of one’s goal criteria is rare. Most artists, like most experts, stay with (indeed are stuck in) successful solutions that (with minor variations) can sustain the conditions that support flow, but not domain-changing creativity. In short, most artists are not Monet.

Glossary

Creativity The generation of effective novelty.

Ethics Guidelines on how a moral person should behave.

Immoral creativity Creativity that places personal interests above the common good.

Infusion The entire school curriculum is influenced by a general principle (such as behaving in a moral way), rather than confining application of the principle to special, isolated lessons or activities.

Morals A framework for working out which behaviors are virtuous.

Moral creativity Creativity that seeks to promote the common good.

Moral development The process of acquisition of increasingly other-oriented, abstract, and general moral values in the course of personal development.

Moral education Education aimed at fostering moral development by instilling a sense of right and wrong into students.

Moral values Qualities of behavior that are regarded as inherently virtuous such as responsibility, fairness, integrity, sincerity, generosity, or fortitude.

Service learning Children learn by carrying out classroom chores, mentoring younger children, or performing service activities.

Wisdom The ability to balance individual and group interests.

The Nature of Morals

According to Marc Bekoff and Jessica Pierce, morality is "a suite of interrelated other-regarding behaviors that cultivate and regulate complex interactions within social groups." This definition directs attention squarely to the social nature of morals and, especially, to the central role of concern for the well-being of other people (morals are 'other-regarding'). Morals will be treated in this chapter in the sense of normative ethics: a framework for working out which actions are 'virtuous' and which are 'wicked' (e.g., good as against bad, right as against wrong, righteous as against objectionable, or worthy of emulation as against unworthy). Morals will not be examined in the sense of religious morality, where good and evil are defined by received beliefs and sometimes by specific rules dictating behavior in specified concrete situations, and transgressions are threatened with sanctions arising from divine displeasure. The focus in this article is on the implications of moral values for creativity. The core questions are: Can creativity be judged according to moral precepts of this kind? What can be done to ensure that creativity is moral (as against immoral) in the sense the term is used here?

Moral precepts are not physical laws or forces of nature such as gravity, but are ideals that have been worked out by philosophers, religious authorities or other thinkers, although they may have demonstrated their worth in people's practical experience of life (as the evolutionary view of morals discussed below particularly emphasizes). Morals and moral values are generally associated with a personal view of values, so that they are psychological rather than tangible. They often reflect the influence of religion or philosophy, culture, family, and friends. Morals are a matter of subjective internal conviction rather than concrete evidence or physical or even legal coercion. Although there is obviously a connection between them, morality and law are not the same thing. An example would be the use of creativity to persuade children to eat foods that

are harmful to their health (as in advertising). This is legal, but of dubious morality. On the other hand, cheating on your tax return is illegal, but is regarded by many people (perhaps most) as moral. (The relationship of law to morality will not be further dwelled upon in this article, because it lies outside the focus of the article.) Although moral transgressions may be punished by condemnation, rejection, public shaming, or other external sanctions, they are enforced at least as strongly by internal sanctions such as pangs of conscience or feelings of shame. The truly moral person behaves in a moral way out of personal conviction.

A sister topic to morals is ethics: Ethics is concerned with how a moral person should behave. Ethical behavior involves doing what is morally right and proper, and not simply what is legal or easy, that is, expedient. According to Plato, for instance, there are four 'cardinal' virtues (courage, temperance, prudence, and justice) which should guide actions. All other virtues are thought to spring from these. Immanuel Kant argued that there is a 'moral imperative' to treat other people with dignity, and never to exploit them as instruments of one's own satisfaction. According to John Locke, no-one should act in such a way as to harm anyone else's life, health, liberty, or possessions. For Locke, these were natural rights, given by God.

Unfortunately, despite Locke's attribution of moral principles to God, different observers' ideas of what is right and proper are highly subjective, and often differ sharply from person to person, from society to society, and, indeed, from era to era; Galileo's publication of his (factually correct) thesis that the earth rotates around the sun (and not vice versa) was regarded in his own time as so morally reprehensible as to constitute heresy, and led to years of house arrest. Thus, being factually correct does not guarantee moral or ethical goodness, especially where preexisting fixed sets of specific, concrete 'goods' and 'bads' exist, as was the case with Galileo. Nonetheless, some ethical values transcend cultural, religious, or ethnic differences, and thus involve something approaching

a universal moral worldview. Examples are responsibility, fairness, concern about the well-being of others, good citizenship, integrity, sincerity, trustworthiness, generosity, and fortitude, all of which are mentioned by numerous writers in the area. These writers are not all representatives of the Western, Aristotelian tradition. The Confucian construct of *ren* is an example of a broad definition of what is right and good that is widely accepted in Asian countries and beyond. *Ren* can be translated as 'righteousness.' It includes moral virtues such as loyalty, consideration, conscientiousness, or altruism.

Morality and Creativity

When applied to creativity, questions of morality are initially centered on whether creativity can be judged at all in terms such as 'good' versus 'bad,' 'virtuous' versus 'wicked,' or 'worthy of emulation' versus 'unworthy.' Robert McLaren pointed out that creativity has come to have a 'quasi-religious function' in modern life. He cited writers who emphasize that for many people it is, for instance, the new way of finding solace in an imperfect world in which religion no longer offers sufficient consolation. This spiritual tone was already present at the beginning of the modern creativity era. Jerome Bruner saw creativity as the last bastion of the human spirit in an age in which electronic devices are taking over most noncreative functions: It thus marks the boundary between the human being and the intelligent machine. Discussions along these lines have not infrequently argued that creativity is a primal force of nature, and that it is, by definition, a universal beneficial factor fostering growth and rebuilding in all organic systems, and is thus automatically good. Brian Henning referred to creativity along these lines as "the *dynamic process* of the universe [emphasis added]." As a result, according to Friedrich Nietzsche, creativity involves "*deification* of existence [emphasis added]" and is beyond all considerations of good and evil.

However, despite Nietzsche's dictum it is difficult to regard, for instance, the effectively novel systems for killing people in large numbers generated by Hitler or Stalin, or the undoubtedly novel – since such a thing had never been seen before – as well as highly effective – it led to a large number of deaths and caused widespread disruption to various aspects of life in the United States – attack on the World Trade Center as the same in principle as the works of, let us say, Shakespeare or Mozart. It is conceivable that the cognitive *processes* are similar in all four cases (for instance, generation of alternative ways of seeing things, linking of ideas usually kept separate, or branching out from the known in a new direction). However, apart from the differences in the nature of the *products* – works of art vs. technological and management systems – there is a clear difference in the effects of the creativity of Hitler and Stalin versus Shakespeare and Mozart: on the one hand, death and destruction for people not actively engaged in any directly hostile activity, on the other, things of beauty. Furthermore, and of central importance for this article, there were substantial differences in the intentions of the *persons* involved: on the one hand a desire to generate truth and beauty, on the other, a desire to do harm and wreak destruction for essentially political purposes.

Nonetheless, even monsters of evil such as Hitler and Stalin are regarded by some people as having been great leaders.

Robert Sternberg made the point that both these men did indeed introduce high levels of effective novelty (including previously unknown systems for murdering people that worked well), and had a very substantial impact on their societies. However, as he pointed out, those who praise Hitler and Stalin as great men focus only on the novelty and effective impact of what they did. Sternberg argued that, while it is true that they produced what he calls 'originality,' in the absence of moral goodness they cannot be said to have been creative. This is in accord with the intuitive feeling of many people that it is disgusting to refer to such monsters as 'creative,' despite the fact that they generated effective novelty and, in this sense at least, really were creative.

In order to find a way of distinguishing systematically between the creativity generated by Shakespeare and Mozart (to remain with these two examples), on the one hand, and Hitler and Stalin, on the other, and thus to understand creativity more fully, it is necessary to consider not just the novelty and effectiveness of products, or the degree of divergence of processes, but also the 'goodness' or 'badness' of the outcomes (products) and the motives behind them (person), as well as of the processes that led to the outcomes. These issues lie in the domain of morals, and imply that not everything that is creative is moral, thus raising the idea of immoral creativity. The introduction of morality into discussions of creativity expands understanding of creativity beyond simply generation of effective novelty, as does the addition of aesthetics: consideration of whether the results of creativity are pleasing, elegant, or beautiful. This is not just an academic search for ever more differentiated conceptualization of a scholarly concept. Being able to distinguish systematically between the creativity of an Osama bin Laden and a Mahatma Ghandi – both of whom were interested in developing novel and effective ways of persuading what they saw as an oppressive foreign regime to withdraw – is essential for understanding matters such as how to foster and support the creativity of the one and counter, suppress, or perhaps rechannel the creativity of the other.

Immoral Creativity

The most obvious examples of immoral creativity are to be seen in the generation of novel products that harm other people. This involves what Keith James called 'negative' creativity. The harm to others can be simply a collateral effect; an employee who devises a novel and highly effective way of avoiding work may expose other people to the stresses of overwork, but this is not the primary intent of the negative creativity. Even more obviously immoral is creativity which has the deliberate and planned primary intention of harming others, referred to by me and my colleagues David Cropley and James Kaufman as involving 'malevolent' creativity.

A gray area is to be seen the field of crime. As Lorraine Gamman and Maziar Raein pointed out, "resourceful offenders" constitute a group "... whose creativity is rarely acknowledged." According to them, some "... criminal 'projects' may exhibit the 'wow' factor," and even represent paradigm-breaking creative breakthroughs. For this reason, observers are tempted to admire such projects, even though their intention is antisocial. Gamman and Raein mention the Great Train

Robbery, which is often cited in the relevant literature as an example of a criminal breakthrough with the 'wow' factor. Ronald Biggs, probably the most famous of the Great Train robbers, showed enormous ingenuity in escaping and successfully evading capture for many years, until old age and physical infirmity persuaded him to surrender. Despite the fact that one of the train personnel was severely beaten and died after seven years as an invalid, Biggs and his colleagues were widely regarded with sympathy or even admiration, and Biggs was subsequently pardoned by the UK Government in 2009.

Russell Eisenman gave easily understandable examples of the generation of effective novelty by criminals in the form of brief case studies of the use of creativity by prisoners in the correctional system to manipulate supervisory personnel to their own advantage, for instance to make it easier for them to smuggle drugs, while Jennie Singer gave the example of creative use by prisoners of unusual materials to make, for instance, a knife, intended for use against other prisoners. Thus, evil intention may nonetheless attract grudging respect, so that there is a certain moral equivocation associated with creativity.

Some negative effects are very difficult or impossible to anticipate: the lifesaving discoveries of Louis Pasteur and Edward Jenner, for instance, laid the foundation for germ warfare. Some people may even create obviously immoral products despite generally having positive moral values and wishing to behave in an ethical manner. They may, for instance, consciously or subconsciously blind themselves to the immoral consequences of their work, be unable to or unwilling to anticipate negative consequences, or succumb to temptation. This may occur, for instance, because of their fascination with what they are doing, or because they are deceived or coerced by factors like the prospect of money and fame or the manipulation of a despotic government. Maria Zaitseva gives the example of how this happened with some participants in the Soviet Union's program for the development of weapons of mass destruction, while David Hecht made a similar analysis of the role of American nuclear scientists in the US atomic bomb program late in the Second World War.

A related moral issue in connection with creativity is described by Kevin Hilton. One person's acclaimed and highly respected artistic/esthetic creativity may inspire another person's antisocial behavior, despite the absence of any negative intention on the part of the creative individual. An obvious example is the copying of evil deeds depicted in imaginative works. Hilton gives the examples of a murder committed using a technique described in the novel *Shibumi*, and a double murder committed by copying a scene in a Clint Eastwood film. Another example is the 'Werther effect': a wave of suicides inspired by Goethe's book *The Sorrows of Young Werther*, which caused the book, a masterpiece by one of the world's greatest authors, to be banned in several countries. An artistic creation that is successful in informing, entertaining, even inspiring readers, listeners, or beholders (which seems moral enough), may simultaneously encourage, promote or provide models of behavior which should not be emulated. Perversely, it even seems that in such situations more novel and effective creativity is more likely to promote antisocial behavior: the greater the creativity, the worse the negative effect.

The Clash of Moral Creativity with Private Interests

The crucial event that started the modern creativity era was the widely felt need in the Western world for novel products capable of contributing to the welfare and safety of society during the Cold War. In other words, the initial impetus involved concern about the general good. With the passage of time, however, the beneficial effects of creativity came to be looked at mainly in terms of the advantages it brings the individual: personal growth, self-fulfillment, and similar aspects of individual well-being. The result was that the purpose of fostering creativity came to be seen as promoting the personal development of individuals, not fostering the common good. Margaret Boden pointed out that this involves the risk of making the main purpose of creativity 'glorification of individuals,' a goal far removed from justice, altruism, fairness, or promoting universal well-being, and therefore on shaky moral ground.

Indeed, the generation of effective novelty that contributes positively to the common good – moral creativity in the terms of this article – is not necessarily greeted with unrestrained approval by all parties concerned. Introduction of such novelty may conflict with private or narrow interests, and the two may clash. Sometimes selfish interests prevail, even when the effective novelty makes a massive and obvious contribution to the common good. In such cases, moral creativity is blocked by self-serving ways of looking at things. A historical example is to be seen in what happened to the Austrian obstetrician, Ignaz Semmelweis. In 1840, he dramatically and rapidly reduced the incidence of death from puerperal fever in the lying-in hospital in Vienna simply by requiring the obstetricians under his supervision to wash their hands before touching women who had recently given birth, thus avoiding cross-infection, although this concept did not exist in Semmelweis's time. However, this novelty, although highly effective in reducing the death rate, was seen by other doctors as implying that they were dirty. Far from showing gratitude, his colleagues labeled him a crackpot who was insulting their honor, and he was rejected and hunted into madness. The death rate returned to its earlier levels! The private interests of the other doctors prevailed despite the overwhelming evidence that the novel procedure was capable of making a substantial contribution to the common good.

Immorality Inherent in Creativity

Despite the conclusion of some writers such as Mark Runco that creativity or creative thinking processes are neither moral nor immoral in themselves, or even that creativity is above such considerations, the problems associated with morality in creativity are, to some degree at least, inherent in creativity itself. The essence of creativity is changing what currently exists. Among other things it:

- shakes the foundations of the received order and brings uncertainty for other people;
- questions the value of existing knowledge and skills (often laboriously acquired);
- threatens loss of status and authority for experts, leaders, or established creators;

- encourages dissatisfaction with the *status quo*, restlessness, or rebellion;
- encourages putting your own needs and resolving your own dissatisfaction ahead of the needs of others;
- opens the doorway to dark and destructive material that needs to be handled with great caution (see below).

These processes can easily become destructive, especially if they are self-centered and self-serving, or are applied recklessly. They yield moral results only when they promote fairness, justice, good citizenship, altruism, and the like, rather than furthering the narrow self-interest of an individual or a special group. Thus, the seeds of immorality are inherent in the very nature of creativity.

One of its potentially destructive aspects of creativity is that it involves dissatisfaction with what already exists and an inability or unwillingness to accept the *status quo*. Arthur Miller referred to Albert Einstein's description of how his recognition that existing theories of electrodynamics were inadequate motivated him to develop the special theory of relativity and then the general theory. Einstein continued to be dissatisfied with his own theory, and worked on it for much of the rest of his life. America's most distinguished inventor, Thomas Alva Edison, was never satisfied with his own inventions, and over the years took out more than 100 patents on the electric light bulb alone. Michael Mumford and Peter Moertl described two case studies of innovation in social systems (management practice and student selection for admission to university), and concluded that both innovations were driven by 'intense dissatisfaction' with the *status quo*. Thus, seeing that something is wrong with existing knowledge, criticizing this knowledge and seeking to overthrow it are core elements of the creative process. These can be very threatening for people around the creative individual.

Focusing on artistic and aesthetic creativity, Liane Gabora and Nancy Holmes gave examples of its destructive power, listing, for instance, numerous twentieth century poets, writers, musicians, and painters who committed suicide. They also reviewed discussions of the question of whether creativity causes psychological disturbance or psychological disturbance leads to creativity. They referred to the 'shadowy swamplands of the creative mind,' and suggested that creativity may lead people to delve into destructive elements of the unconscious in a process of 'deep mining into the darkness,' sometimes bringing to the surface material that less creative people – wisely – leave undisturbed. They suggest that precisely this process of going where others fear to go may lead to an 'allure of darkness' that makes the immoral side of creativity attractive to some creative individuals as well as to some of the people who admire their work, sometimes with ultimately destructive results. Is such creativity moral, or immoral, even if it yields works of great artistic merit?

Moral Creativity

Among other things, moral actions are responsible, promote fairness and the well-being of others, lead to justice, and contribute to good citizenship. The implications for creativity are obvious: moral creativity seeks to generate benefits for all,

and is motivated by the wish to promote the common good. The idea that moral creativity can be defined in such a straightforward and yet broad and sweeping way as generation of effective novelty that seeks the common good may seem excessively simplistic. However, it is consistent with the views of philosophers who have wrestled with the issues at stake. Immanuel Kant defined creativity as "the aspiration to create a perfect world for *everyone* [emphasis added]." He also defined creative genius in terms of producing ideas that are both original and *exemplary* [emphasis added]. By 'exemplary' he was referring to the categorical imperative to fulfil one's moral duties. Brian Henning worked out a number of 'obligations' for moral creativity from the writings of Alfred North Whitehead: The obligations include beauty (to bring about the *widest possible* universe of beauty [emphasis added]), love (to maximize the intensity and harmony of oneself and *everything within one's sphere of influence* [emphasis added]), and peace (to avoid destruction). All of these obligations involve a responsibility to avoid doing harm to others and to promote the common good of the larger society.

Recognition of the link between moral creativity and furthering the well-being of other human beings is not new. The Chinese Emperor, Han Wudi, who reigned until 86 BCE, was intensely interested in finding innovative thinkers and giving them high rank in the civil service, and reformed the method of selection of mandarins to achieve this. Both Francis Bacon and René Descartes, two of the founders of modern science, saw creativity as involving the harnessing of the forces of nature for the betterment of the human condition (i.e., for moral purposes).

How Do People Become Moral?

Moral creativity can bring great benefit for human beings and their environment, but immoral creativity can bring great harm, as was discussed above. It seems to lie in the public interest that creative people possess positive moral values and apply them to their own behavior. How does this occur? Evolutionary biologists and sociobiologists believe that morality develops as a result of evolutionary forces. Seeking justice, fostering the well-being of others, showing courage, co-operating with others, and similar behaviors are not the only behaviors of which people are capable. Unfairness, lack of concern about others, avoiding danger, and exaggerated individualism are also possible (and indeed, are not especially uncommon in real life). The widely accepted morality outlined above is thus not absolute, but relative, and in theory any set of values could be adopted. However, properties such as justice, concern about the well-being of others, co-operation and courage enhance the survival both of the individuals who display them and also of the collective to which the individuals belong. As a result, such moral values have come to prevail through the process of natural selection. Simple versions of what humans regard as morality are seen, according to biologists, in all species. The greater complexity of human moral systems is attributable to their greater brain size, living in larger groups, and more complex interactions among individuals and groups.

In psychological thinking, however, the acquisition of moral values is mainly regarded nowadays as the result of learning from other people. According to the psychoanalytic view, morals are imposed upon the developing child by its parents, and are resident in the super-ego, from where they may cause neurotic symptoms in the individual when they conflict with innate drives that are oriented towards the satisfaction of individual, self-centered urges, possibly at the expense of the collective. However, the most influential modern description of the psychological process of moral development is that of Lawrence Kohlberg, who further developed the work of Jean Piaget. According to Piaget, development is not merely the result of gaining more knowledge, but consists rather of a sequence of qualitative changes in the way an individual thinks. This involves moving from understanding events in terms of their immediate concrete properties and effects (as in the case of young children) to understanding them in terms of abstract, general principles (as is the case in cognitively well-developed individuals). Within any stage of development, thought is organized according to the constraints of that stage: the understanding of morals grows in parallel with cognitive growth in general.

Kohlberg proposed that children acquire understandings of concepts such as justice, equality and concern about the welfare of others as they move through a series of six developmental stages. At the lowest level, young children define right and wrong in terms of immediate concrete effects on themselves (e.g., an action is bad if you get punished for it – Stage 1, or an action is good if you get something desirable out of it – Stage 2). As children become more cognitively mature, they come to understand that other people have interests that differ from their own, that these may also vary from person to person, and that good and bad reflect an interplay among the array of interests. At the highest level, people understand that morals are higher-order abstract principles that promote smooth functioning of the society at large, and are based on reciprocal relationships marked by characteristics such as trust, loyalty, respect, or gratitude; these protect everyone, not just in the short but also in the long term. There is an understanding that morals such as, for instance, respect for life and human welfare transcend particular cultures, societies, and eras. Although Kohlberg's stages may no longer be regarded as a literal and exact description of the course of moral development, they offer substantial insights into the course of moral growth and how to foster it (see below).

How Can Moral Creativity Be Fostered?

This section focuses on the contribution of education to the growth of moral creativity. The traditional approach involved teachers explicitly advocating virtues such as honesty, kindness, patience, or strength, for instance through direct communication of their belief in such virtues, by personal example, and by giving students opportunities of practising these virtues and rewarding such expression. This process was frequently supported by separate classes on moral and ethical behavior, such as religious instruction or civics. A common teaching method for doing this was to present a moral dilemma to

students and ask them to work out an appropriate moral course of action. Class discussion would then focus on deviations from justice, fairness, or other moral principles.

The goal of the cognitive development approach to moral education, however, is to encourage individuals to develop to higher stages of moral reasoning. According to Piaget, children understand events in their environment in ways dictated by their level of cognitive development. When they encounter new information that is inconsistent with their existing world view they must adjust their current understanding of how the world operates in order to make sense of this new information (i.e., 'accommodate'), or else ignore the information or distort it so that it can be incorporated into their existing understanding of how things hang together, after all (i.e., 'assimilate'). The process of adjustment is called 'equilibration', that is, reaching a new and stable, expanded understanding of the nature of things by accommodating new and previously discrepant information. It is through equilibration that cognitive development occurs. At the heart of this model is the idea of confronting students with information contradicting their present level of cognitive development, in order to make it necessary for them to accommodate and thus reach a higher level.

In order to achieve this, writers such as Piaget argue that educators should provide students with opportunities to discover morals themselves, rather than simply being indoctrinated with norms. Kohlberg argued that moral education also requires more than individual reflection, and should include students functioning within a community. This could be done by emphasizing cooperative decision-making and problem solving, in order to make it possible for them to work out for themselves ethics based on fairness, consideration for others, altruism, loyalty, and the like. The 'infusion' approach emphasizes that, rather than simply being an add-on, education offering such experiences should permeate the entire school experience. It is not a competitor with or an ancillary to the acquisition of academic knowledge and skills, but supports this process: responsibility, respect for others, self-control and diligence foster academic learning. The point is to convey to young people an image of the kind of people the particular culture admires and wants them to emulate. Teachers should speak openly of 'good' and 'bad' and of 'right' and 'wrong.' Words such as 'responsibility,' 'honesty,' 'consideration,' and 'perseverance' should be used in discussing actions and behaviours.

Infusion with moral and ethical issues is most obviously possible in language arts, social studies, history, and similar areas, but it is also possible in science, sport, technology education, and similar areas of curriculum, where honesty, consideration for others, fairness, ethically acceptable behavior, and similar values can be discussed. Infusion also involves out-of-class activities, even behavior in the schoolyard, the toilets, the locker room or the lunchroom. Infusion involves the development of a positive moral climate in an entire school. A related approach is service learning, in which children are given classroom chores such as passing out library books or straightening the desks and chairs, at the simplest level, tutoring or mentoring younger children later, and, eventually, performing service activities such as carrying out an internship in a seniors' residence or a day-care center.

The Role of 'Wisdom' in Moral Creativity

Hilton mentioned censorship as one possible way of avoiding immoral creativity, but did not recommend it, since it is incompatible with individual freedom and is thus harmful to the common good – the cure might well be more immoral than the original disease. Hilton saw a need for 'social wisdom,' which is based on a 'multi-perspective community approach,' and essentially considered the effects of creativity in its social context. He also called for emphasis on 'the hard-won insights of the past,' thus incorporating the historical context and the accumulated wisdom of previous generations into the understanding of morality in creativity.

Sternberg, too, identified the crucial factor in moral creativity as 'wisdom.' He sees wisdom as involving awareness of the need to balance personal interests and the general good, willingness to do this, and the ability to do so – to find a compromise path that satisfies both sets of interests. Creativity without wisdom runs the risk of not being moral, but when it is tempered by wisdom it is of necessity moral. The central characteristic of wisdom – as against, for instance, 'mere' intelligence – is concern for the common good: a wise person tries to contribute to the common good, not to pursue solely his or her own advantage, and moral creativity seeks to generate effective novelty in order to promote the common good. The Great Train Robbery would thus be seen as not involving creativity, since it was directed against the common good and, indeed, left one victim so seriously injured that he never recovered his health and died a few years later. From an American point of view, the 9/11 attack did not display wisdom, since its intention was not to serve the common good, so that it was immoral and ultimately not creative. Nonetheless, it may well have seemed to the attackers – rightly or wrongly – to be advancing the common good of some other ethnic or national group(s), so that even wisdom is relative. In times of war this issue becomes particularly acute. People who generate effectively novel devices with the sole purpose of inflicting damage and death are frequently judged to be acting in a moral way by one side in the conflict, even though it is clear that they understand the 'common' good in a narrow way.

Sternberg argued that wise thinking can be developed, and outlined activities students should engage in: these include reading classic works of literature and philosophy (i.e., engaging with 'the hard-won insights of the past,' as Hilton put it), and participating in class discussions, projects, and essays that encourage discussion of the lessons to be learned from these works and how these lessons can be applied to everyday life. He also recommended particular emphasis on the development of dialogical and dialectical thinking. Dialogical thinking involves understanding significant problems from multiple points of view and understanding how others can see things differently. Dialectical thinking involves understanding that ideas pass from the past to the present and from the present to the future. Students need not only to acquire factual knowledge, but also to develop their own values through reflecting upon such knowledge. Instruction should place greater emphasis on critical, creative, and practical thinking that benefits not only the individual doing the thinking but others as well. Students would be encouraged to think about

how almost everything they study might be used for better or worse purposes, and to realize that the ends to which knowledge is put do matter. Sternberg and colleagues have constructed a program for teaching American History based on these principles.

Concluding Remarks

Despite the commonly voiced view that creativity is beyond questions of virtue and wickedness, to paraphrase Sternberg, the ends to which creativity is put *do* matter. We need concepts that make it possible to distinguish between the creativity of people who bring great benefits to humankind in both artistic/aesthetic domains (fine art, literature, music, and the like), as well as in technology, business, science, public administration, and similar areas, and the creativity of those whose creativity harms other people. Moral precepts provide guidelines on how to do this. Although morals are, in theory, arbitrary, at their core is a set of values that are shared by a wide variety of cultures over a long period of time. The heart of these is the idea of fostering the well-being of others. Thus, the application of creativity to serve narrow interests at the expense of the wider community is immoral, whereas applying it to enhance the common good is moral.

Morals are acquired, and can be taught. However, rather than being imposed by exhortation or diktat they should be worked out by each individual, and should be based on shared experiences, both of what past generations worked out and recorded in, for instance, great works, as well as on direct interactions with contemporaries, especially in activities that involve contributing to the common good. In this way, people acquire wisdom, and wisdom makes it possible for them to apply creativity in ways that balance private and common interests, and is thus moral. The purpose of placing emphasis on moral issues in creativity is not the self-righteous imposition of a rigid set of pre-specified values on the generation of effective novelty, but encouraging those who generate or use such novelty to examine their own efforts from the moral point of view.

Glossary

Extrinsic motivation The motivation to engage in an activity in order to obtain an incentive or reinforcer that is separate from the activity itself, such as a monetary reward or a positive evaluation. Extrinsic motivation can undermine creativity.

Inspiration A motivational state that emerges following a creative idea and energizes transforming the creative idea into a creative product.

Intrinsic motivation The motivation to engage in an activity for the enjoyment, satisfaction, or personal challenge that arises from the activity itself. Intrinsic motivation fosters creativity.

Motivation The energy underlying behavior. A person's motivation to initiate and persist in a specific action explains

why the person chose that specific action, given the circumstances.

Motivational synergy The process by which intrinsic and extrinsic motivation combine to support creative work. Synergy is most likely when intrinsic motivation is initially high and extrinsic motivators are perceived as supportive, rather than controlling.

Personality trait An enduring characteristic of a person. Traits generally refer to a person's tendencies in social and emotional responding, rather than physical characteristics or cognitive abilities.

Reinforcer Any consequence of behavior that increases the likelihood of that behavior occurring in the future.

Early studies of personality traits established that highly creative persons are indeed different in some important ways: they are enthusiastic, they produce more ideas and more unusual ideas than their peers, and they have the courage to follow through with their ideas, even when their ideas are not popular. Some theorists believe that this energy and courage are so powerful because creative work expresses strong emotion. A small body of research has shown a relationship between affective disorders and high levels of creativity, suggesting that emotional dysfunction may fuel creative expression. On the other hand, a humanistic approach suggests that creativity is an expression of healthy psychological functioning. This idea is consistent with a larger body of literature linking positive affect with creativity. A simpler explanation comes from behaviorists, who propose that some people become more and more creative because they receive powerful reinforcers for their creative efforts. However, evidence from social psychological studies of creativity shows that intrinsic motivation fosters creativity, while extrinsic reinforcers such as reward can often inhibit it. Several lines of research suggest that the creative process is self-reinforcing. Flow, a motivational state that facilitates creativity, is thought to occur during activities that are inherently rewarding or 'autotelic.' Recent research shows that the development of a creative idea provides inspiration to produce a creative product.

Despite the clear differences between these attempts to explain the energy underlying creativity, taken together, an important message emerges. The motivation to create will sustain itself when the right conditions are present. When our personality, mental health and the social environment all contribute to the intensity of our work, we are likely to become immersed in the highly engaging process of producing creative products.

Personality Traits of Highly Creative Individuals

Attempts to define the personality traits of highly creative persons must be interpreted with caution. Clearly, all kinds of people, from all backgrounds, with a variety of personality characteristics, have made creative contributions to all domains of endeavor. Nonetheless, systematic attempts to study the personalities of highly creative individuals have uncovered two categories of traits that highly creative persons seem to share. One category includes descriptors such as spontaneous, playful, curious, open to experience and flexible. The second category includes traits like determined, independent, confident, and persistent. Clearly, creative persons are quite complex. At once, they are childlike in their ability to be open and interested in all possibilities, and exceptionally mature in the intense focus they maintain on their work.

Donald MacKinnon and Frank Barron were the first to attempt to capture this complexity in their landmark studies of creative lives at the Institute of Personality Assessment and Research in the 1960s. They conducted in-depth investigations of highly creative individuals from many disciplines; their participants included well-known mathematicians, architects, and writers. By administering a wide range of personality inventories, interviewing and observing these people over several days, and using appropriate controls, researchers were able to describe these highly creative people with an impressive degree of clarity and depth. They found the highly creative to be more complicated, imaginative, flexible, and original in their thinking than matched groups of less creative professionals in the same fields. They were also more individualistic, courageous, independent, and confident. These qualities seem to propel their work in two directions. They are excited about new possibilities, and so generate a range of new ideas.

They also have faith in the value of their ideas and are thus able to pursue them assuredly.

The continuous stream of novel ideas that is characteristic of creative people may emerge from a chronically low level of latent inhibition. Latent inhibition is a process by which individuals filter out much incoming sensory information as a way of focusing attention on new or salient information. Those with low latent inhibition have less of a tendency to do such filtering. Jordan Peterson and colleagues have conducted research linking low latent inhibition with openness to experience and the production of creative ideas. Not all individuals with low latent inhibition are highly creative, however, suggesting that personality characteristics that support following through with creative efforts are also important.

Most current theories of creativity include personality traits related to openness as well as traits related to persistence. For example, both categories of traits appear in Teresa Amabile's componential theory of creativity, within the 'creativity-relevant processes' component. The first category includes spontaneity and tolerance for ambiguity, leading a person to take in and produce a wide variety of perceptions and ideas. The second category includes a high degree of self discipline in matters concerning work; an ability to delay gratification; perseverance in the face of frustration; independence of judgment; a high degree of autonomy; an internal locus of control; a willingness to take risks; and a high degree of self-initiated striving for excellence. Taken together, these two types of traits allow a person to both generate and follow through with creative ideas. Robert Sternberg's investment theory also names personality as an important component necessary for creativity. The personality traits proposed in that theory also would facilitate unusual responses, such as tolerance for ambiguity and moderate risk taking, and support follow-through, such as willingness to surmount obstacles, perseverance, and self-esteem.

Research provides support for the notion that highly creative persons are highly energetic persons – both in generating ideas and in pursuing them. Although there can be strong differences in personalities, especially across fields, this feature emerges consistently. One study found highly creative persons to have a passion for autonomy, a high degree of self sufficiency, and a heightened sense of identity. Another showed that the most creative individuals tend to be highly ambitious and confident in their views. This self-assurance may allow creative people to focus on personal motives and goals, rather than being overly influenced by the opinions of others. In order to study this possibility, Teresa Amabile and colleagues developed the Work Preference Inventory, which assesses motivational orientation as a personality characteristic. They identified two primary directions for work motivation: intrinsic motivation, which is marked by a focus on the challenge and the enjoyment of the work, and extrinsic motivation, which is marked by a focus on external reward for one's work. This research found that an intrinsic motivational orientation is positively correlated with creativity on a variety of tasks, in several different subject populations. Also, people involved in creative professions, such as artists, poets, and research scientists, were higher in intrinsic motivation and lower in extrinsic motivation than the general population. Recent work by Vikram Prabhu and colleagues confirmed

that intrinsic motivation is an enduring personality trait with a positive relation to creativity.

This kind of research is important in that it extends beyond the basic personality traits of creative persons and begins to explore the motives that underlie these traits. Research on personality traits describes creative individuals, but does not explain them. How does the motivation that characterizes creative persons arise?

Emotion as Energizing Creative Passion

Creativity has been thought to emerge from the strong and vacillating emotions that characterize mental illness, although it paradoxically has also been associated with positive emotion and psychological health. A greater incidence of affective disorders is observed in highly creative individuals; creative expression may be a positive means of coping with strong and conflicting emotions. Low levels of latent inhibition have been found to be associated with psychosis (particularly affective disorders) in some individuals, and with high levels of creativity in others. People confronted with a lowered ability to filter sensory information may find creative work an effective strategy for using all of the information they perceive.

Highly creative individuals may be those who are able to use self-expression in their work as a way to endure their mental illness. For example, when individuals write about emotional experiences, their physical and mental health improves as a result. A crucial component of therapy is self-disclosure. While feedback of some kind is inherent in the therapy process, simply expressing painful emotions can have a substantial beneficial impact on psychological functioning. The creative process, because it often involves self-expression, may be a useful means of working through psychological problems. In fact, various kinds of creative activities have been incorporated into some therapeutic efforts. Clinicians have used artwork, music, and drama to encourage creative expression and thus improve mental health.

Creativity might also support mental health by promoting feelings of self-worth and competence. A great deal of self-esteem can come from creative accomplishment. Those suffering from affective disorders, or any form of mental illness, may have a fragile sense of worth. A deep involvement in creative work may allow them to channel their anxieties into a valuable pursuit. The work itself may represent a part of the self that is valued and under the individual's control. The recognition that comes when the work is complete can be self-affirming. Of course, the criticism and failure that are also an inevitable part of efforts toward creativity may have the opposite effect. When creative work is progressing well, it may be wonderfully supportive. In times of difficulty, individuals may seek therapy as a way of coping with their symptoms.

In addition to promoting personal growth and fulfillment in those vulnerable to mental illness, creative work has been thought of as a sign of superior mental health. Humanistic psychology places a great deal of importance on respecting the potential of individual people. It is grounded in the belief that people have a great capacity for creativity. Humanists believe that creativity arises from a natural human tendency toward growth and self-actualization. Self-actualization,

a focusing on important problems rather than oneself, represents the height of mental health. Mihaly Csikszentmihalyi has studied 'optimal experiences,' which support self-actualization. Self-actualizing individuals take great pleasure in their work. At times, they experience states of complete and utter absorption in the work. They lose all sense of time. Csikszentmihalyi has labeled this highly enjoyable state 'flow.'

Work produced during flow is often highly creative. Through extensive interviews and field studies, Csikszentmihalyi has identified the conditions that facilitate flow. The most important appears to be an optimal level of challenge in relation to a person's level of skill at a task. If challenges are too great, the person becomes anxious, and his enjoyment and concentration are disrupted. If the task is not challenging enough, it is experienced as boring. One way that highly creative people maintain their motivation is by seeking optimally challenging work. As their skills develop, they will pursue more and more difficult problems. This process likely contributes to the self-reinforcing nature of the self-actualizing tendency.

Recent research in business organizations provides support for the view that creative behavior emerges from positive affect. This evidence on creativity following mood upswings fits well with experimental research on the effect of emotion on creativity. Most experimental studies, which have used participants from nonclinical populations (such as university students), have found that induced positive mood leads to higher creativity but induced negative mood leads to lower creativity. Moreover, the research in business organizations suggests that doing creative work contributes to positive mood; this process can establish a self-reinforcing cycle of creativity and positive affect.

Uniting work suggesting that creativity emerges from psychological problems with work showing that creativity emerges from psychological strength, Celeste Rhodes proposed that both deficiency needs and growth needs can motivate creativity. From these two categories of needs, Rhodes defined two types of creativity. The first satisfies the deficiency needs in Abraham Maslow's hierarchy (such as the need for the love and respect of others). This type of creativity aids psychological functioning, can serve to work through psychic conflicts, and increases self-esteem. The work leading to this type of creativity has a driven quality. Such individuals *need* to be creative in order to be satisfied with themselves. The second type of creativity is motivated by growth needs (such as the need for self-actualization). This type of creative work is pursued for the beauty of the work itself, in order to reach a higher level of understanding, or to solve an important problem. The motive of the artist, according to Rhodes, has an important impact on the final product. The audience can appreciate the transcendent understanding expressed by the self-actualizing creator.

Robert Vallerand's recent work on harmonious and obsessive passion provides empirical support for these ideas. His concept of passion is analogous to a strong drive to create. He proposes that passion can emerge in psychologically unhealthy or healthy ways. Those who possess a harmonious passion have an enduring commitment to their work and experience positive emotions when engaged in it, yet enjoy other activities as well. Those with an obsessive passion are compulsive about doing their work and experience negative emotion if they are prevented from working.

Our analysis, thus far, has focused on the creative person. Are there factors outside the person that motivate creativity? Can creativity be encouraged or thwarted by the social environment? Behaviorists focus on efforts to encourage creativity with rewards.

Reinforcing Creative Efforts

B. F. Skinner championed the effort to develop the scientific study of observable behavior, an approach known as behaviorism. Because internal states could not be measured directly, Skinner focused on the influence that the external environment has on behavior. After years of carefully controlled experiments, Skinner became convinced that the most important principle underlying the control of behavior was operant conditioning. Operant conditioning is the process by which behavior is followed by consequences that influence the frequency of that behavior in the future. If a reinforcer follows a behavior, it will occur more frequently. If a punishment follows a behavior, it will occur less frequently. Because of the pain and fear that punishment causes, Skinner advocated the use of reinforcers to control behavior. His analysis of creativity followed this principle precisely. Creative behavior could be promoted, he argued, by following it with a reinforcer.

Reinforcers gain their motivating properties by satisfying a basic need or drive. Food is a commonly used reinforcer in animal experiments. Hungry people also find food reinforcing, but many other items have been used in experiments with children and adults, including money, praise, awards, stickers, and small toys. When a person is behaving in order to obtain a reinforcer, that person is motivated by the need that will be met by the reinforcer. So, rather than the creative activity itself satisfying the need, the need is satisfied by the consequence that follows the activity. The motivation to be creative, from a behaviorist view, is simply the tendency to seek reinforcing consequences and avoid punishing ones.

There is much support for the notion that rewards for creativity are essential for encouraging it. Even Freud once wrote that money, prestige, and sexual rewards were essential to maintaining creativity. Certainly, an environment where creative outcomes are followed by desirable consequences is likely to be an environment where creative efforts are frequent. Using the Torrance Tests of Creative Thinking, Mark Runco has shown that providing rewards for divergent thought can increase the fluency of responses. Robert Eisenberger and his colleagues have also demonstrated that reinforcing divergent thinking on word construction and picture drawing tasks can enhance future divergent thought. Teresa Amabile's work in business organizations has shown that when there are rewards for creativity in the work environment, work teams reach more creative outcomes. The reinforcement principle, applied in the most global sense, holds true.

Some behaviorist thinkers go a step further, and propose that creative responses can be shaped by contingencies of reinforcement. They conceptualize every creative behavior as a combination of simpler behaviors. If a creative behavior is broken down into the series of behaviors that compose it, a program of reinforcement could be devised to strengthen the likelihood of each component behavior. As Skinner explained

it, some people will display true creativity, but before that can happen they need something to be creative with. Previously established behavior manifests itself in new situations in orderly ways. When the environment facilitates it, this order can result in high levels of novelty. Creativity, according to these theorists, is simply connecting previously learned behavior in new ways.

The practical problem with this approach, however, is that in order to develop a reinforcement plan, it is necessary to know all of the component skills involved in a creative outcome before the outcome occurs. Naturally, for truly original work, this is impossible. A second problem is the evidence that not all component parts of creative behavior are responsive to reinforcement. Kenneth McGraw distinguished between tasks that are algorithmic (clear and straightforward) and heuristic (require exploration and discovery). His research showed that algorithmic tasks are responsive to reinforcement while heuristic tasks are not. Teresa Amabile further developed this idea by proposing that some elements within creative activities are algorithmic and will, thus, respond very well to reinforcement. Reinforcing heuristic aspects of a creative task is more difficult; reinforcers may be effective if they are not salient, if the person is highly interested in the activity, or if the reinforcer provides useful feedback. Amabile's work points to the importance of considering the subjective experience of the recipient in order to determine the impact of a reinforcer.

The behaviorist approach represents an advance over previous work that considered only the individual's characteristics and motives in understanding the source of creativity. Research from this perspective highlights the importance of the external environment for supporting creativity. Yet, it also presents an incomplete picture. By considering only rewards and punishments, behaviorist thinking omits an important source of creative energy: intrinsic motivation. This motivation, too, can be influenced by the external environment.

Intrinsic Motivation and the Social Environment

Contemporary approaches to understanding the impact of the social environment on creativity propose that external factors, including reinforcers, influence creativity by the effect that they have on the individual's motivational state. Teresa Amabile, in her componential model of creativity, was among the first to advance such a proposal. According to the model, an individual's level of creativity is determined by three primary factors. The first is the person's level of domain-relevant skills, which include knowledge, developed talent, and special skills in the target domain. The second is the person's level of creativity-relevant processes, which include personality characteristics, styles of thinking, and styles of working that facilitate creativity. The third is the person's motivation toward the task. The componential model describes the impact that the social environment has on all three components, but emphasizes the role of the social environment in determining task motivation. The intrinsic motivation principle of creativity specifies that intrinsic motivation (stemming from interest in and enjoyment of the activity itself) is conducive to creativity, but extrinsic motivation (directed at a goal separate from the task) can be detrimental.

Thus, the intrinsic motivation principle considers the impact of the social environment on creativity, as the behaviorist approach does. At the same time, because intrinsic motivation is seen as rooted in normal human curiosity, the intrinsic motivation principle is compatible with the work of humanistic psychologists. Intrinsic motivation is the inherent satisfaction that we derive from productive, engaging, personally challenging activity. The intrinsic motivation principle states that, when intrinsic motivation is supported by the social environment, people are more likely to be highly creative. If they are pressured, constrained, or driven by extrinsic motivators, they are less likely to be creative. Similarly, Mihaly Csikszentmihalyi proposes that creativity arises in autotelic activities, where rewards stem from engagement in the activity itself, rather than from an external source. A concern for extrinsic rewards, or reinforcers, could interfere with an individual's focus, and disrupt the fragile process of discovery.

There is considerable empirical support for the intrinsic motivation principle. When extrinsic motivators are offered or extrinsic constraints are imposed on individuals doing an intrinsically interesting task in the laboratory, the work they produce is, on average, less creative than when extrinsic motivators or constraints are not imposed. Teresa Amabile and her colleagues have shown this effect with several different kinds of creative activities, including making collages, writing stories, and building paper towers, and with a variety of subject populations, including preschoolers, elementary school children, college students, and creative writers. This effect has been observed when research participants expected their work to be evaluated, when they were being observed (surveillance), when they contracted to do the activity in order to obtain a reward, when they were asked to compete with other participants, when they were denied choice, and when they were simply led to focus on extrinsic motivators. Many of these same extrinsic constraints have been observed to undermine creativity in real-world settings. In one study, research scientists reported that strong extrinsic incentives interfered with the development of creative ideas in their laboratories.

Although there is substantial evidence that extrinsic motivators can undermine creativity, recent experimental and non-experimental evidence shows that in some circumstances, extrinsic motivators have no influence, or even enhance creativity. To explain the patterns of results that have been observed, Teresa Amabile has formulated a theory of motivational synergy. The central premise of the theory is that, although intrinsic motivation is necessary for high levels of creativity, extrinsic motivation is not always detrimental. Some forms of extrinsic motivation may combine positively with intrinsic motivation, and thus boost overall levels of creativity. The theory proposes that this is most likely when intrinsic motivation is initially high and when the extrinsic motivators are perceived as supporting, rather than limiting, autonomy and skill development. The motivational synergy theory acknowledges the motivational potential of extrinsic reinforcers, while emphasizing the importance of maintaining the highest levels of intrinsic motivation in order to facilitate creative accomplishment.

Other social psychological theories consider the impact of the wider social environment. For example, David Harrington's work on long-term collaborative groups, proposes that a

'creative ecosystem' must develop within the group, in order to support ongoing creativity. Because creative people tend to be curious and active, their ecosystems need to provide them with encouragement and opportunities for playful task engagement. These opportunities sustain their intrinsic motivation toward their work. Reinforcing creative effort is also important. A multifaceted reward system can capitalize on the variety of motivations that creative individuals bring to work. This work suggests that the principles of motivational synergy apply to work groups as well as individuals. Other theorists have considered the influence of the larger community in their analysis of the motivation underlying creativity. Keith Sawyer's concept of 'collaborative webs' for creativity serves as a compelling example.

Dean Keith Simonton considered the broad cultural, social, political, and historical influences on creativity. Findings from his program of archival research both support and go beyond those uncovered in experimental and traditional observational studies. In one study, he found that musicians who had a higher number of contemporary competitors were less creative than those who faced less competition. This research demonstrates that factors in the wider cultural environment can impact creativity. Many of these factors are analogous to those identified as influencing creativity in the immediate social environment. Other researchers have adopted a perspective that incorporates the wider cultural climate, the physical surroundings, and the immediate social environment. These factors influence people differently depending on their past experiences and their personality characteristics. Thus, social psychological approaches to creativity motivation range from those concentrating narrowly on the influence of particular motivators on an individual to those broadly considering the full range of influences across the lifespan.

While this work confirms that the social environment has an important influence on intrinsic motivation and creativity, it does not explain how motivation operates in the translation of ideas into reality. What makes a creative process ultimately satisfying? What is the crucial element that keeps the creator engaged in the hard work of bringing a creative idea to fruition? Recent research calls this motivational force 'inspiration.'

The Inspiration to Create

While creativity scholars have long recognized the creative process as being inherently rewarding and self-reinforcing, until recently, the role of inspiration in motivating creative work was largely ignored. Even in Csikszentmihalyi's work on flow, which highlights the intensely engaging nature of the creative experience, there is little mention of the motivational potential of the ideas that emerge from the creative process. Work by Todd Thrash and his colleagues has brought the concept of inspiration to the attention of psychological researchers, and has documented the central role that inspiration plays in motivating creativity. Specifically, this work suggests that inspiration *follows from* creative ideas, energizing creators to bring those ideas to fruition.

Todd Thrash and Andrew Elliot define inspiration as having three components: transcendence, evocation, and approach

motivation. When an idea highlights possibilities to transcend present reality, the idea evokes a motivational state in which the person is inspired to act on the idea. Inspiration is approach oriented in that it is directed toward acting on the idea and bringing it to life in some sense. This definition reflects a common conception of inspiration as defined across disciplines, particularly in the humanities. In a recent paper by Thrash and several colleagues, empirical indicators of these three components converged to predict a single inspiration factor. In the same series of studies, inspiration was also related to but conceptually distinct from effort, creative ideation, and awe.

A central role for inspiration in the creative process has been questioned on several fronts. There is evidence from studies of the creative process that most creative products result only after many revisions. Thus, we can dismiss the romantic notion that a burst of inspiration fuels creative production in its final form. The possibility remains, however, that the most creative works are produced by the most inspired creators. Further, a given creator may be most creative when most inspired. Research on the personality traits of highly creative individuals suggests that these individuals work hard consistently, that they have the persistence to work through challenges. Recent evidence shows that inspiration is more frequent in those who are high in work-mastery motivation, suggesting that these individuals are often inspired rather than slavishly devoted to their work.

Personality traits have been linked to the likelihood of experiencing inspiration, as well. Those high in openness to experience, specifically openness to aesthetics, are more likely to experience the cognitive insights linked to inspiration. The intensity of the inspiration experienced is linked to extraversion. This relationship makes sense, in that extraverted individuals are approach-oriented and inspiration is a form of approach motivation. Another correlate of both inspiration and creativity is positive affect. Positive affect is thought to fuel creative efforts. Experiences of inspiration may generate positive affect to support the creative process.

Thrash and collaborators have documented that inspiration comes with a unique set of motivational experiences. They found that the evocation of inspiration involves a sense that the idea is of unconscious origin, that it enters awareness without the individual's control, and that it exerts a compelling press on the individual. Following this experience, research participants were more efficient and productive – hence working in a way that optimized the chances that a creative idea would be effectively translated into a creative product. Inspiration was specifically related to a product's creativity, not simply overall quality. Indeed, writers' ratings of inspiration while writing were strongly related to judges' ratings of the creativity, but not the technical merit, of the written product. These findings generalized across scientific writing, fiction, and poetry, and were observed in both naturalistic and laboratory contexts using both between- and within-subjects designs. Interestingly, effort predicted technical merit but not creativity in these same studies.

Recent work on inspiration fills an important gap in the creativity literature. This work brings together the two elements of the creative personality, by linking creative ideas with effective motivation to work. The role of inspiration in producing

positive affect fits nicely with work on creative passion. Finally, the construct of inspiration helps us to understand the intrinsically motivated process that supports creativity.

Conclusion

Highly creative individuals are also highly motivated individuals. They stand out as curious and playful, yet persistent and committed. They appear to be driven, and in some cases, unstable or even mentally ill. Their energy seems self-perpetuating: an inspired, growth-promoting force. Their efforts can pay off, when those around them appreciate their work and generously compensate them for it. At the same time, they are devoted to what they do. Rather than being slaves to fame, status, or wealth, highly creative persons often seem most excited about the pleasure of engaging in the work that they love.

The five approaches reviewed here start in very different places in their attempts to explain the motivation to create. The essence of each approach has merit, leading to a picture more complete and more complex than any single explanation could provide. The social psychological approach comes the closest to recognizing the diversity of energy sources that support creativity. An understanding of how a person can become completely absorbed in creative activity emerges by focusing

both on the individual's motives and on the enormous influence of the social environment. This combination illuminates both the everyday creativity of noneminent people, as well as the widely-recognized work of creative geniuses.

Glossary

Camera lucida A *camera lucida* is a small hand-held, four-sided prism used to facilitate accurate sketching of objects in broad daylight.

Camera obscura A *camera obscura* is a darkened space with a small opening admitting light through a mirror and lens arrangement. This set-up projects an image of the outside world onto a viewing table or plate.

Eponymy The practice of affixing personal names to all or a part of what someone has invented, discovered, or supported (e.g., Euclidean geometry, daguerreotype, Planck's constant, Boyle's Law).

Matthew effect A complex pattern of giving greater increments of recognition to scientists of considerable repute while withholding such recognition from those who

have not yet made their mark. Derived from a verse in the biblical Gospel of Matthew (25:29) that reads: "Unto every one that hath shall be given, and he shall have abundance: but from him that hath not shall be taken away even that which he hath."

Parallel discoveries Independent and similar discoveries. A synonym for multiple discoveries or 'multiples.'

Pluralism Grants a kind of equivalence to many possibilities, making them seem more or less equal.

Problem-finding The recognition, identification, and definition of an anomaly, obstacle, or problem that must be resolved in order for problem-solving to begin.

Singleton Something only invented or discovered once.

Zeitgeist Spirit of the times. The actual spirit of a Zeitgeist can only be understood in a long retrospect.

Overview

Multiple discovery is the technical concept used to explain the difficulty in assigning independent priority when two or more scientists or inventors give expression to a similar theory, form, model, or invention. An incomplete list would include:

1. the independent invention of the differential and integral calculus by Isaac Newton and Gottfried Wilhelm Leibniz;
2. the discovery of the light bulb by both Sir Joseph Wilson Swann and Thomas Edison;
3. the independent discovery of the fundamental principle of analytic geometry by Pierre de Fermat and René Descartes;
4. the discovery of Neptune, generally credited to the British mathematician John Couch Adams as well as Urbain-Jean-Joseph Le Verrier of France;
5. the non-Euclidean geometries independently discovered by Nikolai Ivanovich Lobachevsky, Janos Bolyai, Karl Friedrich Gauss, and George Friedrich Bernhard Riemann;
6. the discovery of anaesthesia in the nineteenth century attributed to Crawford Long, Horace Wells, William Thomas Green Morton, Charles Jackson, and others; and
7. the controversial discovery of single-wall carbon nanotubes and methods to produce them using transition-metal catalysts generally attributed to groups led by Donald S. Bethune at IBM and Sumio Iijima at NEC in the 1990s despite evidence showing that Russian researchers had independently reported this discovery in the 1950s.

This article introduces case studies that demonstrate multiple discovery in action and analyzes the difficulty in attributing discovery to a particular individual or group. The text also examines cases that show not all discoveries are easily fit into the multiple discovery framework. This first section provides

an overview of multiple discovery as a concept. Contextual issues related to scientific institutional practices, values, and unexpected discoveries are presented in the next section. The penultimate section explores the relationship between the individual and the community, focusing primarily on examples combining science and the visual arts. The final section integrates multiple discovery with cultural, philosophical and educational issues.

Overall, multiple discovery entered the science studies lexicon as a term to convey that scientists work within a community and that this community, by definition, is a domain where several people are using similar methods and technologies in exploring problems of scientific interest. Arguments favoring multiple discovery are based on the evidence that shared ideas and shared instruments are an integral part of each individual scientist's biography and that many discoveries share patterns of similarity. Moreover, it is argued, the extensive number of parallel discoveries that have been documented support the idea that something critical is lost when discovery is simply reduced to psychological thoughts and subjective processes within the heads of creative individuals. As a contextual idea, multiple discovery is also broadly defined so as to include the auxiliary products that are often needed for a discovery to be practical. For example, the invention of the telephone – be it attributed to Elisha Gray, Alexander Graham Bell, or both – necessitated the invention of switching devices, amplifiers, transformers, and transmission mechanisms.

Critics of the multiple discovery characterization say that conceiving of scientific innovation simply in terms of community exchange pushes aside many unresolved issues in regard to what creativity actually is and the actual body of knowledge we bring to our work. Moreover, when we look closely at particular discoveries we find that some fit into the multiple

framework more easily than others. These unresolved areas, the critics add, include the 'art' of science, the evidence that chance only favors the prepared mind, and the particular kinds of education, focus, and passion creative individuals bring to their work. In addition, the multiples characterization does not account for those inventions or discoveries that are only discovered once (termed singletons). Similarly, the multiple discovery designation does not address why one individual makes exceptional multiple contributions. For example, recognized as one of the most creative people ever to have lived, Albert Einstein revolutionized scientific and philosophic inquiry in the twentieth century. His reputation was largely a result of work done during his *annus mirabilis* (1905), when he published five papers that laid the groundwork for shattering cherished scientific beliefs.

An unusual individual like Albert Einstein, who opened more than one door in his field, offers a good touchstone for conceptualizing the amorphous quality of multiple discovery discussions. First, this kind of exceptional work raises the question of whether the high points of one individual's achievement and the comprehensive nature of an individual's contributions can be fully addressed using a model highlighting communal influences. In Einstein's case, multiple discovery theorists argue that all of Einstein's discoveries would have happened even without an Einstein. From this perspective, the discoveries may have taken more time, and required more minds, but the climate was ripe for these problems to be solved and thus they would have been solved. Critics of this position say the multiple discovery argument does not actually explain why Einstein was able to conceptualize so many ideas that were not yet directly a part of his culture and transform the theoretical physics in a way that extended beyond physics and into the culture-at-large as well.

Scientific Issues and Historical Examples

Institutional Practices and Values

Twenty-first century discussions of multiple discovery continue to rely heavily on the ideas of sociologists, anthropologists, and historians of science of the twentieth century (e.g., William F. Ogburn and Dorothy S. Thomas, Robert K. Merton and Elinor G. Barber, Alfred L. Kroeber, and George Sarton). These earlier researchers catalogued a vast number of discoveries that emphasized the role of context (rather than a particular person/genius), institutional practices, and values. These have been characterized as multiples since Merton. Merton's idea of the 'Matthew effect,' presented in the 1960s, has also had a significant impact on the debates. According to *Matthew* (25:29) "Unto every one that hath shall be given, and he shall have abundance: but from him that hath not shall be taken away even that which he hath." Merton's point here was that whether the discovery is recognized through the commemorative use of eponymy or simply results in better funding, those who are credited with priority are elevated to influential positions and thus have the leverage to disproportionately increase their stature on an ongoing basis. This view contrasts with Donald Campbell's argument that credit for multiples often goes to more obscure scientists because the latter have more eponymic value. Scientists who make lots of discoveries dilute the value of their name for this purpose.

The ideal of science has always included a picture of dedicated individuals working toward human good and the presupposition that humility is a part of a cooperative effort to reveal (and apply) universals. Yet, and despite the value placed on humility in scientific practice, proof of personal accomplishment is a critical component in gaining professional employment, prestige, promotion, and funding. Thus, the ideal is often contrasted with a reality that points to scientists working for the rewards associated with professional recognition within the institutional system, a view that suggests that humility and ideals do not fully explain scientific practices and values. More recently, researchers have probed cultural factors more systematically in an effort to ferret out how we develop expertise and how different family backgrounds influence performance and creativity. One particularly fertile idea is Malcolm Gladwell's outlier. An outlier is situated away from or classed differently from a main or related body. Using the outlier concept to expand on Merton's idea of 'accumulative advantage,' Gladwell suggests that family background, access to tools and training, and the time in which one is born plays a role in the development of (multiple and individual) creative contributions.

All in all, the evidence supporting background, training, and position does not resolve many of the anomalies associated with multiple discoveries. With multiple discoveries in a particular geographic area (e.g., the West), priority is often disputed, many of the disputes involve values, and many of the disputes are acrimonious, long-standing, and aggressively pursued. For example, the controversy between Newton and Leibniz over the invention of the calculus is one of the best known examples of a priority dispute involving parallel discoveries. It did not involve an esteemed individual and one on the margins of science. Rather, the dispute involved two individuals of high repute. This example shows how hard-fought some priority battles are. Although Leibniz published first, Newton developed his version of the calculus several years earlier. While it is now generally agreed that the two systems use different approaches and were developed independently, at the time each man accused the other of plagiarism. It was an emotional disagreement, to put it mildly. When Newton became the President of the Royal Society he decided to appoint a committee to adjudicate the rival claims of Leibniz and himself on the matter of priority. Historical records reveal Newton packed the committee, directed its activities, and wrote many of the published reports issued by the group. The second report (a draft of which was written in Newton's handwriting) is especially noteworthy because the anonymous author (Newton!) states that: "no one is a proper witness in his own cause." Given the way the investigation was conducted (by Newton), it is not surprising that the committee voted in favor of Newton.

Other cases reveal efforts to resolve a priority controversy are often totally unsuccessful. This was the case with the discovery of anesthesia. Eventually the US Congress was called upon to settle the heated debate that had resulted in an intense bitterness among the four American claimants (Long, Wells, Jackson, and Morton). Even Congress could not decide. The upshot was that the US House of Representatives passed a bill granting Morton credit and money for the invention of anesthesia, but the Senate failed to adopt it. As in many of the cases, the anesthesia controversy had a tremendous impact on the personal lives of those involved. One claimant, Wells,

committed suicide in 1848. Another, Jackson, died in an insane asylum in 1880.

This is not to say that multiples are synonymous with animosity and rancor. Moreover, given the 'Matthew effect,' it is also important to note that in some cases the wrangling appears to be oversimplified when characterized as the esteemed as opposed to the marginal. When Charles Darwin received a copy of Alfred Wallace's theory of evolution he spoke of the striking coincidence to his own theory, actually developed several years before Wallace's publication. In this case, even Darwin's chapter headings used Wallace's terms. This striking coincidence illustrates that regardless of whether one wants to credit Darwin for the theory of natural selection or characterize the insight purely as a multiple discovery and then attribute it to Darwin and Wallace – their work was presented together in a joint paper at the Linnaean Society on 1, July 1858) – does not change the fact that the theories took form at a particular point in time. This 'coincidence' has encouraged many to apply the idea of *Zeitgeist* to parallel discoveries and to emphasize that parallels appear to reflect the spirit of a time.

All do not accept *Zeitgeist* correlations as sufficient explanations, however. In terms of the Darwin/Wallace comparison, for instance, we find that there are significant differences in how they conducted their investigations. Darwin studied marine invertebrates while at Edinburgh University and then traveled to the Galapagos Islands, where he began to systematically formulate his theories of natural selection and evolution. Wallace, by contrast, did extensive fieldwork, in the Amazon River basin and in the Malay Archipelago. In weighing the different backgrounds the two men brought to their work one additional factor stands out: some say that it was unlikely that Wallace's views would have been taken seriously without Darwin's support given that Darwin's social and scientific status was far greater than Wallace's.

Zeitgeist, which implies inevitability, also brings additional issues into play. First, if we define discovery in terms of a 'spirit of a time' how do we accommodate developmental aspects of discovery? Second, *Zeitgeist* fails to contend with factors that are not a part of a culture per se, such as natural catastrophes and serendipity. Although these kinds of events significantly impact individual ideas as well as the broader community, they do not germinate from within a culture or even from within an individual. Specific concepts proposed to explain (or explain away) *Zeitgeist* in light of the existence of inexplicable events include God, free will, fate, causality, chance, and determinism. Third, there are also concrete, contextual debating points that are often a part of *Zeitgeist* discussion. These turn on the evidence that some individuals within a specific cultural environment will see theoretical and actual possibilities their colleagues miss. In addition, *Zeitgeist* does not adequately address unexpected discoveries; these are the discoveries that happen despite the evidence that no one was working toward solving the problem involved.

Unexpected Discoveries

The crux of the debate surrounding unexpected discoveries in science centers on the question of what drives individual creativity. Why do some *choose to investigate* anomalies in nature

and theory that others noticed and did not pursue? In other words, often a scientist chooses to focus on more solvable or socially esteemed problems that reflect the interests of his or her scientific community. Later, with the evidence that an important and unexpected discovery touched upon material he or she had seen and ignored the scientist is likely to acknowledge having seen a facsimile and put it aside. As such, the multiples issue is not just that history books, perhaps in error, tend to refer to discoveries in terms of individuals (e.g., we speak of Halley's comet, the Copernican revolution, and Linnaean system). Rather, there is also evidence that a contextually defined focus for discovery can overlook that neither products nor minds are generic – and the minds of particular individuals have made a difference.

Sir Alexander Fleming's discovery of penicillin and Wilhelm Conrad Röntgen's discovery of X-rays are examples that show that context alone does not account for how an individual's attentive focus on an anomaly can lead to an extraordinary discovery. In Fleming's case, for instance, in 1928 he noticed a bacteria-free circle in a Petri dish had been spoiled by a mold that killed the bacteria. Investigating, he found a substance in the mold that prevented growth of the bacteria and he termed it penicillin. Historical records indicate that similar observations had been made 50 years earlier; the primary difference between the earlier work and Fleming's is that only Fleming's work led to the discovery of antibiotics.

Röntgen, on the other hand, discovered X-rays in 1895 when he found that invisible radiation could not only penetrate solid, opaque substances but was also capable of producing images of the interiors. His investigation began only after Röntgen observed his bones were visible on a photographic plate during one of his experiments. At this time, Röntgen was working with cathode rays and a variation of a Crookes tube designed by a younger colleague, Philipp Lenard (who later demanded credit for the discovery). After Röntgen investigated the anomaly, he deduced that the rays created the image of his bones, which were easily discernible through his skin due to the different qualities of bones and flesh. The critical point here is that many scientists were working with Crookes tube and cathode rays at this time. For example, A. W. Godspeed of the University of Pennsylvania and a friend W. J. Jennings had made similar pictures six years earlier and filed them away. In addition, Crookes, the inventor of the tube, had observed that photographic plates fogged when placed near a Crookes tube. The evidence of these earlier observations has encouraged some to argue that the discovery of X-rays was inevitable and thus a multiple. Critics of adopting this hard line view note that the distinguishing element Röntgen brings to the picture is his willingness to investigate when he saw something that logically should not have appeared before his eyes (the image of his bones through his opaque skin). In Crookes's case, for instance, he did not ask what could be gleaned from the fogged plates. Instead, he returned the tubes to the manufacturer with the claim that they were defective.

Neither the Fleming nor Röntgen discoveries fit cleanly into a multiples category. Still, both are often, correctly, classified as products of their time. These examples demonstrate that some discoveries are more complete than others. In addition, both examples raise the question of whether unexpected discoveries should be considered as equal to similar discoveries that were

made earlier when the earlier 'discoverers' decided not to pursue what they noticed. Finally, these examples raise the question of whether there is a contradiction regarding discovery embedded in the multiples definition. In other words, the multiples definition does not convincingly account for anomalies that were 'seen' and ignored a number of times before the individual credited with the discovery recognized that he was seeing an event worthy of investigation.

These brief examples illuminate why some state that characterizing unexpected discoveries as multiples omits the importance of identifying a problem to solve, attention, background, training, and interest. Attention, background, training, and interest also speak more to the importance of the individual in discovery than social construction or a particular methodology. Examples that focus on the individual in turn raise the question of how each individual is related to the broader community environment. This is explored in the next section by turning to examples that combine science and the visual arts.

Science and the Visual Arts

The literature regarding visual art has always characterized multiple discovery somewhat differently from what is found in science and social science publications. For this reason, many social scientists argue that multiple discoveries are not applicable to the visual arts. Yet, the diversity of art and art as a practice show that the art within any particular culture is compatible with ideas about multiple discovery in a general (contextual) sense. This is because art has been a part of all cultures and has also developed along with cultural traditions. Moreover, throughout most of history artistic styles have changed gradually, reflecting that practitioners made subtle refinements as the cultural wisdom passed from generation to generation. One result of this gradual evolution is that it has often been difficult to look at the art of a culture and identify the hand of any one particular artist. In part this can be explained by the fact that a good artist was not striving to achieve something new. Rather, the belief was that good art was art made according to time-honored formulae. Toward this end, artists generally used traditional tools and techniques to produce a product that conformed to the community's standards.

Within this matrix, some cultural periods stand out as exceptions to this statement. These periods thus offer benchmarks useful in bracketing the practice of art in relation to multiple discovery. Well known benchmarks include (but are not limited to) classical Greece, Renaissance Florence, Elizabethan London, and the nineteenth-century *fin-de-siècle*. The styles associated with these periods are distinct and thus capable of demonstrating how particular artists have invented new technologies, redefined long-standing formulas, and altered time-honored practices.

Two points are critical here. First, in the visual arts, as in science, we can identify both multiple and singleton contributions. Second, because artists produce a different kind of product than scientists, and have different intentions when engaged with the practical problems that govern artmaking, it is harder to integrate art into the type of contextual presentation identified with multiple discovery in science. This section cannot comprehensively address the difficulties and will present three

case studies (the invention of oil painting, Galileo's illustrations of the Moon, and the impact of photography on nineteenth-century painting) to offer an overview that combines science and art. Before proceeding to the specific examples, it should be noted that while art and science are often represented in terms of dichotomies (e.g., imagination and logic, objective and subjective, inner and outer), scholarly work in the history of art has increasingly acknowledged that these kinds of dichotomies distort the many interactive elements that are a part of discovery in art. The use of dichotomies thus tends to obscure that visual artists and scientists alike grapple with concrete materials and subtle relationships. As they do so, their work combines theory with experiment and the individual, probing mind with the products that result.

Individual Contributions and Multiple Discoveries

The invention of oil painting

Two early sources on the lives of artists, Giorgio Vasari's *Lives of the Artists* (1550) and Karel van Mander *The Lives of the Illustrious Netherlandish and German Painters*, from the first edition of the *Schilder-boeck*, (1603–1604), described oil painting as a sudden technical innovation that was discovered by Jan van Eyck (c. 1395–1441) after much experimentation. In recent years extensive documentation has established that many painters were experimenting with oil, even as far back as the eighth century. What van Eyck (and other Netherlandish painters) did was see the optical possibility of using systematic glazing to make a painted surface look more realistic. Still, and despite the evidence that clearly documents the invention of oil paintings was a cultural (and thus a multiple) discovery, research has yet to explain why people continue to be drawn to agree with the attribution of priority to van Eyck. His paintings are often introduced in books with the statement that in viewing them one can see why van Eyck had long been credited with the invention. This tendency to attribute the discovery to van Eyck is then explained by looking closely at his work and at descriptions of van Eyck's virtuosity. For example, to demonstrate that van Eyck knew ways to make oil paint behave that no one had displayed before him, the eminent art historian Erwin Panofsky wrote that van Eyck's eye operated as both a microscope and a telescope. As a result, according to Panofsky, the beholder's eye is compelled to oscillate between a position reasonably far from the picture and many positions very close to it.

In sum, it is because the art establishes these complex relationships with the viewer that people are inclined to agree that Van Eyck was not a technician. He had a style of application most of his contemporaries could not duplicate, even when using the same materials and a comparable approach. This evaluation highlights that something particular to van Eyck is evident in his paintings. His 'eye,' his attention to detail and color relationships, his patience in application, and the rich quality of his descriptive product cannot simply be reduced to his knowledge of painting techniques and the evidence that the invention of oil paint was actually a multiple discovery.

Galileo and the Moon

Galileo Galilei's illustrations of the Moon expand on the van Eyck example. Galileo also offers an example that explains why many claim that what an individual contributes by virtue of his

or her unique background needs to be factored into multiple discovery discussions, for individual contributions often show that discoveries can reflect a community larger than the particular field in which the multiple is generally explored. Briefly, the activity of looking at the Moon and other planetary objects through telescopes excited many scientists early in the seventeenth century. What set Galileo apart from his contemporaries was that he had some training in drawing and watercolor. He also had a relationship and ongoing correspondence with the artist Lodovico Cigoli. Thus, while research has convincingly shown that the telescope was a multiple discovery, a multiples explanation per se deletes that Galileo brought a cognitive advantage to the activity of deciphering what he saw when he looked at the Moon through the telescope due to his background. This need not be defined as innate genius. Rather the advantage was environmental. His training in artistic perspective made him aware of how to translate a three-dimension surface onto a flat plane. Because he understood how to create a naturalistic rendering of the rough texture he was able to convincingly convey the nature of the Moon's terrain, and to do so in a way that allowed his peers to fully interpret what they saw.

Galileo's now well known astronomical observations/illustrations were published in *Sidereus Nuncius* (*The Starry Messenger*, 1610). In the text Galileo both includes paintings of what he saw when looking at the Moon and explanations of how he observed the geography of mountains, valleys, and craters through his telescope. By making reference to how the light and shadows change their disposition as the Moon moves from one phase to another, Galileo forthrightly asserts the difference between the terrain he saw and the long-standing Aristotelian belief that the Moon must be a smooth surface. The unique body of knowledge he brought to the project and his contacts helped him overturn a longstanding cultural meme and the prevailing Aristotelian idea that the moon was a smooth surface.

Ironically, the information about the Moon's texture information was readily available even to the inquiring and thoughtful naked eye, despite the tendency to explain it away. In fact, William Gilbert, best known for his research with magnetism, had earlier produced naked-eye maps of the Moon's geography. The outstanding element here is that Gilbert's maps did not draw upon the perspective techniques Galileo knew and used to render a naturalistic picture. In Gilbert's studies it was hard to decipher that the Moon had a geography similar to that of the Earth. Thomas Harriot offers another counterpoint. He is now generally credited with making the first rendering of the Moon as seen through a telescope and thus has the somewhat dubious distinction of being one of the first to fail to 'see' the rocky surface until viewing Galileo's images. Having no previous cognitive understanding of how a rough three-dimensional image would appear on a lens, Harriot, it seems, did not conceptualize he was viewing ridges and shadows – until he had Galileo's work to reference. Harriot, too, was among those more constrained by Aristotle's view that the Moon was smooth despite the evidence we see with the naked eye.

The differences among these images and the conclusions drawn from them explain why critics of multiple discovery say the multiples concept is overly generic. By reducing discovery to loosely defined products (like oil paint and the discovery of

the telescope), the concept under-emphasizes how attention, experience, and training inform discovery. In light of this, it should be mentioned that historians of science have long been interested in the community of science and multiple discovery complements this area of community by showing scientists comprise a community in which all scientists participate. Galileo's illustrations likewise affirm the scientific valuation of community and add that the more communities connected to a particular scientist, the more potential there is to bring information outside of one's domain into one's creative ventures. Galileo's work also demonstrates that scientific discovery has often been fostered by cross-disciplinary exchange and that cross-disciplinary examples inform the shared problems/parallel product style of inquiry. History, however, also offers examples of multiple discovery that underline a community tends to explore several lines of inquiry simultaneously, even when addressing one product or discovery. This accounts for the tendency to see products in *Zeitgeist* terms. Yet, for example, the painter Jan van Eyck produced three paintings in the fifteenth century that included naturalistic depictions of the Moon's rocky terrain. His paintings, unlike Galileo's, were not included in the philosophical and scientific discourse, where it was unquestioned that the Moon was smooth.

Zeitgeist

The history of photography speaks directly to the *Zeitgeist* issue, offering a classic case of how artists and scientists often work on problems in tandem. In this case, practitioners in both domains were interested in developing better methods for representing the world we see. This is not surprising given that representation has been an ongoing practical problem for both artists and scientists, and a practical problem easily separated from the philosophical arguments centered on 'appearance' and 'reality.' Many of the prephotography solutions (the *camera obscura*, the *camera lucida*, studies of optics, and perspective) aided the hand and the eye tremendously. But what was wanted was something that would allow an individual to fix an image and forego the need for long calculations and/or systematic tracing. Eventually determining a combination of light and chemicals capable of copying and fixing images solved this problem. The exciting solution, photography, made it possible to record visual images permanently and offered a level of detail that led some to exclaim that it was like looking at nature with a telescope.

Many helped develop this exciting technology. As early as 1727 a German professor of anatomy Johan Heinrich Schulze had shown it was possible to render images using sunlight and silver salts. In England, as early as 1802, Thomas Wedgewood, the son of the famous potter Josiah Wedgewood, successfully recorded images on paper. In 1819 the chemist John Herschel, the son of William Herschel, the discoverer of the planet Uranus, likewise discovered how to fix images and by 1839 could print them on paper as well. Independently, William Henry Fox Talbot, an English scientist who became interested in the problem because he was unable to draw easily using a *camera lucida*, determined how to create a single negative from which multiple copies of positive prints could be made. The Frenchmen Joseph Nicéphore Niépce and Louis-Jacques Mandé Daguerre conducted other independent investigations early in

the nineteenth century. Their experiments grew out of lithographic techniques and eventually, after Niépce's death, Daguerre fixed a single positive photographic image (a daguerreotype) on a metal plate coated with chemicals and exposed to light.

Assuming these examples represent multiple discoveries, and many think this is an incorrect assumption, does not explain why the mechanical representations of nature changed the cultural environment of art in ways quite unlike their influence on science. This aspect of multiples is of great importance to how one defines creativity and to how one applies the *Zeitgeist* characterization to multiples. Some elements of disparity thus need to be briefly explored. This inquiry will clarify that multiples take form in a context and form a context as well.

In a general sense, the photographic image provided a means for both scientists and artists to quickly record information about nature. Many found the efficiency attractive and astronomers and others quickly adopted the camera as a professional tool in the natural sciences. They immediately saw the technology eliminated the bothersome tasks of drawing and were pleased to no longer have to bear the burden of tracing moving images (although early prints often included after-images). In addition, the images satisfied several cultural demands. These included the desire for relatively inexpensive images for books (or as separate items) and the desire for cheap portraiture. The way in which the camera could record faces was a source of so much delight that some enthusiasts marvelled at how the camera was able to make the fugitive images of the mirror permanent.

The excitement, however, was not all-embracing. Generally, there was some concern that a photograph could be staged to give the impression it was a snapshot and thus be used to deceive people about events. Moreover, especially in the arts, many still preferred something included in the cognitive exercise of rendering by hand and eye. Even those artists (e.g., Manet) who did choose to incorporate the possibilities the camera offered had reservations about the mechanical nature of photographic reproductions. This is not to say that artists were against reproduction per se. Art has always been reproducible in principle, and multiples had always been printed using various technologies (e.g., woodcuts, etchings, etc.). It was the mindless mechanical reproduction of the camera that was disdained. Critics felt the camera was only capable of rendering surfaces. This argument was not a 'multiples' (Talbot's technique) versus 'singletons' (the daguerreotype) argument in regard to the multiple discovery of the photographic process per se, although the differences between the two processes were a part of the argument. Rather, the concern centered on the mindless nature of the mechanical images and whether mechanical images of surfaces could capture all that art and reality include. In other words, people believed, rightly, that mechanically produced copies did not contain the history, the pulse, and the depth of understanding embodied in an original.

In terms of *Zeitgeist*, the photographic images and the multiple reactions beg two questions. First, why did disciples of art and science have contrary reactions to the multiple discovery of photography. Second, how do we define a product of a time. The key point in evaluating these questions is that scientists were more likely to see photography as a tool. Painters, however, felt compelled to compare the nature of their images with

those the camera produced. The overall conclusion of the painters was that the mechanical images were not a replacement for painting or a reason to deny that the so-called objective reality of nature was of painterly interest. It would be more accurate to say that nineteenth-century painters continued to see an objective reality and to believe in the importance of rendering it. But the process of evaluating what images include also changed the nature of painterly problems. In sum, photography was one of many discoveries that reframed numerous nineteenth-century ideas regarding invention, mechanism, discovery, the mind, appearance, reality, the artist, the scientist, nature, seeing, and knowing. Some other factors include the nineteenth-century political situation and the turn toward Romanticism at the end of the eighteenth and through the mid-nineteenth centuries.

The details surrounding the entry of photography in the nineteenth century have been introduced to highlight a recurring question in discussions about creativity and multiple discovery: where do painters like Vincent Van Gogh (1853–1890) and Paul Cézanne (1839–1906) fit? Both nineteenth-century painters are hard to reconcile with multiple discovery in a generic sense, especially when a *Zeitgeist* model is implied. Now deemed as superior artists, their work was considered virtually worthless when they lived. What must be stressed in considering how these men 'fit' into models of creativity and discovery are, first, that the paintings done by van Gogh and Cézanne depicted the 'objective' natural world and were thus deeply rooted in the nineteenth-century tradition. This tradition, as noted, included the development of photography. Second, while both men were marginal in their time, each tried to integrate his work while he lived and failed to receive community acceptance. Finally, it is now said that the authenticity of their paintings and they way the forms conjure up a sense of presence that seems to go beyond the surface turned art in a new direction.

Putting these elements together raises the question of how do we evaluate the contextual incongruence the discoveries of van Gogh and Cézanne present? Many have pointed out they were people of their time. Yet, it is hard to align their productive lives and the intrinsic motivation that guided them with the idea that community acknowledgement of one's efforts is an integral part of being a successfully creative individual. It is equally difficult to align their lives with multiple discovery as generally defined. The problem is best summed up by asking why and to what degree are the individual and the culture connected in the discovery process, be it multiple or singleton? While it is true that most highly creative people do achieve success in their fields and are well-respected by their peers, in the visual arts we do find significant exceptions to this. As van Gogh and Cézanne attest, if we assume a discovery is contextually created, that the quality of a creator's work is evaluated by experts and institutions, and that only one who is 'accepted' by the community can be justly deemed creative in a complete sense, we are left with examples where a person, who is not defined as creative during his or her life, has, nonetheless, left behind products that are deemed creative long after the person has died. This time lag is especially problematic if we want to define artistic and scientific creativity using similar terms and in relationship to one another.

Cultural Issues and Conclusions

Reviewing the historical examples and the literature surrounding scientific breakthrough we find that even in earlier eras there was a tension between the individual genius model of creativity and the idea of a group working together to develop new ideas. For example, the philosopher Francis Bacon's (1561–1626) *Novum Organum* (1620) argues for multiple discovery when he states that discoveries are the products of 'joynt labours,' of people working together on common problems. The genius model, by contrast, is built on the image of God, the Creator, and glorifies individual accomplishments. Compatible with both theories of genetic determination and chance theories, the genius model suggests creative insight comes from out of nowhere, as if one is touched by something akin to the divine.

The long-standing debate about multiple discovery, as this article has shown, has raised many questions about creativity that remain unresolved. The issues and debates include:

1. the fact that the contribution of one individual may be significantly more complete than that of another in parallel discoveries;
2. the question of whether multiples theories adequately address individual creativity, especially given the differences between artistic and scientific creativity;
3. the length of time that separates what are termed 'multiple' discoveries;
4. the length of time that separates an individual's creative process of discovery and the community's acceptance of the work produced;
5. whether it is useful to define all discoveries as inevitable products of a time, an idea that *Zeitgeist* implies;
6. the individual priority disputes that have resulted from parallel discoveries throughout history;
7. the greater emphasis on team work in scientific research today; and
8. how the growth of team work makes it harder to recognize the contribution of any one individual.

The complexity of these unresolved questions tends to give rise to philosophical explanations. Given this, and although philosophical theory has not been the primary concern of this article, some precedents related to multiples need to be mentioned.

Briefly, both Plato and Aristotle grappled with the 'one' and the 'many' and did so because each saw human development and education as key concerns. Moreover, despite their differences, both Plato and Aristotle were deeply committed to an inquiry premised on logic and reason. Both were also in agreement that scientific knowledge is universal knowledge and that it is the same for all people, for all times, and for all places. These points of agreement were to become the backbone of natural philosophy and science in the West. As such, Platonic and Aristotelian ideas gradually set the stage for some of the ambiguities that have come to define the concept of multiple discovery today, as well as western views of creativity.

Since Plato and Aristotle have come to be defined more in terms of how they disagree, with Aristotle being seen to

emphasize studies of the natural world to a greater degree, it is often overlooked that both men did adopt a language/logic prototype for inquiry. The western allegiance to this prototype is no doubt why the concept of multiple discovery per se works better in a scientific (or verbal) context than in the visual arts. This language/logic preference, moreover, has generally been adopted by cognitive science in their search for universals.

Presently this long-standing preference for logic-based explanations is being counterbalanced by contextual case studies, systemic studies, research into the psychology of history, cognitive-historical analysis, and multiple intelligences research. Within this broad range many possibilities coexist. One that might foster viable information connecting individual and community approaches is the evidence of brain plasticity now being generated in cognitive neuroscience, for it appears that new tools might offer ways to align the focus on universals with individual case studies. Even if bridging studies are pursued, however, social and cultural interpretations will still have to be judged on their own terms.

Plato, himself, is not only a foundational reference for these ideas. He also offers a powerful example of the limitations within critical interpretation, albeit indirectly. Plato, who had a creative mind and was in awe of artistic inspiration in the sense that he saw it as divinely inspired, solved the problem of the one and the many with a philosophy premised on the idea that individuals could all discover the one Truth. In order to ensure it is the 'right' Truth, Plato banned artists from his ideal Republic, arguing their facility for imitation could too easily turn people toward appearances and thus turn them away from a genuine engagement with moral purpose. As philosophers, sociologists, and others have often noted, societies that mold people in 'one' way cannot be reduced to simple philosophical conundrums. Rather, manipulative social foundations pose numerous questions regarding education, individual growth, and governance. How people answer these kinds of questions, in turn, has a tremendous impact on what we discover in general – as well as conclusions pertaining to multiple discovery. The heart of the issue is multidimensional: How does a society differentiate between a discovery that is a 'correct' product in the sense that it is in line with a culture's norms and the discovery of something that is actually new and unique? How does the dynamic challenge of intergenerational education influence creativity? Each generation needs to be educated, and each educational process must align technological advances with ever-emerging cultural issues. Within this, one over-riding problem is fostering excellence in discovery, be it multiple or singleton. How does a culture balance individual potential and honor models that include structure, cooperation, teamwork, pluralism, and the exceptional?

The exceptional is of exceptional importance within this – especially because exceptional people defy neatly packaged conclusions about multiple discovery, as the example of Albert Einstein's *annus mirabilis* (1905), discussed earlier, shows. In sum, multiple discoveries can be defined as products that emerge from scientific exchange. Within this, definitional challenges exist due to the difficulty in precisely balancing the many variables that contribute to individual and communal change.

Multiple Intelligences

S Moran, Stanford University, Palo Alto, CA, USA

Glossary

Creativity A purpose or outcome of the interaction of individuals' intelligences and a domain of symbolic knowledge. The resulting solution or product is initially considered novel and unusual by the field but is ultimately accepted as appropriate and valuable. The creative breakthrough becomes part of the domain's knowledge base that is passed on to future generations of practitioners.

Domain A discipline, craft, area of work, or system of symbols used in a cultural activity; a set of practices associated with an area of knowledge.

Field The collection of practitioners, leaders, and institutions that judge work in a domain in a given historical period.

Intelligence A cognitive ability to solve problems or fashion products.

Intelligence profile A depiction of a person's intelligences in terms of relative strengths and weaknesses.

Purpose An intention to accomplish some outcome that is meaningful to the self and of consequence to others.

For much of the twentieth century, leaders, educators, and employers have been interested in predicting which individuals are more likely to succeed and, perhaps, even to change the world. 'Intelligence' has been a key psychological construct used to assess individuals for future performance. However, accurate prediction – especially of transformative or creative outcomes – has proved elusive.

IQ and general intelligence measurements have failed to account for why some people, and not others, change the course of history. Psychometric tests of intelligence and creativity do not correlate strongly above IQs of 120. In addition, Lewis Terman's landmark longitudinal study of high-IQ children produced few, if any, creative groundbreakers. Furthermore, the high-IQ criterion eliminated historically important creators, such as physicist William Shockley, inventor of the transistor.

Multiple Intelligences (MI) theory was devised, in part, to better explain the variety of performance outcomes individuals can produce. Psychologist Howard Gardner suggested that real-world achievement beyond academic tasks could be accounted for better by examining the interactions of an ensemble of relatively autonomous intelligences rather than the measurement of one 'general' intelligence. An analogy to building block toys may be helpful. IQ or 'g' is like having only one giant block. People can 'bang' that block in a variety of situations, but there are a limited number of items they can build with it. Multiple intelligences is like having several smaller blocks with different shapes. The scope of possibilities for individuals to build solutions or products is much wider, and the possibilities for researchers to understand how intellectual abilities interact in performances are more nuanced.

A Brief History of Intelligence

Intelligence is a capacity to learn, to gain knowledge and meanings, to understand relationships, and to reason. It has been a key construct in psychology throughout the twentieth century, especially in discerning individual differences and predicting

future performance on academic-type tasks. The measurement of intelligence has focused on IQ and the g-factor.

IQ, or intelligence quotient, is a quantitative measure based on scores on a battery of standardized tests of verbal comprehension, quantitative reasoning, perceptual reasoning, processing speed, and working memory. Tests such as the Stanford-Binet Scale and the Wechsler Adult Intelligence Scale compare an individual's score normatively to a bell curve centered at 100 such that 68% of people fall between 85 and 115.

The g-factor, or 'general' intelligence, relates to the positive correlation among various cognitive abilities measures. Derived using statistical factor analysis, 'g' is the dominant first factor on which many intelligence tests strongly load. Thus, 'g' is interpreted as a summary measure of intelligence of the person, although it primarily reflects a consistency across various intelligence tests.

In contrast to reducing cognitive ability to a single number, a few psychologists, in addition to Howard Gardner, have proposed more complex models. In the first half of the twentieth century, several theories, such as J. P. Guilford's Structure of Intellect Model or Louis Thurstone's Primary Mental Abilities, comprised hierarchical models of cognitive abilities subsidiary or in addition to 'g'. More recently, Robert Sternberg's Triarchic Theory of Intelligence posits three capacities: analytical, practical, and creative. His approach emphasizes the purposes toward which intellectual capacities are used. Raymond Cattell factored 'g' into fluid and crystallized intelligence. Fluid intelligence finds meaning, makes inferences, and solves new problems, whereas crystallized intelligence applies acquired knowledge. His approach emphasizes the situations toward which intelligence is applied. Stephen Ceci's Bio-Ecological Theory of Intelligence emphasizes that intelligence, rather than being an independent property of individuals, is fashioned by and in relation to the surrounding context. His approach depicts how intelligence is an interaction not only among a person's cognitive capacities but also among the person, the immediate environment, and historical circumstances.

Multiple Intelligences Defined

In the 1970s and 1980s, with revisions continuing today, Gardner devised Multiple Intelligences theory by synthesizing findings from research in psychometrics, neuroscience, anthropology, developmental psychology, evolutionary psychology, experimental psychology, and cognitive psychology. Not all cognitive capacities qualify as intelligences. MI takes a 'middle road': the senses, and fundamental perceptual or motor abilities, are too fine a grain to be useful for the ends to which intelligences are put, whereas one general intelligence or broad personality traits are too diffuse. To be named an intelligence, a cognitive capacity must satisfy eight criteria:

1. Potential isolation of brain damage that shows neurological separation of functions.
2. Existence of savants and prodigies that shows individuals can be strong in specific abilities without necessarily having high general ability.
3. Experimental psychological tasks that show performance on two simultaneous tasks do not interfere with each other.
4. Psychometric findings that show certain abilities factor separately.
5. Developmental trajectories and end-states that show capacities have different speeds, building blocks, critical periods, and pathways.
6. Evolutionary history that suggests different capacities can be found separately in earlier or less complex species.
7. Identifiable core set of operations for processing information that shows a relatively modular organization of capabilities.
8. A cultural symbol system providing information for which the intelligence is needed. Such a system may catalyze educational institutions that foster the development of an intelligence within a community.

At first, Gardner named seven intelligences, then later added '1-1/2' more. Although several other scholars and educators have suggested various other intelligences, such as spiritual intelligence or emotional intelligence, Gardner limits the intelligences satisfying the above criteria to the following list:

1. Linguistic intelligence: ability to process words, language, and verbal meanings.
2. Logical-mathematical intelligence: ability to process numbers, mathematical and logical patterns and operations.
3. Musical intelligence: ability to process sound and rhythm as well as meanings derived from them.
4. Spatial intelligence: ability to process shapes, arrays, and directions as well as meanings derived from them.
5. Bodily-kinesthetic intelligence: ability to process sensations, movement and coordination and to manipulate objects with one's body.
6. Interpersonal intelligence: ability to process information related to other people and social interaction, such as discerning feelings, needs, and intentions.
7. Intrapersonal intelligence: ability to process self-related concepts and sensations, such as differentiating one's own feelings, mental models, and self-knowledge.
8. Naturalistic intelligence: ability to process lists and categories and to classify and build models based on phenomena's features.

9. Existential intelligence (provisional '1/2' intelligence): ability to process profound, hard-to-grasp abstractions.

Gardner concluded that individuals possess differing degrees of these intelligences. Barring brain damage, all humans possess some of each intelligence, yet individuals can differ in their profiles. Some people may have smooth profiles with relatively equal degrees of the intelligences. These individuals are described as having 'equipotentiality,' although a smooth profile could depict low levels across the intelligences as well as high levels. Other people may have jagged profiles with one or two intelligences 'spiking' to a higher level than the others. Among these individuals are often found the savants and prodigies who may have difficulty in common tasks but can calculate complex equations in their heads or play sophisticated musical compositions by ear on first try.

Furthermore, profiles can be influenced by historical and social circumstances: some types of information are more prevalent or important in one time period or culture than another, and thus intelligences that process those types of information, for a time, will be more valued and supported. In the historical past, bodily-kinesthetic and naturalistic intelligences, as well as linguistic intelligence for storytelling, may have been preeminent for survival and growth. For most of the twentieth century in developed countries, linguistic and logical-mathematical intelligences have been the most highly valued. In the twenty-first century, interpersonal intelligence may become more valued as individuals must interact with a diverse array of people, and spatial intelligence will gain importance with the rise of computer graphical user interfaces and the Internet. Perhaps existential intelligence may rise in the ranks, as much of the knowledge that cutting-edge scientists produce is beyond the scope of our direct perception.

In summary, according to MI theory, an intelligence is a capacity to process certain forms of information that are available in the environment or produced by other cognitive faculties. Cultures value and support intelligences through schooling, symbolic *domains* of knowledge that utilize particular intelligences, and *fields* of practitioners in which individuals can apply their intelligences.

Multiple Intelligences in Interaction

Although researchers and practitioners continue to debate what constitutes an intelligence and to suggest further intelligences, theoretical work on MI has turned to how the intelligences interact. Although defined, in part, by their independent functioning, brain locations, psychometric factors, and developmental pathways, the intelligences do not work in isolation to create performances. The power of an MI approach is that individuals' diverse profiles of intelligences can be used in concert to engage tasks, achieve goals, solve problems, and create products. For example, dancing combines musical intelligence's processing of rhythm and bodily-kinesthetic intelligence's movement control.

Furthermore, different people can demonstrate similar performances using different combinations of intelligences. For example, compare three equally good dancers: one dancer may

draw on spatial intelligence to navigate the dance floor and spin his partner around, whereas another dancer may call on logical-mathematical intelligence to count steps and keep in time, whereas a third dancer may emphasize the connection with his partner using interpersonal intelligence.

Also note that most performances are not completed by one person. People work and play in teams and groups; outcomes are based on complementarity of resources, including intelligences. One person's intelligences interact with other people's intelligences. Ballroom dancers must adjust to each other, which may mean calling on intrapersonal, interpersonal, bodily-kinesthetic, spatial, and linguistic intelligences in a way they might not have needed if they were dancing alone.

Moran and Gardner discuss how intelligences can interact in three broad ways: bottlenecking, compensation, and catalysis. Intelligences bottleneck when one interferes with the expression or development of a different intelligence. For example, a language-based paper-and-pencil test may bottleneck the expression of other intelligences, such as when the subject matter examined is musical or logical-mathematical. Intelligences compensate when a stronger intelligence offsets the impact of a weaker one. For example, in *Creating Minds*, Gardner discussed how Albert Einstein was relatively weak in math, for a Nobel Prize winning physicist, but he more than made up for it with his strong spatial intelligence. Intelligences catalyze when one stimulates the use or growth of another. For example, while attempting to sway an audience, a public speaker's spatial and bodily-kinesthetic intelligences can multiply the effectiveness of their interpersonal intelligence.

Interactions may help explain why there is much diversity in expression of intelligences. A public speaker and a poet both may have strong linguistic intelligences. However, public speaking also draws on bodily-kinesthetic and interpersonal intelligences, and poetry draws on musical and perhaps logical-mathematical intelligence for structuring, and existential intelligence for addressing big issues. Thus, with multiple intelligences, there can be multiplicative as well as additive effects of intelligences. The moderate correlations among multiple intelligences scales may reflect these interactions. Furthermore, neuroscientific studies continue to show that higher 'intelligence' seems associated with higher interconnectivity among brain regions.

Finally, these interactions caution researchers and teachers not to confuse an *intelligence* with a *domain* – even when they have the same name. Intelligences interact to produce performances valuable to a domain. Domains are subsets of culture that focus on the use and perpetuation of a particular symbol system or body of knowledge. Examples of domains are history, music, visual art, physics, and business. Musical intelligence is not the only intelligence used in the music domain. Linguistic intelligence for lyrics, bodily-kinesthetic intelligence for playing an instrument, and interpersonal intelligence for coordinating with others in a symphony also may be called for. Similarly, someone with strong musical intelligence may employ it in a variety of domains, including poetry, acoustic engineering, or medicine to understand the sounds and rhythms a body makes in health or disease.

Assessment of Multiple Intelligences

In part, MI theory arose from Gardner's frustration over the failure of standardized intelligence tests to explain the diversity of human performances. Yet, assessment of 8-1/2 intelligences, plus their interactions, is much more complex than a test score or first factor. Adding to that complexity is the need to find assessment techniques that people can efficiently and reliably use in schools or workplaces. Assessment is the aspect of MI that the majority of intelligence researchers and school practitioners most criticize. Assessment also seems to be on the rise, especially in other countries such as Portugal or in Asia, and is, thus, increasingly emphasized in empirical studies of MI.

Branton Shearer has written extensively on MI assessments. In his chapter in *Multiple Intelligences Around the World*, he reviews the variety of MI assessments that have arisen. Several paper-and-pencil tests of each intelligence have been proposed and used. Gardner believes these tests suffer from a bottleneck of linguistic intelligence. Questionnaires, checklists, and interviews, such as the Multiple Intelligences Profiling Questionnaire (MIPQ) or the Multiple Intelligences Developmental Assessment Scales (MIDAS), ask students, and sometimes teachers or parents, to evaluate students' intellectual abilities. Gardner suggests that these self-report measures may suffer from a bottleneck of intrapersonal and/or interpersonal intelligence.

The Key Learning Community, a school widely known for adopting a schoolwide MI perspective, as well as other public and private schools, uses rubrics to evaluate portfolios of student work as the work develops. Project Spectrum assessments developed at Harvard Project Zero have trained adults to observe young children as they engage with carefully designed problem-solving materials. The portfolio and observation approaches pose less of a bottleneck and are more ecologically valid and 'intelligence fair,' but they have been criticized as time-consuming and too subjective.

Importantly, intelligence-fair assessments evaluate each intelligence directly, rather than through a linguistic-oriented paper-and-pencil test. Object manipulation tasks evaluate spatial intelligence; group collaborations evaluate interpersonal intelligence; self-reflections evaluate intrapersonal intelligence. Danfoss Universe's Explorama, a children's science museum in Denmark built on MI theory principles, is an example of intelligence-fair assessments. As with Project Spectrum, Explorama exhibits feature activities in which individuals can interact with materials to employ various intelligences. For example, one exhibit provides biological specimens for students to touch and move (tapping bodily-kinesthetic intelligence), arrange (naturalistic), create relationships among (logical-mathematical), tell stories about (linguistic), or even compare themselves to (intrapersonal). Yet, unlike Project Spectrum, which is designed for young children, the Explorama is used by people of all ages and backgrounds, from school children to business executives.

These assessments differ from testing in that they are more contextual and conducted in the course of performance rather than via decontextualized questions. MI assessment is considered to be part of the natural process of learning and engaging with the environment, rather than a task set apart. Yet, the difficulties of MI assessment are three-fold. First, MI assessment

does not have a 'norm' or 'standard' for comparison because children's different intelligence profiles can follow various developmental paths. Assessment results are qualitative as well as quantitative. This type of assessment may help people find their 'niche' in their societies and cultures, but it leads to two further issues. MI assessment is not as quick, efficient, or cheap to administer as paper-and-pencil tests. Hence, many schools find MI assessment cumbersome when teachers or counselors are under time and resource pressures. And MI assessment does not produce a single number that can be used to label and compare students. If the purpose is to categorize or place students in 'higher' or 'lower' bins, such as gifted or remedial programs, then practitioners find more traditional intelligence testing easier.

However, policymakers, educators, and business leaders increasingly realize that one norm, standard, or pathway applied to everyone does not produce the variety of talents and skills needed in a complex society or economy. 'Meets standard' may not equate with 'maximize potential' or 'able to make a contribution to society.' Individuals have different sets of intellectual resources and potentials that lead to different ways those people can contribute to their communities. An expert mother, entrepreneur, architect, bus driver, or computer programmer each requires different skills that draw on different intelligences. Yet, most cultures need *all* of these skills spread among their members.

Purposes of Multiple Intelligences

As more emphasis has been placed on how multiple intelligences are assessed, educators and scholars have turned to the question of purpose. This exploration of the practical dimension of MI theory has come to the attention of educators worldwide. An assessment is meaningful in light of a reason for the capacity. *Why* do individuals' MI profiles matter?

Intelligences are often considered an individual property, a capacity a person 'has.' However, intelligences are not important so much for their own sake as for what they accomplish. One of the reasons to understand intelligences is that they contribute to the achievement of personal and cultural goals. Intelligences operate within cultural contexts. As cultures develop different domains and develop domains differently, some intelligences may be more valued, and thus developed and supported, in one culture than in others, or within one culture at different times.

In *Five Minds for the Future* published in 2007, Gardner elaborated five ways that intelligences could be focused toward particular purposes: to master a particular discipline, which converges intelligences on one cultural domain; to synthesize information from a variety of sources, which uses intelligences to cross the boundaries within and between cultural domains; to create new ideas or products, which expands or transforms cultural domains; to be respectful of differences among individuals, which may synthesize or expand notions of belonging and acceptance; and reaching for ethical ideals, which emphasizes the impact of one's efforts on others now and in the future.

Although many cultures have these purposes operating concurrently, sometimes they may clash. For example, the emphasis of a disciplined mind to maintain expertise within

a domain may conflict with the emphasis of a synthesizing mind to expand the boundaries of the domain. Similarly, the creating mind that develops something new, unknown and untested may conflict with the ethical mind that evaluates what has traditionally been considered right or helpful in a domain. These conflicts can occur contemporaneously within a democratic culture, or across historical time within a culture as the culture changes. For example, some educators in Asian countries realize that MI theory returns their educational systems to traditional purposes, such as Confucian education principles. Or these conflicts can occur across cultures as different cultures express different values. And conflicts can occur across subcultures within a nation, such as has been promoted in debates on race/ethnicity and IQ.

In *Multiple Intelligences Around the World* published in 2009, educators in countries on five continents discussed the impact of MI in their school systems. The main purposes of intelligences *assessment* they provide remain the traditional reasons of placement and educational tracking/planning. However, several other purposes are presented for the *development and education* of intelligences, including harmony among people and their skills, inclusion of a wider variety of talents into the realm of cultural acceptance, self-understanding and personal fulfillment, and contribution to society. These purposes point to two increasingly important values: flexibility and cooperation. Within an MI framework, education aims to enhance a culture's collective information-processing potential to use the culture's collective knowledge base effectively to complete more varied tasks. As societies become more complex and interactive globally, a similarly complex and interactive view of intelligences strengthens individuals' and cultures' abilities to adapt and thrive.

Multiple Intelligences and Creativity

One purpose to which intelligences is increasingly summoned is creativity. MI theory provides a way of thinking about education and performance that allows and supports a wider variety of talents and skills to be expressed and to contribute to the community. An MI approach invites more diverse array of intelligence profiles to become producers rather than just consumers of culture. That is, by taking a broader and more inclusive view of intelligences, MI supports an increased probability of creativity in two ways. First, more people can access domains in which they can make creative contributions because MI is more inclusive of different groups of people exhibiting distinctive profiles. Second, more contributions may be judged as creative because of a wider array of acceptable ways to use one's talents.

MI addresses the 'novelty' aspect of creativity by recognizing how different profiles can result in different performances and also by realizing that intrapersonal intelligence can help the self-direction and self-regulation of creative work. By its very nature, creative work aims to transform a domain and, thus, may encounter resistance from domain practitioners already in power who like the domain as it is. Under such circumstances, intrapersonal strength may be particularly important for orchestrating not only the creator's other intelligences but also his or her motivation during challenging times.

MI addresses the ‘appropriateness’ aspect of creativity by recognizing how difficult and potentially conflicting it is for people to process different types of information in reaching a judgment of value. Each intelligence, by processing a different type of information, contributes differently to how a creative work is perceived. Individuals have different intelligences, thus process the whole of the creative work differently. Such differences may contribute to controversies over value. Furthermore, intrapersonal and interpersonal intelligences may be particularly important for the ‘appropriateness’ aspect as these intelligences may be most directly involved in creativity’s main aim to ‘change minds.’ Through reflection and communication, a creative work influences the way others think.

Creativity is an *extraordinary* contribution to culture in that it eventually changes the culture. Thus, creativity, over time, can change the value of different intelligences within a culture by altering types of information available, importance of these types, and the purposes toward which such information is used. Thus, the interaction of multiple intelligences and creativity is bidirectional.

Music

M J Lewis, University of Northampton, Northampton, UK

© 2011 Elsevier Inc. All rights reserved.

Glossary

Composition Music that is created and then written down using notation to produce a score, or recorded by some other means that permits copying, so that it can be read and played by others. However, performers and conductors may still have freedom to interpret the piece according to their own preferences.

Emotions Feelings of which we are consciously aware, which can result in behavioral and bodily changes such as tears, sensations in the stomach, a lump in the throat, heart palpitations, skin tingles, and increased perspiration. The physiological mechanisms involved are complex, involving different parts of the brain, and both the sympathetic and parasympathetic nervous systems. Playing and listening to music can be emotional experiences.

Music An auditory, nonverbal medium of communication: the language of feelings, compared with speech which communicates information and ideas.

Musical creativity Composing and interpreting music makes use of skills that are not just logical and convergent, but are emotional, divergent, artistic, and original. There is evidence that musical training, especially for school

children, can enhance other aspects of intellectual development.

Music therapy The use of music by a trained therapist to help communicate with, and help, people with specific behavioral or emotional needs, where the use of words alone may fail.

Musical sound Noise that is structured rather than random, and which comprises melody, rhythm and, if more than one note is played at once, harmony. Different instruments, or combinations of these, produce their characteristic tone color (*timbre*), and dynamic variations in loudness and tempo also influence the overall musical effect. The vibrations of sound can be felt by the body as well as being heard, and some successful musicians are in fact totally deaf.

Song Musical pieces that are composed to be sung, with or without instrumental accompaniment. The words need to be processed by the speech areas of the brain, and singing adds the element of aural communication by one (or more) human beings to another. Researchers who are interested in music per se invariably restrict their stimulus material to nonvocal pieces, in order to limit the influence of confounding variables.

What is Music?

Sound

Music is a type of sound. When a suitable object vibrates, it alternately compresses and decompresses the air around it forming waves. These waves travel through the air at a speed of about 740 miles an hour, and are intercepted by the ear, within which the ear drum (tympanic membrane) moves back and forth in synchrony with the pulsations of the air pressure. Then, via a series of structures within the ear, the signals are conveyed by the auditory nerve to the brain and are perceived as sound. The particular noise that is heard is determined by characteristics of the vibrations, such as frequency (number of wave cycles per second) and amplitude (the height of a single wave). Where several sounds are generated at the same time the wave forms can interact and become very complex.

The Sound of Music

Almost anything struck will yield a sound but, in the case of random or nonmusical sound, the waves formed will tend to be irregular and unstructured, and will likely be perceived simply as noise. For sounds to be musical, the waves must be structured into time and space, that is, be regular rather than random. The structuring then needs to yield a sequence of notes that is recognizable as a *melody*, and arranged in a

pattern that generates some form of *rhythm*. If more than one note is sounded concurrently, these need to blend into an acceptable *harmony*. Finally, to be perceived as pleasing, the resulting sound needs to have a characteristic *timbre* (tone color), and this will vary according to the instrument that generates it. However, the final decision on whether or not the sound can be regarded as music lies within the perception of the beholder. What qualifies as music (and particularly harmony) has changed over the years, and is subject to the whims of taste, fashion, culture, and social context (see 'Historical Development of Music').

Sounds of Nature

Can sounds of nature be regarded as genuine music? Birdsong, for example, can have a melodic structure and tone color, and also a rhythm. Ralph Vaughan Williams (1872–1958) is but one composer who was inspired to create a composition based on bird song, with his evocative *The Lark Ascending* (1914), in which a violin replicates the sound of the bird. The decision on the authenticity of music not of human origin remains a matter for debate, but a possible criterion could be that the sound is intentionally composed or created by human beings for human beings, as an artistic expression that is conveyed through performance by the self or others (see 'Sounds of Nature').

Origins of Music

Prehistory

Music has probably been present since the dawn of civilization, and is found in every culture and historical period, so far as can be ascertained. Its precise origins remain uncertain, but some (including Charles Darwin) believe that it arose from an increasing tonal range of emotional speech, including verbal exchanges between mothers and their babies which itself indicates emotional bonding. Another possible origin, or at least influence on the development of music, is that our early ancestors mimicked and adapted the 'musical' sounds of nature – the wind blowing through reeds, the sonorous tone of an object hitting a hollow log, and the vocalizations of animals including birds (see 'Sounds of Nature').

Early Musical Instruments

What is believed to be a fragment from a flute made from the thigh bone of a bear has been dated to between 43 000 and 67 000 years ago, an era when Neanderthals still existed. Also, part of a 40 000-year-old flute fashioned from a vulture's wing bone, probably *Homo sapiens* in origin, was discovered in a German cave. Later, more certain flute specimens have been dated to about 27 000 BC. Evidence suggests that drums have existed from the earliest of times, that stringed instruments such as early forms of the harp and lyre (Figure 1), plus bells, date from about 3000 BC, and that the lur, an ancient form of trumpet, originated around 1000 BC. Around the time of the medieval period, early versions of many of the more modern

Figure 1 The ubiquitous ancient lyre design is reflected in this lyre guitar C1815. Image courtesy of Pamela Wilson Collection, UK.

instruments in use today were being evolved, such as the fiddle, trombone (sackbut), and harpsichord (Figure 2).

Notation

The oldest known attempts at musical notation – written music that allows many pieces to be shared and copied without the need for rote learning, were in Babylon circa 1250–1200 BC, although the symbols are very obscure. A more systematic attempt to write music was made in the seventh century in the context of sacred monastic chants. This became more effective only by the eleventh century, although it comprised little more than dots above the words of a song, indicating when the voice should be raised or lowered in pitch. As notation became more sophisticated, so did the opportunities for composers to embellish their written scores with more complex timings, harmonies, and expression (Figure 3).

The Harmonic Series

Leonard Bernstein, twentieth century American composer and conductor, referred to music as sound that is produced by beating, blowing, plucking, striking, or frictionalizing with a bow. In about 500 BC, the Greek philosopher and mathematician Pythagoras discovered that the note from a plucked string becomes progressively higher as the string is shortened, according to simple arithmetical ratios. It is now known that, with only slight discrepancies, these ratios agree with changes of frequency as measured in megahertz, and thus they comply with natural physical laws. If a string is shortened by half, the note plucked will be an octave higher than that produced when at full length, the ratio between the two notes being 2:1. When the string is shortened to a third of its original length, the sound it generates will be five tones higher than when it was at half length (known as a 'fifth'), with a ratio of 3:2. Likewise, when shortened to a quarter of its original length, the note will be a further fourth higher (ratio 4:3) and, when a fifth of its original length, it will sound another third higher (ratio 5:4). These examples can be deemed simple ratios, but the process can continue almost indefinitely and the ratios become very

Figure 2 This archaic serpent C1835 is an early brass instrument. Image courtesy of Pamela Wilson Collection, UK.

music. Research by Sandra Trehub and colleagues found that infants as young as 4 months were superior to adults in being able to detect melodic changes within the same key signature. Trehub has concluded that there is present at birth a biological predisposition for understanding musical structure, as well as an innate preference for what can be termed 'good' (consonant) melodies.

If there is an inherent universal ability to understand and respond to music, why do only some individuals become talented musicians? Many factors are involved, including encouragement, interest, musical environment, opportunity, and sheer hard work. Hayley Goldman and Michael Lewis investigated the respective influences of genetic and environmental factors on the development of musical ability in children. They used Edward Gordon's *Advanced Measures of Music Audiation*, which assesses both rhythmic and tonal aptitude, to test a sample of young people drawn from the United States and the United Kingdom, along with their parents. The children also completed a self-report questionnaire on environmental influences such as musical training, music listening, and concert attendance.

Whilst the results supported the role of environmental (nurture) factors in the development of musical skills, an additional intriguing finding was of a significant link between fathers and children specifically for rhythmic ability. Could there be an evolutionary advantage in inheriting rhythmic skills, passed only through the male line? Not only is rhythm an essential component of music, but it is also evident in marching, chanting, drumming, and other warlike behaviors such as hunting and fighting. In most cultures these would have originally been male pursuits. Such spatial skills are predominantly controlled by the right cerebral hemisphere, held to be more dominant in men than in women, and this region is also responsible for much of the musical processing. Additionally, some research has implicated the cerebellum in the processing of rhythm, this being the area of the brain responsible for the coordination of voluntary motor movement that would include the behaviors mentioned above (see 'Cerebral Processing').

The nature or nurture issue on the development of musical talent has yet fully resolved, and this is particularly relevant to the question of musical geniuses, of which Mozart (1756–1791) is cited as a prime example. Mozart came from a family of musicians which could imply that he had some innate ability, but it also means that he was surrounded by music from birth, and even *in utero*. His father, Leopold, was a music teacher and a hard, even ruthless, taskmaster forcing his young son to practice for many hours a day. Anders Ericsson and colleagues have searched for strong scientific evidence for innate talent and giftedness, but as yet have not found rigorous reproducible outcomes that support this. Perhaps the debate should continue, with the provisional conclusion that nature and nurture might both have a part to play in musical development.

Emotional Experiences

Music is a medium for communicating emotions, in some cases very extreme emotions. How and why it does this is still

not fully understood, despite research that includes measuring brain activity during music listening trials (see 'Cerebral Processing'). Most, although not all, research into the effects of music has been carried out using selections from instrumental (that is nonvocal), classical repertoires, which are sufficiently complex to require a degree of cognitive processing. When melodies are sung, the human voice introduces the confounding element of verbal meaning plus the expression of emotion.

In the 1960s Abraham Maslow described *peak* (emotional) *experiences* that can occur in practically everyone, and could manifest as moments of great awe, a feeling of oneness in the world, seeing the ultimate truth, satisfaction of vague, unsatisfied yearnings, stepping into heaven, or being detached from time and place. Others think of them as altered states of consciousness, but the emotional impact needs to be much more profound than just great pleasure or enjoyment for it to qualify as a *peak*. Maslow said that aesthetic events, particularly music, could act as triggers for peaks, and that some individuals could rely on certain pieces of music to help them bring them about.

Is it possible to identify what it is about music that can lead to such heightened emotion? Music in major modes tends to sound happy, whereas minor modes can evoke sadness. Likewise slow tempi sound dignified and calm, fast tempi happy and exciting, high pitches sprightly and humorous, and low pitches solemn, sad, and dignified. Research on hymn tunes, carried out by Adrian Hughes and Michael Lewis, found that higher scores for emotional and spiritual impact were awarded for hymns in triple time, when compared with those in quadruple time, and that there was a similar effect with hymns in minor modes compared with those in the major.

Lewis and professional musician Colin Touchin exposed participants to 30-min selections of classical music, and asked them to press a button each time they experienced a peak emotional reaction conforming to a predefined description. The music scores were then scrutinized for specific events that coincided with the main clusters of peaks. Only a few were identified with any certainty, for example at the start of a solo passage, where one instrument takes over from another, at a fortissimo, at percussive impacts, crescendos, and a full-blooded climax. Others such as John Sloboda of Keele University, United Kingdom, have cited appoggiaturas, descending fifths, earlier than expected changes in harmony, and unexpected changes or tensions, as being responsible for producing what have been variously called 'chills' or 'thrills' or 'shivers.' Although increased arousal could be responsible for such responses, especially with upbeat music, it is likely that other factors are also involved, especially in the case of gentle music that can generate a dreamy or even hypnotic state in the listener.

Does the knowledge of such triggers mean that composers simply make use of a 'cook book' technique to build emotional expression into their music? Opinion is divided on this question. Philosopher Susanne Langer did not believe that a work of art expresses the feelings of the artist, adding that music is (just) a form of logical expression of emotions that can enable listeners to experience them. The composer Stravinsky stated that music is powerless to express emotions, and that any indications to the contrary are simply illusions. However, he did not deny that music can have *apparently* expressive qualities that can be perceived as such by the listener. Hindemith,

another composer and performer, opined that melodies can be constructed rationally, making use of experience that indicates which musical patterns correspond with particular emotional reactions. Others, such as Sloboda and Deryck Cooke, maintain that music does indeed have inherent characteristics that promote affective responses, and that it can convey the subjective experiences of the composer.

Vladimir Konečni looked for evidence from previous studies, and was able to make a distinction between $M - E$, the notion that music can represent or *express* emotion that is perceived as such by the listener, and $M \rightarrow E$, in which music is believed to *induce* emotion in the listener. Konečni concludes that, whereas music can certainly depict and represent emotion, the evidence for the direct induction of emotion by music is weak.

In any discussion on music and emotion, it is necessary to consider the roles of the performer and listener respectively. Whilst most composers include expression marks on their musical scores, to help performers recreate what was intended, often some freedom remains for the artist to add his or her own expressive interpretation. This can be done through manipulation of tempi, dynamics, or sheer virtuosity to reinforce the structural features that the performer (or the conductor) believes are intrinsically important. Performers may not be able to clearly explain why they interpret the way that they do, but rather simply follow their intuitive feelings.

The listeners will be influenced by the degree of musical training they have received, and the musically sophisticated will probably hear what is being played in a more cognitively involved way than do their more naïve colleagues, as well as liking the more complex musical styles. Finally, another important quality of music is its ability to evoke memories of association, especially if the piece was being played at the time of an earlier, emotional, event such as a wedding, funeral, or the first meeting with a future marriage partner ("darling, they are playing our tune"). Rehearing the music could either generate an emotional response that was not specifically intended by the composer, or enhance an emotion that was so intended, perhaps sufficiently strongly to stimulate mental imagery of the earlier occasion. Daniel Levitin has delved deeply into the biological processes underlying how we experience music, and why it plays such a unique role in our lives. He concludes that our brains are hardwired for music and that our musical preferences begin to form even before we are born. Rather than music being just an addition to our lives, Levitin is convinced that it is an obsession at the heart of human nature.

Cerebral Processing

Music, being a nonverbal (if purely instrumental and not sung) medium of auditory communication, is processed predominantly (but not exclusively) in the right cerebral hemisphere, at least for right-handed individuals.

Lauren Stewart and colleagues reviewed findings from imaging studies on the normal musical brain, obtained from procedures such as functional magnetic resonance imaging (fMRI) or magnetoencephalography (MEG). They also examined similar data from patients who had brain lesions caused by surgery, accident, or stroke. From this information, the

authors were able to identify the areas of the brain where different types of musical processing mostly took place. With normal brains, Stewart and colleagues report bilateral hemisphere activation during analysis of pitch sequences, but with a degree of right-lateralization, and additional activity in the right frontal operculum when participants were required to follow a melody. For rhythm, some studies revealed activity in the cerebellum, suggesting that motor mechanisms may be required for its production. Evidence from patients with brain lesions in areas involved in processing music indicated that the regions concerned are widely distributed, but with a preponderance of locations in the right hemisphere. For example, the areas involved in pitch interval, pitch pattern, and tonal structure ranged across several areas in the right brain, although there were some indications that the two hemispheres work in cooperation. For rhythm, again several right hemisphere areas were involved, although a minority of studies also implicated the left parietal lobe but, unlike the studies with normal brains, not the cerebellum. The work with damaged brains also showed that the right hemisphere was involved in emotional responses to music.

There is evidence from a number of studies that differences exist between the brain lateralization of musicians and nonmusicians. For example, trained musicians also utilize the left brain more than do casual listeners, because they tend to cognitively analyze the structure and complexity of the music they hear. Christian Hoppe and Jelena Stojanovic used MEG scans to compare the neural responses of musicians and nonmusicians to changes in melodic contour, and found that the responses were 25% higher in the former. The musicians also showed higher gray matter density in the left inferior frontal lobe (Broca's area) which is a region used for language processing; the authors explain that this part of the brain is also used for sight reading of musical notes. Hoppe and Stojanovic also found that children who started to learn the violin before they were seven years old had enlarged primary motor areas that controlled the fingers of the left hand used for forming the notes. Other studies have shown that this use of the left hand also leads to some restructuring of the right, visual side of the brain.

The final stage of Lewis' investigation into the nature of peak emotional experiences (see 'Emotional Experiences') involved a small study using electroencephalogram (EEG) brain mapping whilst participants were either relaxed or listening to the music selections (Figure 4). Circumstantial evidence suggested a dual hemisphere involvement when such peaks were felt, as both cognitive and emotional processing were suspected to occur before the experience could be identified for what it was. The hypothesized outcome of right hemisphere (temporal lobe) activity only when relaxed, but dual hemisphere activity during peaks, was confirmed with only 25% of the participants, partly due to strong extraneous 'noise' on the EEG tracings that could have masked significant data. Thus the evidence for dual-hemisphere processing of peaks remains speculative, and justifies further investigation.

Leonard Bernstein believed that there was a musical grammar that parallels speech grammar, and he devoted much of his 1973 Harvard lectures to descriptions of the former from the musician's point of view (see 'Whither Music?'). Ani Patel, John Iverson, and Jason Rosenberg used a somewhat different

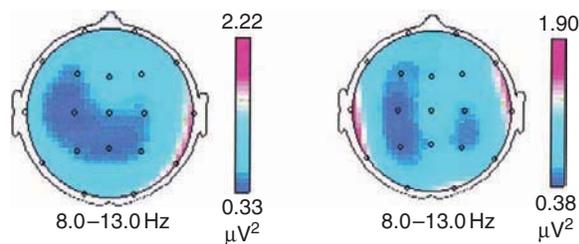

Figure 4 Head viewed from above with nose at the top. A narrow, light strip between the ear region and dark inner banding indicates an area of high activity in these monochrome images. *Image by the author.* A similar illustration appeared in *Journal of Applied Arts and Health* (2010), vol. 1, number 1, p. 89. approach, starting with the premise that humans produce organized rhythmic and melodic patterns in two forms: prosody (versification) and music. They explored the notion that the prosody of a culture's native language is reflected in the rhythms and melodies of its indigenous music. From an analysis of the speech spectrograms of sentences, and the duration of musical themes of both British and French speech and music, the authors concluded that the joint (not individual) properties of melody and rhythm are involved in defining national characteristics of music.

Patel also noted that language and music show a degree of overlap in the brain for specific aspects of processing. He cited previous research using MEG that showed harmonic processing to originate in a left frontal language region (Broca's area) and its right hemisphere homologue. Patel then specifically examined syntactic processing in both language and music, that is, the set of principles governing the combination of discrete structural elements such as words or musical tones. He concluded that linguistic and musical syntax share certain processes in the frontal brain areas that apply over different domain-specific representations in posterior brain regions.

Uses of Music

Music Therapy

Music therapy is an established health profession that aims to help people who have difficulties with social, physical, mental and emotional functions such as communication, cognitive functioning, learning difficulties, autism, dementia, and depression. Because music is such a powerful communication medium, it can sometimes be used to interact with a client when attempts to do so through words alone have failed. Following an assessment of the client's needs the music therapist, who is a skilled and experienced musician, will use a range of musical styles including improvisation, to try and establish interaction with the client. The music that is successful may provide an indication of the client's prevailing mood. The practitioner can then manipulate the music to facilitate positive outcomes such as mood improvement and confidence, and encourage transfer of these to other aspects of the client's life. Song writing, singing, or other musical performances may also be introduced as part of the procedure.

The Mozart Effect

In 1993 great interest was generated by the publication of research by Frances Rauscher and her colleagues, which claimed that listening to ten minutes of Mozart's *Sonata for two pianos in D major* resulted in a short-term (10–15 minutes) improvement in scores on a spatial-temporal problem-solving test. In attempting to explain this phenomenon, the authors built on an earlier notion that similar neurons fired when either listening to music or performing spatial tasks, and they proposed that hearing the right type of music might 'warm-up' neurons prior to completing this type of test. Another suggestion is that appropriate music stabilizes arousal level by either raising one that is too sedentary for efficient operation, or reducing excessive arousal that might be caused by anxiety or hyperactivity, so that the level of concentration for addressing the task is optimal for good performance. William Thompson, Glenn Schellenberg, and Gabriela Husain conducted a controlled experiment with a Mozart composition and another piece, measuring enjoyment, arousal and mood, in addition to performance on a test of spatial abilities. Statistical analyses of the outcomes suggested that the Mozart effect is an artefact of arousal and mood.

In an attempt to identify just one aspect of classical music that could enhance performance, this time on verbal as well as spatial tasks, Catherine Sutton and Lewis digitally manipulated a piece of music composed by Handel, to create two identical versions, except that one was now in the key of F-major and the other in F-minor. The major mode version was rated by participants as emotionally more positive than was the minor, and performance on verbal tasks by females was enhanced by listening to this version. However, no other significant results were obtained for either sex on spatial or verbal task performance.

Such inconsistent research findings on the ability of music to enhance task performance, including the so-called Mozart Effect, rather than suggesting that all such claims are spurious and not to be taken seriously, instead merit further controlled studies. A particularly interesting theory on why specifically Mozart's music might have beneficial effects, but one difficult to prove, is that Mozart himself suffered from what is now known as Tourette's syndrome, and he instinctively created compositions that were therapeutic for his own condition. If this is so, and the calming effects of his music can be passed on to the listener, then Mozart did not suffer in vain.

Other Health Benefits

Further uses of music include social aspects such as the promotion of group solidarity, cultural identity, and trust and cooperation brought about by playing or singing in groups. These are of particular benefit to the physical and mental health of the elderly, including those with various stages of dementia, and the neurologically impaired. Because music is a medium of communication, as well of having the power to evoke memories, appropriate musical selections enable people to maintain links with the real world, even when verbal communication and facial recognition become difficult (see 'Music Therapy').

Laura Mitchell and colleagues investigated what they called 'audioanalgesia,' the use of music for pain control, either by

distracting attention from the discomfort through emotional engagement with the music, or by creating a feeling of control over the pain by having a technique to decrease its severity. Such applications can have far-reaching clinical applications, for example in recovery from, or tolerance of, pain of surgery, childbirth, accidents, or other medically related conditions. Paul Robertson describes studies that were carried out in a German hospital by Dr Ralph Spintage; it was found that just 15 minutes of soothing music allowed the dosage of sedatives and anaesthetic drugs used to control the pain of operations to be reduced by 50%.

Creativity

A dictionary definition of creativity would refer to aspects such as originality or imagination, novel solutions or reinterpretation without being bound by conventional rules or procedures. Psychologist Carl Rogers defined creative process as the emergence in action of a novel relational product, growing out of the uniqueness of the individual on the one hand, and the materials, events, people, or circumstances of his (*sic*) life on the other. Rogers emphasized that there must be some observable end product such as a work of art, or an invention. At a basic level creative thinking is often referred to as divergent, compared with the more rational, convergent thinking. However, if Rogers' requirement is to be achieved, the former is of little practical use without the latter in order to convert the novel idea to a practical reality.

Robert Sternberg stated that creative individuals work long and hard studying their chosen field, in order to build on what has gone before and become experts. They then draw on this knowledge for insight – to see new relationships or make breakthroughs in understanding. Creative people prefer novelty to tradition or convention, and are open to new ways of seeing. They are also intrinsically motivated by the desire to solve problems, and obtain much enjoyment from doing so. An examination of the lives of those whom we regard as creative will invariably reveal many of these qualities, and Mozart is but one example (see 'Musical Aptitude: Nature or Nurture?').

Can musical skills help the creative processes in other disciplines? Based on correlational evidence, Robert Root-Bernstein noted that skills associated with music, such as pattern forming and recognition, analogizing, and imagining are equally evident in creative scientists. Many leading scientists are, in fact, also musicians. Albert Einstein, for example, is quoted as saying that his theory of relativity occurred to him by intuition, and that music was the driving force behind that intuition (he studied the violin from the time he was six years old). Other scientists have reported that they work best when listening to music, and this can be especially useful in mathematicians as some music, for example, baroque, is very mathematical in form, and thus there is an overlap or priming of neurons common to both skills. Root-Bernstein states that the creative ideas of scientists often manifest as sensory images or kinaesthetic feelings, which must then be converted to words or mathematics in order to be communicated.

Can training in music enhance abilities in other spheres? Norman Weinberger reviews some research evidence, including a study where high school music students were compared with nonmusic students on a measure of creativity involving

devising unusual uses for common objects. A significant correlation was found between music and creativity; whilst this does not prove causality, it does confirm a relationship between these two variables. In another study, with school children in the first grade, one group received 30 minutes of music instruction per day for a full year, whilst a control group did not. The music group scored significantly higher on creativity tests and in perceptual-motor skills, than did the controls. A similar trial was carried out in Hungary with preschool children, and the results also demonstrated an increase in creative ability. Interestingly, however, there was no parallel increase in intelligence quotient, showing that the effect of the music education on creativity was quite specific.

Naomi Ziv and Efrat Keydar in Israel were interested in the degree of complexity of musical selections that creative individuals prefer (see 'Emotional Experiences'). They subjected participants to a range of music of differing complexity, and then measured their preferences, liking and perceived complexity of the selections, in addition to administering a test of creative potential. As hypothesized, a positive and significant relationship was found between creative potential and preference for (but not necessarily enjoyment of) the more complex musical pieces, although musical tastes and familiarity with specific musical styles were also relevant factors.

The evidence that creative benefits arise from (preferably active) music involvement, and that there is a positive relationship between the amount of time and intensity of such involvement, the preference for complex musical stimuli, and the accompanying increase in scores on tests for creativity, cannot be ignored. Thus, if we want to improve and develop the creative ability of humankind, inclusion of musical training in the school curriculum would seem to be indicated.

Whither Music?

This was 'the unanswered question' discussed by Leonard Bernstein in his six lectures at Harvard in 1973, published in book form in 1976 (see 'The Harmonic Series'). Bernstein's thesis was that people are born with an innate musical grammar, which is universal regardless of culture, in the same way that theorists such as Noam Chomsky claim that there is a universal grammar underlying human speech. How the language or music skills develop is influenced by aspects such as culture, history and individual creativity. Bernstein developed his ideas by pointing out that music comprises mathematically measurable elements such as frequencies, durations, decibels and intervals, as does language. He presented many examples of musical structures, phonology, syntax, semantics, and ambiguities. Does this mean that the science of music has now been fully explained, and that the original question 'whither music?' has been addressed? Surely not, as even a full understanding of the technicalities of an art form does not explain the aesthetics, and Bernstein himself is happy to admit that music is 'a mysterious and metaphorical art.'

This article has included some scientific ideas, for example, on the physical basis of the harmonic series, and the brain areas involved in the processing of music. Mostly, however, it has accepted that music is a medium that can generate and communicate emotions, sometimes extremely profoundly,

probably has some benefits to cognitive ability and health, and gives pleasure to most people both through performing and listening. There still remain many unanswered questions, and it would be surprising if they were ever all resolved (and perhaps disappointing if no mystery remained). One particular question still lingers: why did music evolve and why has it survived the process of evolution, when there seems to be so little practical use for it apart from enjoyment and pleasure? (see 'Emotional Experiences').

Music has a very long history and universal presence and, from its association in earliest times first with nature and later with religious practices, it is not surprising that it became associated with the supernatural. It has also been held to have a divine origin, perhaps being the only particle of the divine essence that humankind has been able to capture, and that it is the language of higher entities. Are such ideas just flights of fancy, the products of naïve minds that have little understanding of scientific principles? Perhaps, but the fact that so much about music remains a mystery despite the discoveries of modern science, leaves us with a point on which to ponder: is the propensity to create and enjoy music simply a gift and, if so, from whom?

Glossary

Behavior genetics Behavior genetics is the field concerned with investigating the role of genetics in human behavior, particularly through twin studies to study the inheritance pattern of traits.

Emergenesis A process whereby novel or emergent properties arise from the interaction of more elementary (and partly genetic) properties.

Genotype The genetic constitution of an individual (or cell).

Lamarckianism A principle according to which the mechanism for evolutionary change is environmental: organs which assist an organism in altered conditions are strengthened, else they atrophy through disuse.

Furthermore, such acquired characteristics are inherited.

Log-normal distribution The distribution of a variable can be modeled as log-normal if it can be considered as the multiplicative product of many independent random variables. Log-normal distributions are skewed to the right, although the logarithm of the random variable is normally distributed.

Molecular genetics Molecular genetics is the field concerned with investigating the structure and function of genes at a molecular level. Its methods can be employed to study how variation in molecular features is related to the expression of behavioral traits.

Phenotype The appearance of an organism, determined by the interaction during development between its genetic constitution (i.e., genotype) and the environment.

Introduction

The idea that creativity and genius are influenced by nature and nurture is not new. Joy P. Guilford reemphasized this notion in his classic presidential address at the meeting of the American Psychological Association in 1950. However, *scientific* interest in the question of genetic and environmental contributions to creativity must be traced back to Sir Francis Galton's seminal book *Hereditary Genius*, published in 1869. Galton believed that genius was a biologically transmitted trait, and that it would run in families in a Lamarckian fashion. Galton's own lineage may have prompted him to ponder this hypothesis, given that his blood relations included his grandfather Erasmus Darwin, his cousin Charles Darwin, Charles's scientifically eminent sons Francis the botanist, Leonard the eugenicist, Sir George the physicist, as well as the latter's son Sir Charles Galton Darwin the physicist.

A critical issue for Galton concerned how to define his key dependent variable of Interest – genius. Galton defined genius in terms of achieved distinction or *reputation*, in turn defined as “the opinion of contemporaries, revised by posterity . . . the reputation of a leader of opinion, of an originator, of a man to whom the world deliberately acknowledges itself largely indebted.” Galton devised novel statistical and methodological techniques to support his hypothesis that eminent scientists tended to have eminent relatives at a much higher rate than would be expected by base rates in the population. Nevertheless, Galton's work was plagued by its own shortcomings. For

example, there were uncertainties regarding the actual relatedness of some individuals, as well as the questionable inclusion of some others as *bona fide* geniuses. This meant that on the whole the evidence was not very convincing. However, had Galton not focused on eminence (which has a log-normal distribution) but instead shifted his attention to any of its normally distributed component factors (e.g., talent, IQ), he would have succeeded in showing that creativity is influenced by genetics. I shall present evidence from behavior and molecular genetics to demonstrate that genetic factors exert a strong influence on the expression of creativity. In fact, despite considerable reluctance by some scholars to embrace the role of genetics in creativity, there is reason to believe that our current estimates for its role may in fact be too low. The implications of this evidence for educational interventions to boost creativity are discussed.

Genetics of Creativity

Behavior Genetics

Personality, cognitive ability, and behavior are heritable to varying degrees. Heritability is a statistic that tells us the proportion of phenotypic variance that can be attributed to genetic factors. When genetic contributions are additive, the heritability quotient is calculated by doubling the difference in the intraclass correlation between identical (monozygotic) and fraternal (dizygotic) twins. On average, cognitive abilities and

personality traits tend to have higher heritability than many medical disorders such as autism, schizophrenia, and alcoholism. In fact, 30–60% of the variance in most personality traits and cognitive abilities can be accounted for genetically.

Many researchers view creativity as an emergent trait. A term initially coined by David T. Lykken, *emergence*, refers to a process whereby a trait is expressed if and only if a number of independent subtraits or abilities are simultaneously present. Because the relationship among the subtraits is not additive but multiplicative in nature, the absence of any one component is sufficient to block the occurrence of the emergent trait altogether. Thus, even though many of the subtraits may themselves be normally distributed throughout the population, the emergent trait itself shows a log-normal distribution. This makes it extremely uncommon for any individual to possess simultaneously all the necessary subtraits for the expression of an emergent trait such as high-level creativity or genius. Among the traits that seem necessary for real-life creativity are IQ of at least 120, capacity for analogical reasoning, and high motivation, to name but a few. In fact, emergence explains why, contrary to Galton's assertion, creative achievement does not run in families: even though members of a given family possess genetic similarities, it is unlikely that they will possess all the necessary characteristics for the expression of creative behavior.

In an early study to compute the heritability of creativity, Robert C. Nichols conducted a large-scale review of twin studies and compared the heritability coefficients of twelve types of cognitive abilities. The heritability coefficient of divergent thinking, widely recognized as an aspect of creativity, was only 0.22. This was lower than the coefficient of all other cognitive abilities, which had an average heritability of 0.42.

However, the studies Nichols reviewed have been criticized because the sample sizes were very small, and the measures of divergent thinking were not very reliable or valid. This shortcoming was rectified by Niels Waller and colleagues who conducted a much more systematic investigation using data from identical and fraternal twins. For identical twins, they found an intraclass correlation of 0.60 for the Creativity Personality Scale, whereas for fraternal twins the intraclass correlation for the scale was essentially zero (–0.02). Note also that the Creativity Personality Scale has been shown to predict scientific creativity. These results indicate the presence of a substantial multiplicative genetic component in even potential creativity.

Recently Dean K. Simonton made a significant contribution to our understanding of the heritability of creativity. His approach employed a unique combination of features. He focused on scientific talent rather than eminence, and defined *scientific talent* as any feature of natural endowment that has one or both of the following two effects. First, talent must enhance training. For example, although it is generally known that it takes a person about ten years to become an expert in any given field, those with higher natural endowment (i.e., talent) will require less time to gain expertise in the field. Second, talent must enhance performance. For example, given that two scientists have the same level of accumulated experience, the scientist with higher talent will be more productive than the one with lower talent. Simonton further clarified his definition of talent by noting three refinements. First, talent is not a 'diffuse' gift. Rather, it consists of a composite of highly specific abilities and

characteristics. Second, the natural endowments for training and performance need not be the same. For example, although general intelligence probably contributes to training and performance, the personality trait Openness to Experience probably contributes more to the latter. Finally, natural endowment may be genetic or nongenetic. Genetic endowment involves the direct transmission of genes from the parents to the offspring, whereas nongenetic endowment involves any personality or intellectual variable present at birth that can be ascribed to other developmental factors, such as the intrauterine environment during pregnancy.

Although for the purpose of his analysis Simonton focused on genetic endowment, it is important to note that endowment is not synonymous with *genetic* endowment. Simonton generated formulae for three quantitative estimators of *criterion heritability* that can be applied to meta-analytic and behavior genetic research to predict the intellectual and personality components of scientific training and performance.

Criterion heritability was defined as follows. Let us suppose that a given criterion of scientific training or performance can be predicted using a set of intellectual and personality variables. Furthermore, assume that each of these predictor variables has a heritability that corresponds to the proportion of variance in that variable that can be attributed to genetics. Using these two bits of information one can calculate the criterion heritability, which is the proportion of the variance in the criterion variable that can be explained using genetic variation. Here we will focus on one of the criterion variability estimators developed by Simonton (i.e., *hc32*).

After specifying the ideal data requirements for the application of the estimator, Simonton applied his analytic procedures to previously published results. He focused on personality and intellectual traits. The personality factors were derived from the California Psychological Inventory and the Eysenck Personality Questionnaire. For criteria that distinguished scientists from nonscientists and creative scientists from less creative scientists, he was able to show that between 37 and 48% of the explained variance was explained by genetic variation, the rest attributable to environmental factors and error variance. He then applied the same analytic procedures to analyzing intellectual traits in a different data set using the Miller Analogies Test with respect to seven criteria (first-year graduate grade-point average, graduate grade-point average, faculty ratings, comprehensive examination scores, degree attainment, time to finish degree, and research productivity). Here the heritability estimates ranged from 3% for research productivity to 27% for comprehensive examination scores. Simonton's results demonstrated that by applying the proper analytic procedures to datasets that adhere to the proper statistical specifications, the substantial contribution of genetic endowment for personality and intellectual criteria becomes clearly apparent. He also presented considerable evidence to show that if certain analytic improvements were made – such as if the profiles of the predictive traits were coupled more closely with the specific criteria and the phenotypic predictors made more exhaustive – the criterion heritability estimates could reasonably double in size. In combination, the behavior genetic work of Simonton and Waller and colleagues strongly suggests that a substantial portion of the variance in creative potential and talent can be attributed to genetic factors.

Molecular Genetics

Recently, the study of gene–behavior relationships has become much more sophisticated by the introduction of quantitative genetic technology into molecular genetics. It is now possible to link a genetic polymorphism at a particular neurotransmitter site on a chromosome to behavioral, personality, and cognitive variables. Theoretically, the most important departure point has been to move away from a one gene–one disorder model (OGOD) toward a view of complex traits as being caused by or mediated through the effects of a composite of potentially distinguishable genetic constituents. The majority of traditional genetic studies investigating the association between genes and behavior have relied on linkage analyses. Linkage analysis involves testing a model that is proposed to explain a particular inheritance pattern. Specifically, one posits a specific location for a trait-causing gene and tests that hypothesis against the null hypothesis, which by definition posits the lack of a trait-causing gene in that location. The systematic nature of linkage studies allows for a high degree of confidence if an association between a genetic locus and a phenotype were to be discovered.

On the other hand, because linkage studies follow the OGOD model, they are only appropriate for investigating the genetic bases of dichotomous traits. The major shortcoming of such an approach for studying creativity is obvious: Because complex traits are caused through minor effects originating from multiple genetic loci, they are likely to be distributed as quantitative dimensions rather than qualitative syndromes. Therefore, linkage approaches will not be successful in identifying such multiple-gene influences in complex systems.

In contrast to linkage approaches, *allelic association* has provided geneticists with a powerful tool to solve this problem. Geneticists define complex traits as those that are caused by the influence of multiple genetic loci, or as “phenotypes that do not exhibit classic Mendelian recessive or dominant inheritance attributable to a single gene locus.”

The definition of a complex trait is analogous to that of an emergent trait, such as creativity. In other words, because creativity is a complex trait with a strong heritable component, it is highly probable that it is under the influence of several gene loci that influence its various components. This characterization brings us to the forefront of genetic research involving allelic association. Alleles are different forms of DNA found at a particular locus on a chromosome. Allelic association refers to the relationship between allelic variants (i.e., polymorphisms) and quantitative variables, such as cognitive variables or personality traits. Because complex traits are hypothesized to be influenced by several genetic loci, they are also referred to as polygenic traits. The multiple genetic sites that contribute to the observed variance in complex traits are referred to as Quantitative Trait Loci (QTL).

Unlike linkage analysis which is systematic but not powerful, QTL mapping is less systematic but much more powerful, especially when using large sample sizes and comparing individuals from the extremes of a phenotypic distribution. Most importantly, allelic association is ideally suited for locating multiple gene loci, each of which contributes to a part of the overall phenotypic variance in complex traits. This characteristic makes allelic association ideal for genetic investigations of creativity.

Next, I shall review allelic association work on novelty seeking, a trait long associated with creativity.

Novelty Seeking

Claude R. Cloninger has defined the trait Novelty Seeking as the “tendency toward intense exhilaration or excitement in response to novel stimuli or cues for potential rewards or potential relief of punishment, which leads to frequent exploratory activity in pursuit of potential rewards as well as active avoidance of monotony and potential punishment.” Not only is novelty a core feature of products considered to be creative, but the description of this trait accurately characterizes the personality profile of many creative people. Previous studies using large twin samples have demonstrated that approximately 50% of the additive variance in Novelty Seeking is accounted for by genetic factors. Because Cloninger had hypothesized that Novelty Seeking is mediated by cortical dopaminergic activity, investigating the links between the dopamine pathway and Novelty Seeking became a primary concern for this research program.

The year 1996 marked a breakthrough year in genetic mapping: Two independent teams reported an association between the dopamine D4 receptor gene and Novelty Seeking in Israeli and American samples. The D4 receptor is the product of the D4 receptor gene (DRD4). The DRD4 gene is highly polymorphic, in that its alleles vary along several dimensions. Given the particular region on the gene where the polymorphism was detected, the researchers were able to conclude that the allelic variation at that locus plays a ‘functional’ role in the regulation and expression of Novelty Seeking. These studies were a demonstration of the ability to find association between specific alleles and higher-order traits. Since 1996 the aggregate findings from numerous replication studies have shown that the DRD4 polymorphism accounts for no more than 10% of the variance in overall Novelty Seeking scores. This is to be expected because Novelty Seeking is by definition a complex trait and influenced by the expression of numerous genes, each of which accounts for a small portion of the variance in the observed trait. This is consistent with a componential and emergent view of creativity.

Developmental Trajectories

Much can be surmised about the influence of nature and nurture on creativity by investigating the developmental trajectories of individuals varying in creativity. This can be done in two ways: Prospectively or retrospectively. Lewis Terman’s *Genetic Studies of Genius* (1925–1959) represents a towering achievement of the former variety. Terman was interested in determining whether children who score high on tests of IQ will turn into successful adults by registering extraordinary accomplishments. He carried this out by following children who had scored high on psychometric tests of IQ over their lifetime, and was able to show that there is a positive correlation between high scores on tests of IQ in childhood and genius in adulthood. In other words, achieving eminence is at least partly a positive function of high intelligence in childhood.

The second volume of Terman’s series was written by Catherine M. Cox and published in 1926. Cox argued that to

understand the development of genius, it is critical to understand three factors: heredity, native gifts (i.e., endowment and/or talent), and education. Whereas Galton's work had focused on the role of heredity in the expression of genius, hers would focus on the role of native endowment, which follows logically from considerations of heredity. Furthermore, an understanding of the role of native endowment must precede studies on the effect of education on the gifted person. She also adopted a retrospective, historiometric approach to her investigation. Specifically, she started out by selecting eminent individuals, and then calculated their childhood IQ based on recorded biographical data about early intellectual development. Eminence was computed using the amount of space devoted to each individual in standard reference works. If Terman were correct in hypothesizing that high IQ leads to genius, then the reverse analytic path should lead to the same conclusion by showing higher IQ estimates for individuals who have been recognized as eminent. Indeed, Cox was able to show a positive correlation between the two variables. In other words, prospective (psychometric) and retrospective (historiometric) approaches converged on the same conclusion that early endowment in childhood begets genius in adulthood.

Unbeknownst to many, Cox had also collected mental and physical health data from her 282 geniuses which were never presented in raw form in any publication. Following a lengthy archival search Simonton and Anna V. Song were able to locate Cox's raw physical and mental health data. This made it possible to test some brand new hypotheses using this invaluable dataset. First, how do early physical and mental health relate to intelligence? Specifically, should all three variables be positively correlated? Second, should early physical and mental health predict later eminence the way IQ predicts later eminence? Third, how will the domain under investigation affect the relationship between early physical and mental health and later eminence? The results were intriguing. First, early physical and mental health were related to intelligence, but in opposite ways: IQ was a positive function of mental health but a negative function of physical health. Second, early physical and mental health did not predict later eminence, although, as expected, eminence was a positive function of IQ. Finally, commanders exhibited superior physical health and informative writers inferior physical health compared to the average, whereas politicians and composers displayed superior mental health and imaginative writers inferior mental health compared to the average.

What do these results mean? First, let us focus on the finding that among geniuses IQ was not correlated positively with physical health. This may strike some readers as odd because IQ and physical health are correlated positively in the general population.

Simonton and Song suggest that one reason for this discrepancy may be that genius may be the product of abnormal social and intellectual development. For example, there is evidence to suggest that the early development of geniuses is marred with disrupting events such as economic instability and stigmatization. If so, then poor physical health may contribute to the emergence of genius as a causal factor. Second, neither physical nor mental health predicted eminence, although IQ was a function of physical and mental health. This suggests that the effects of physical and mental health on eminence were mediated indirectly through their effects on IQ. Finally, even among a group as distinct as eminent persons, the influence of physical and mental health varied widely as a

function of domain. This indicates that to understand the effects of physical and mental health on high-level creativity one requires an appreciation for variability among domains.

Summary

I have presented results from behavior genetics and molecular genetics to support the argument that creativity – especially high-level creativity in the form of genius – is influenced by genetic factors. However, eminence does *not* run in families. Because creativity is an emergent trait, it is extremely unlikely that two members of the same family will possess all the necessary components for the expression of this trait.

Furthermore, as argued by Cox, understanding the developmental trajectory of genius requires an understanding of the roles of heredity, native gifts (i.e., talent), and education in the process. Educational interventions to boost creativity will have limited success unless two requirements are met. First, we must develop a better understanding of the ways in which talent facilitates training and performance in order to pinpoint critical intervention opportunities. This lies at the heart of Colin Martindale's observation that creativity appears easy to teach but hard to learn. Knowing the differential effects of factors that affect training and performance can also aid in our choice of training methods. Second, we must develop a better understanding of the ways in which genetic and environmental contributions to creativity differ as a function of domain. Given that different domains (e.g., mathematics, literature, etc.) rely differentially on certain abilities (e.g., spatial navigation, verbal reasoning, etc.), educational interventions to boost creativity must be tailored to the specific domains under consideration. An appreciation of the respective roles of heredity, native gifts, and education in fostering creativity will also diminish the reluctance in perceiving the rightful role of genetics in expressing creativity.

Glossary

Actors Name given to nodes that represent individuals.

Alters Individuals to whom an actor is connected.

Network Pattern of connections among a set of nodes.

Node Entities that are connected or not connected in a network.

Tie Relationship between individuals represented as a line between nodes in a social network graph.

Networking

Networks and Networking

When first thinking of networking, one may envision the savvy job seeker who puts him- or herself in the position to meet as many people as possible – people who may lead to a job. This savvy sort introduces him- or herself to strangers, collects the names and numbers of his or her new contacts, and reaches out to his or her contacts at the appropriate intervals – all with the understanding that these ‘networking’ activities may one day lead to something advantageous, such as a job.

However, social scientists who study networks have focused less on the process of collecting names or amassing relationships at social gatherings or job fairs and more on understanding the network. In this sense, we can think of a network as a map, which displays patterns of connections among individuals. These maps are intended to capture the various social realities that individuals experience. Although not always the case, the emphasis tends to be more on general patterns of interactions rather than snap shot interactions that are not reflective of general tendencies. While instrumental outcomes such as finding a job and career advancement have received attention, networks also can affect cognition and ultimately creativity.

Social Networks Versus Other Types of Networks

If we think of networks as maps, which display patterns of connections, we can envision a variety of networks. For example, cognitive networks are networks which display ideas or concepts and the connections represent how an individual thinks about the association between ideas. We also can visualize connections between organizations. Researchers in business strategy and sociology are often interested in networks among organizations. Such interorganizational networks may represent alliances or formal partnerships between firms. These types of networks, cognitive or interorganizational networks, will not be discussed in this article.

Social networks are networks involving relationships between people. In this case, the connections are relationships or affiliations. It is these types of networks, social networks, which are the focus of this article. This is because more research evidence exists about how social networks rather than other networks influence the creativity of individuals. The focus of this article is also on organizationally based creativity, so the

emphasis is on understanding approaches to social networks that have implications for organizational contexts, although the general principles can be applied to many other contexts as well.

Various Approaches to Understanding Social Networks

Social networks are made up of nodes, ties, and the pattern between ties and can be defined as the pattern of ties among nodes. Looking at [Figure 1](#), the nodes are represented by numbers. Although nodes can be any entity, like individuals, groups, or organizations, individual nodes are widely studied and are often referred to as actors. In network terminology, ties are the connections between nodes, which are displayed in [Figure 1](#) by the straight solid lines. In discussing actors, one may refer to actors in general or distinguish alters from actors. An alter is the individual to whom an actor is connected. For example, if discussing actor 186 (circled with a dashed line), 194 and 192 are 186’s alters. From an actor’s vantage point, ties are either direct or indirect. Direct ties connect two actors, like actor 186 and 194. Indirect ties provide one actor access to another rather than directly through another actor. Focusing again on actor 186, this actor has an indirect tie to actor 109 through actor 93.

The Network Tie

One prominent approach to studying networks is to focus on the characteristics of the relationship or affiliation between actors. One way of thinking about relationships or ties is to characterize them as either weak or strong. Although the strength of ties exists along a continuum from weak to strong, for ease of understanding, we can consider ties as either weak or strong.

Mark Granovetter, in his seminal strength of weak tie theory, defined stronger ties as a combination of frequency of interaction, emotional intensity, and reciprocity. In other words, strong ties are those between actors who interact relatively frequently, have a close relationship – for example, the two consider themselves to be close friends, and have a similar view of the importance of their relationship. Weaker ties in contrast may involve one of these components or low levels of all. For example, perhaps two individuals interact on a regular basis at work, but they do not interact socially outside of work

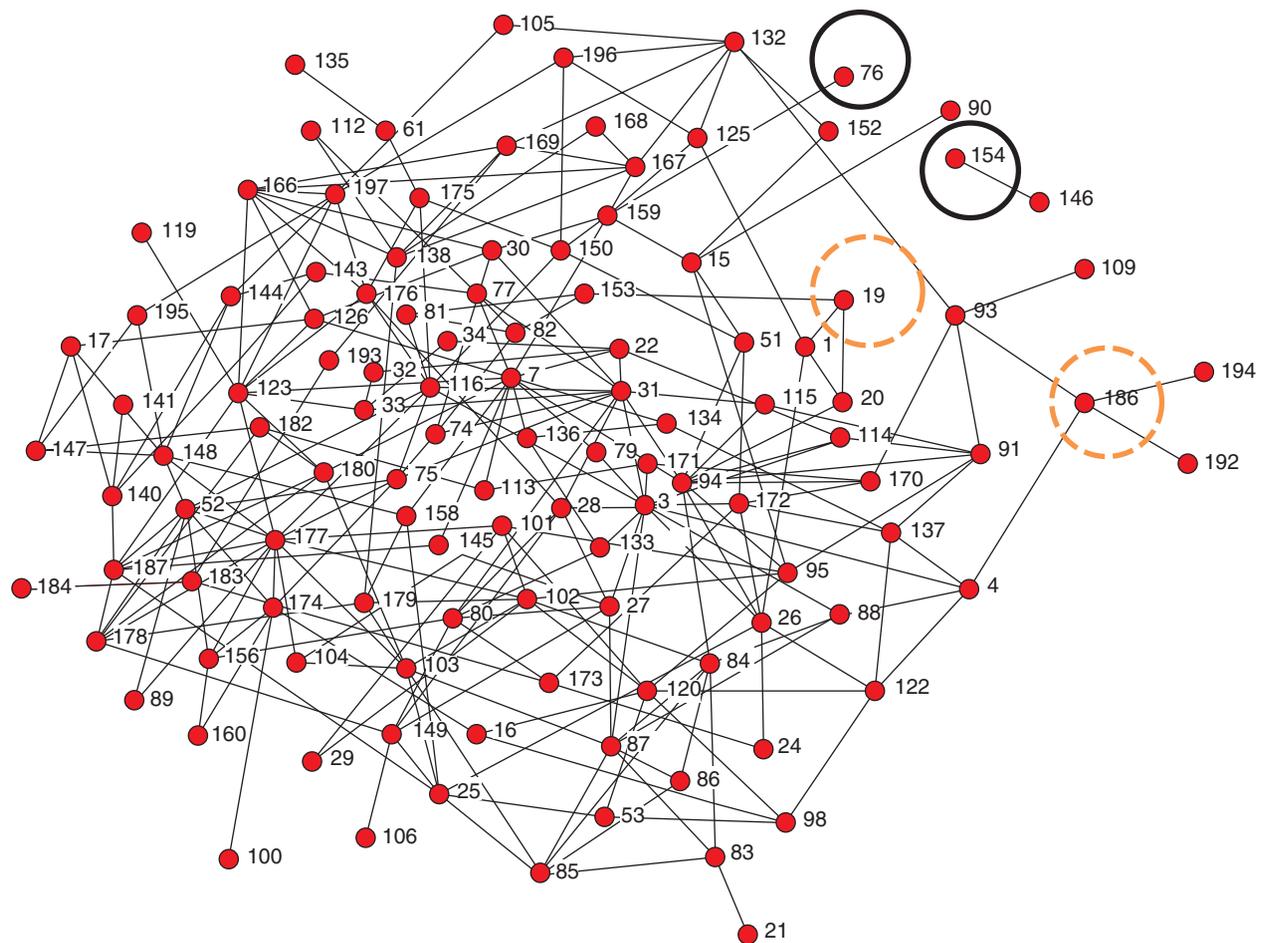

Figure 1 Sample social network.

nor do they provide emotional support to one another. At the extreme end of weakness, individuals may interact only occasionally and also may not exchange any nonwork intangibles like trust or emotional support. These are sometimes referred to as acquaintance ties.

According to the strength of weak tie theory, weak ties are beneficial despite the intuitive benefits of stronger ties. Stronger ties tend to represent close friendships and close friends tend to be similar in some way. Perhaps these friends have similar personalities, similar life styles, or personal beliefs. This is because we are often attracted to people who are similar and form close bonds with them more quickly. As a result, our friends also are likely to be similar to one another. Given that we spend a lot of time with our friends, they will come to know one another over time. The implication of this is that our friends (i.e., stronger ties) are friends of one another. This results in dense pockets of ties where everyone knows one another. Through repeat interaction – both with the actor and each other – and due to similarity, our friends tend to provide the same information and perspectives. In some cases, strongly tied contacts may not initially share the same view, but as friends discuss problems and issues together, their opinions converge over time.

In contrast, weaker ties are more likely to provide access to distinct, rather than overlapping, social circles. These ties are

less dependent on similarity and do not require a lot of time to maintain. So, our acquaintances do not necessarily know one another, so dense overlapping pockets of ties are less likely to form. As a result, these ties are expected to provide greater reach throughout the network. For example, the best way to spread a rumor is through weaker ties whereas a rumor spread through stronger ties is expected to cycle back to the originator.

A widely discussed outcome of weak ties is access to job opportunities. Weak ties are more strongly associated with finding a job than stronger ties, although not in all cases. For example, for some lower status individuals, fewer strong connections to a high status actor may be more helpful.

The emphasis on weak ties is not meant to suggest that strong ties are not beneficial. Strong ties are associated with positive feelings that go along with friendship and a greater sense of obligation to one another. As a result, an actor has a great deal of influence over his or her strong ties in comparison to his or her weak ties. Strongly tied contacts provide social support and encouragement, which are often valuable social resources.

The Node

Another approach to studying and understanding social networks is to focus on the characteristics of the nodes in

the network. Nan Lin and his colleagues emphasize the resources that an actor can access through his or her alters. More specifically, their social resource theory posits the advantages of a network tie to another are the resources that the alter has that the focal actor can utilize. Here, the emphasis is less on the characteristics of the tie, like is it a strong or weak tie, but rather the characteristics of the person (i.e., alter) on the other end of the tie. Nan Lin and colleagues emphasize social resources, which are the personal characteristics of an actor's contacts. They are social in the sense that they are accessed through a social connection.

Although the outcome of interest (e.g., creativity, general performance, career advancement) determines the characteristics that are the most relevant, this perspective emphasizes the status of the contact as one relevant characteristic. For example, when it comes to finding a job, the extent an actor is connected to high status alters within a firm may be instrumental. For career outcomes such as receiving promotions or raises, status of the alter in terms of level within the hierarchy or occupational prestige may be key.

The Network Type

Another way of understanding social networks is to categorize networks in terms of the content that flows through the network tie. With this approach, networks have been studied as patterns of ties that reflect the same content. For example, one may seek to understand the advice network. In this case, members of an organization, for example, are asked to indicate everyone from whom they seek advice. Given the member responses, a network map is drawn that reflects the pattern of advice ties within the organization. Researchers have studied the effects of having more or less advice ties as well as how an individual's overall position in the advice network affects behavior or experiences.

Other kinds of networks studied include various types of support. For example, individuals may be asked to name the individuals that they seek for encouragement. Alternatively, political support may be the focus, where individuals are asked to name individuals they go to with a difficult political problem. Affiliation networks are made up of ties that represent the extent individuals associate with one another, for example on project teams. Another type of network is the workflow network, where ties represent associations required to complete work tasks. For example, perhaps an employee interacts with her boss to get new assignments or to report progress; however, the employee does not seek informal advice from the boss on how to solve a problem or does not turn to the boss for support. This type of tie would comprise the workflow network versus other types of networks which are made up of discretionary ties that are not required to complete work tasks.

It is important to note that for conceptual and methodological clarity, these different types of networks are often considered as distinct networks. However, it makes sense that an individual may have multiple types of ties with the same alter. Multiplex networks or ties exist when an individual has ties with another that simultaneously reflect multiple types of networks. For example, a tie may connect to an individual who is a source of work related advice but also is a close friend.

Network Structure

Given a particular type of network or tie, a structural approach can be considered. A structural approach highlights that while two individuals may have the same number of a particular type of tie, they may experience the social context differently depending on the structure of their ties and their place in the overall network. Consider [Figure 1](#) again. Person 154 and person 76 (both circled with a solid line) have the same number of relationships; however, person 154's alter is an isolate, with no ties other than the tie to 146. In contrast, person 76's alter appears to be well connected to others within the network. As another example, consider person 19 (circled with a dashed line) in the same figure. Person 19 has two alters who also are connected to one another. In contrast, person 186 (circled with a dashed line) also has two alters (1 and 20), but they are not connected. These examples illustrate that it is not only the number of ties a person has, but the structure of ties can lead to very different social realities.

Structural holes

According to Ronald Burt in his seminal theory of structural holes, structural holes exist when an actor's connections to two other actors are not redundant, or more specifically, exist when an individual's contacts are not connected to one another. Consider [Figure 2\(a\)](#) as a simplified example of a social network. Actor A is connected to actor B and C; actor B and C also are connected to each other. In [Figure 2\(b\)](#), actor A is connected to actor B and C, but in this case, actor B and C are not connected to each other. Thus, there is a structural hole between actor B and C. Actor A's connection to B and C are not redundant. In other words, the only way for actor B to reach actor C is through actor A. Thus, actor A's ties, in the case of [Figure 2\(b\)](#) are said to bridge a structural hole and provide unique access to B and C. In contrast, in [Figure 2\(a\)](#) actor A's ties to B or C are considered redundant, because actor A could access actor C either directly or indirectly through actor B.

Structural hole theory suggests a variety of career advancement benefits for individuals who have direct ties that span structural holes. Such individuals (Actor A in [Figure 2b](#)), also referred to as brokers, can control the flow of resources amongst their contacts or may play their disconnected contacts off one another. For example, the only way that a broker's contacts can get information from another one of the broker's contacts is through the broker. As a result, the broker can decide to share or not share information according to his or her needs. This also means that the broker is uniquely positioned to freely take advantage of information from one of her contacts without another contact acting on the information, since they can only hear about the information or opportunity

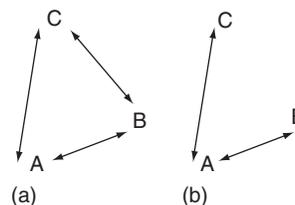

Figure 2 Example of a structural hole.

through the broker who may choose to withhold the information about the opportunity. Alternatively, the broker may selectively share knowledge from one contact with another by highlighting parts of the information that advantage the broker or framing it in a way that advantages the broker.

As a result of control, visibility, and access to information, bridging structural holes are associated with higher salaries, increased rate of promotion, and higher professional mobility. Although research on structural holes has primarily highlighted their advantages, some disadvantages also have been raised, such as stress and conflict.

Network closure

A second and contrasting structural approach highlights the advantages of redundancy or closure among contacts. James Coleman takes more of a systems view and describes the advantages to the network or community of closure. Figure 2(a) represents closure. In particular, closure ensures strong social norms, which may help enforce appropriate versus inappropriate behavior. As an example, in a team of three, we would expect social norms to be stronger and more consistently modeled if closure exists among the ties. If actor C in Figure 2(a) deviates from norms or expectations, actor C will hear about his or her transgression from two sources, actor A and B. A and B may discuss the incident with each other, which makes it more likely that they will approach C with a consistent message. Further, trust and reciprocity flow more freely when closure exists. Thus, if individuals need to work collaboratively with one another, closure may be particularly helpful.

Note that notions of structural holes and closure can be combined. For example, we may envision brokers connecting pockets of closure within an overall network.

Network centrality

A third structural approach is to focus on the position of a node in terms of how central she is in the network. Centrality captures an individual's position in the network relative to others and considers the distance (in terms of direct and indirect network ties) between an individual and all other actors. Central actors can reach the greatest number of actors with the fewest links (or ties). While there are a variety of mathematical formulas used to calculate centrality, conceptually we can understand centrality by looking at Figure 3. Actor C occupies

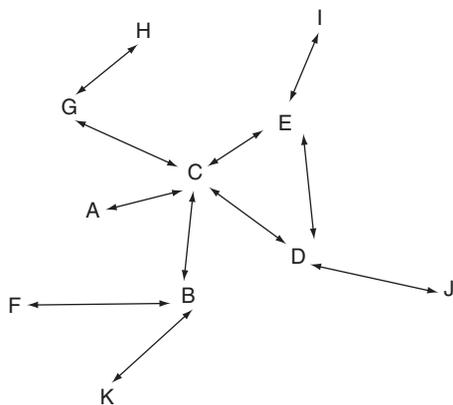

Figure 3 Example of centrality.

a highly central network position relative to actor J who is on the periphery. This approach to centrality, also known as closeness centrality, is a global network measure, because it relies on the entire network rather than only direct ties.

One of the key research findings related to centrality is that central actors have a greater degree of power and influence relative to their less central counterparts. They also experience a greater degree of control over resources due to their central vantage point. When actors with similar levels of centrality are compared, there is some suggestion that actors in similar positions share the same attitudes and perspectives. For example, central actors may have a more favorable evaluation of their work environment than less central actors. Overall, the central actor appears to perform better at work.

The Focus or Target (Three Levels of Analysis)

Given a social network among individuals, there are three different levels of interest: the individual embedded in the network; a group of individuals with a focus on the network among team members or the group embedded in a broader network; and the overall network of individuals itself compared to other overall networks.

The Individual

An individual focus highlights how individual network positions, types of ties, or characteristics of contacts influence behavior. One approach is to understand the network from the individual actor's vantage point, also known as an ego network. Only the actor's direct ties are considered. This may include a count of certain kinds of ties. Focusing on the number of weak ties or the number of advice ties are a few examples. An ego network approach also can include network structure. This may include the structural holes (see earlier section) an actor experiences among her direct ties or the level of redundancy among direct ties.

An alternative approach is to view the individual as being embedded in a broader social network. With this approach, the type of network becomes very important. In other words, the effect of network position on individual emotions, attitudes, or behavior may vary depending on the type of network being considered. For example, centrality within the friendship network versus the workflow network may differentially affect individuals. This approach is a more global approach to networks in contrast to the ego network approach, because the entire network is being considered (see the previous section on 'Network centrality').

The Group

For a small workgroup, either the structure of ties among group members or the strength of ties among group members may be considered. Early research by Marvin Shaw highlighted different patterns of communication among group members. Figure 4 provides two examples from this line of work which emphasizes the importance of understanding patterns of communication flows within groups.

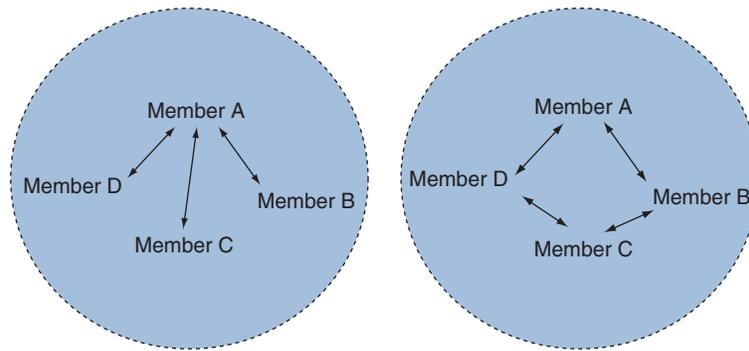

Figure 4 Social network within a team.

Density is often of interest when understanding relationship patterns within the group. Density is the total ties divided by the total possible ties. In some cases, friendship ties may be of interest. In this case, density reflects the level of closeness among group members. Researchers continue to investigate the effects of density on various group outcomes. Generally, Coleman's notion of closure (see earlier section) suggests that redundant trust laden ties help groups perform better; however, the conditions under which this is true continue to be investigated.

An alternative approach to understanding workgroups and networks is to consider groups as nodes. In this case, one may explore how relationships between groups affect either the performance of groups or the performance of a collection of groups. Research confirms the importance of ties between groups for various dimensions of group performance. As discussed previously, the effects depend on the type of tie and the type of network.

The Overall Network

An alternative is to define a network by its boundary and then assess how global structural characteristics of the network affect the performance of the overall network or the performance of individuals within it. This is much more of a cross level approach in comparison to the individual approach discussed previously. In this case, the boundary of the network becomes important. The boundary may be drawn so that the network reflects the pattern of relationships among individual in an organization, industry or even a particular geographical region.

Several structural approaches are relevant to the entire network. At the network level, centralization refers to the extent centrality is clustered among a few individuals versus the extent centrality is evenly distributed among actors. Alternatively, one may explore the level of dense sub groupings within a network, also known as cliques. Some networks have a number of fairly isolated groups of densely connected actors (i.e., clusters of actors where every actor is connected to every other actor). In some cases, these social pockets may have one or two connections to other social pockets.

A limited amount of research exists comparing overall network structures. Gathering data that allows for these comparisons and the effects on individuals is complex. For example, one may be able to collect data from a few professions but

gathering enough professions to make statistically sound inferences would be more difficult. Nevertheless, the concepts are available to allow for comparisons across bounded networks and the theoretical principles can be applied to the network level as well.

How Networks Affect Creativity

When we think about highly creative people, we may think about intriguing or even quirky aspects of their personality, and a rich body of work explores these traits. In contrast to a personality or intraindividual approach, a social network view of creativity is more about understanding how social experiences affect cognition and knowledge in ways that facilitate or constrain creativity. This approach is consistent with contextual views of creativity, which focus on factors external to the individual. With a social network perspective, the spotlight is less on creative types and more on creativity enhancing social situations.

Creativity has been defined as the generation of novel and useful ideas and solutions. Thus, the focus is on how various social network parameters influence the generation of ideas. The emphasis is less on simply transferring ideas from a friend or associate but more about how social experiences influence the way one thinks about problems and forms solutions to those problems. In this section, the node is assumed to be the individual and the target of interest also is the individual. The focus is on the network tie and network centrality perspectives within a communication network.

Weak Ties

Recall that strong ties are more likely to connect individuals who are similar on some dimension, and since we spend more time with our friends than acquaintances, it is likely that our friends interact with one another while interacting with us. Friends also can influence one another, and given that our friends are often friends, social influence pressures can be strong. In contrast, the weaker tie is more likely to connect individuals who differ and represent diverse social circles. As a result, weak ties provide exposure to nonredundant information, perspectives, and ideas.

There are a variety of implications for creativity. If we consider a network of individuals within a profession, such as computer scientists, lawyers, or behavioral research scientists

for example, individuals with weak ties will receive nonredundant information from their contacts which should enhance their knowledge base. Creativity theorists have long described how knowledge provides individuals greater capacity to make unusual connections. Domain relevant knowledge provides an important foundation that individuals can draw from when thinking of creative ideas. Interestingly, however, there is some debate about whether or not detailed complex knowledge or broad exposure is best for enhancing creativity. One perspective is that breadth in terms of general information or broad exposure to different perspectives enhances the type of knowledge that facilitates creative contributions at work. This is the type of information most likely to be gleaned from weaker ties, because complex knowledge or sensitive information is more likely to require the trust of stronger ties.

In addition, weaker ties are expected to enhance creative cognition in comparison to strong ties. As individuals are exposed to a variety of perspectives through a number of weak ties, they have more opportunities to make associations between different viewpoints and become more practiced at thinking broadly. Having a number of weaker ties puts more requirements on the focal actor to reconcile these perspectives and think autonomously in comparison to actors with stronger ties. With stronger ties, because of redundancies and social influence processes, individuals become less required to synthesize due to the greater similarity of perspectives associated with stronger ties. Furthermore, conformity tendencies are greater, which can limit creativity.

Strong ties are not universally bad for creativity. In particular, the social support and positive affect associated with friendships may be helpful for creativity. It makes sense that one may be more comfortable sharing creative, and potentially odd or unusual ideas, with a trusted friend. As a result, one line of argumentation is that these ties may help with the implementation of new ideas and may help an actor gain support for his or her idea. However, when it comes to the generation of creative ideas, rather than their implementation, strong ties may not be helpful and actually may undermine creativity.

Centrality

Central individuals have direct or indirect access to most others in the network. They are aware of what is going on in the network or can be made aware of what is going on if they choose. They also are assumed to be highly powerful and able to influence others to adopt their views. As a result, they have a generally favorable view of organizational life and may be more comfortable taking calculated risks than their less central counterparts. This should enhance creativity in some cases as these individuals are more comfortable exploring creative ideas.

Although research in this area is relatively new, there are several suggested conditions under which centrality is most likely to enhance creative contributions at work. One such condition is the extent a person has connections outside of the network. Central individuals in the network are expected to be highly creative but whether or not they are creative depends on the network ties that they have outside of the network. Typically, in order to study networks, the network must be bound in some meaningful way. The boundary may be drawn to denote those within the network as members of an

organization, employees of a firm, or members of a profession. This type of demarcation can help us understand a variety of features of networks beyond direct ties and the characteristics of these ties. However, if we consider the boundary as a loose circle around a social entity, the reality is that members of that organization, firm or profession have network ties to individuals outside of the network. If we consider ties outside of the network, the expected effect of centrality within the network on creativity may differ.

Let us reconsider the arguments about centrality and creativity. If central individuals are expected to be creative, the converse of this expectation is that peripheral individuals will not be creative. However, if the person is on the periphery of the organization's network but has lots of ties outside of the network, she actually may be highly creative. Here is why. She also is exposed to perspectives outside of her reference group, which is comprised of others within the organization. Relative to her peers with fewer outside ties, this person is influenced by approaches that may not be standard within her organization. In addition, when this person is simultaneously on the periphery of the network, she may not as strongly identify with the organization or the organization's widely accepted practices. Thus, it is easier for this person to question practices and explore new ideas from other domains. As a result, an individual on the periphery of a network but with many ties outside of the network will be highly creative.

Interestingly, we can understand a person's creative life cycle in terms of her movement from the periphery of a network to the center. For example, a newcomer to an organization may occupy a peripheral position at first, but she brings with her a variety of connections and associations outside of the network. For the new graduate, this may include fellow graduates or professors. For the more senior hire, this may include professional peers from other organizations in similar or different industries. This person has the potential to be highly creative. If creativity is valued, as it is in many organizations, others within the organization will be drawn to this creative person. As he or she offers new ideas to solve problems or receives recognition for creative insights, he or she is sought out for advice and guidance. As a result of prior creativity, he or she becomes more central in the network. His or her centrality and increasing comfort with taking risks suggests that he or she becomes incrementally more creative.

The cycle continues where centrality enhances creativity and creativity leads to more centrality until a point of diminishing returns. As he or she becomes too central, the network begins to constrain her creativity. It becomes increasingly difficult to see beyond the *status quo*, as he or she is so immersed in the web of relationships that seeing beyond existing ways and standard solutions becomes increasingly difficult. Ultimately, centrality begins to constrain creativity as the relationship between centrality and creativity has been defined as an inverted U relationships. Centrality is helpful to a point, but then undermines creativity.

How Networks Affect the Implementation of Creative Ideas

When it comes to generating ideas, it is expected that weaker ties and centrality under certain conditions will help people be

more creative. The next step in the process of realizing creativity is to get others to accept the idea and to get others to help implement the idea, particularly within organizations. The understanding of how this works continues to grow and evolve, but there are some generalizations that are becoming clearer and others that are less clear.

Central actors are in a better position to get their ideas accepted. Interestingly, it is the peripheral actor with ties outside of the network that is expected to come up with groundbreaking new ideas, but it is the central actor who is more likely to convince others that her idea is worthwhile. In one study of the Hollywood film industry, Gino Cattani and Simone Ferriani found that key members of film crews with intermediate central positions were more often nominated for creativity based awards by peers and other experts. These individuals had the requisite level of centrality that allowed them to be creative, without stifling their new ideas, but also gave them a degree of influence and connectedness to get others to accept their ideas. In addition, peripheral individuals who associate with a few key central actors may maximize the benefits of both high and low centrality. They may come up with highly creative insights and gain support from their central associates, who can more effectively champion the idea.

While weak ties facilitate generating creative ideas and structural holes are associated with good ideas, closure may help with implementation. Studies by David Obstfeld suggest that redundant ties are helpful because in order to implement a creative idea, it is necessary to bring people together to work cooperatively to advance an idea. In addition, the generator of a creative idea must influence others that the idea is worthwhile. This can be very difficult with creative ideas given that the idea represents something that has never been implemented or at least has been implemented very rarely. However, in a study of an electronics company, Ron Burt found that brokerage rather than closure was associated with organizational members rating the actor's ideas as valuable. One explanation is that individuals with ties that span structural holes are better able to communicate ideas so that various groups will understand the idea's merits.

Conclusions

The social context provides an important means of understanding creativity. Understanding social networks is more complicated than understanding the extent a person gathers names or charms others at a social gathering. A social network lens is way of understanding a person's ongoing social context.

These social contexts vary greatly. As an example, one person may have many friends but may not be very central in the network. Another may not have many friends but may be connected to a highly central person. In contrast, two people may have the same number of contacts, but one person's contacts are also friends whereas the other person's contacts do not interact at all. By considering various social network configurations, we gain knowledge about the extent a person's social context facilitates or constrains creative thinking. Two important ways that networks matter are by providing access to non-redundant knowledge and enhancing creative cognition. Ultimately, creative ideas can be either inspired and nurtured or thwarted and stifled depending on a person's social network context.

Glossary

Constraints Tools for increasing novelty. Constraints come in pairs. One of the pair precludes a reliable, predictable response while the other promotes an atypical, unexpected one.

Domain An area of knowledge or expertise.

Ill-structured problem A problem in which all the parts are not specified. Novelty is only possible in ill-structured problems.

Novelty A kind of variability involving responses that are new and useful (innovative), unusual (original), or domain-changing (creative).

Problem space How a problem is represented by a solver. The space has three parts: an initial state, a goal state, and a search space in which a solution path is constructed. Constraints increment novelty by re-structuring problem spaces.

Variability A measure of how differently something is done. Moderately high variability is associated with novelty; higher variability, with domain-changing creativity.

Well-structured problem A problem in which all the parts are specified. Novelty is not possible in well-structured problems.

Novelty is necessary but not sufficient for a response to be considered creative. Nonetheless, given that the criteria for sufficiency (usefulness, influence, etc.) are many and shifting, novelty may be the optimal object for manipulation and measurement. This article considers how paired constraints preclude low variability, high probability responses, and promote novel ones.

Novelty, Variability Levels, and Learning

Variability can be conceived as a scale, a continuum with minimal and maximal degrees of difference in how something is done. **Figure 1** presents one version of such a scale.

Responses closer to the minimal end of the continuum are predictable because they tend to be performed in remarkably similar ways. They increase in variability from stereotyped (invariant) to reliable (habitual) to expert (variation within a domain-determined range). Responses closer to the maximal end are less predictable because they are, by definition, quite different. Novelty is in this range because new responses appear after more likely ones have been exhausted. The remaining categories include responding that is novel and also useful (innovative), unusual (original), or, at the highest level, influential (creative).

Influential or domain-changing novelty is rare because it substitutes a novel set of criteria and procedures for satisfying the criteria for another, already accepted set. Once the new criteria/procedures are incorporated into the domain and adopted by others (i.e., what influence means), they drop back to a lower variability category.

Learned Variability Levels

Importantly, learned or habitual variability levels (how differently one usually performs or applies a skill) are domain-specific and learned/acquired early in skill acquisition. High levels ensue when training tasks require and reward doing something in

multiple ways. This kind of regime can be thought of as difficult-but-doable; accelerated training is another, in which rapid acquisition of different skill components precludes repetition and promotes variation.

Novelty, Problem-Solving, and Constraints

A counter-intuitive (i.e., counter to common usage) strategy for increasing novelty involves imposing constraints, plural and paired. Since the pairing is a convention from problem-solving, our discussion starts with problem spaces.

Problem Spaces

A problem space is how an objective problem is represented (subjectively) by a potential solver. Experts and novices differ considerably in this: the expert's representation is both more elaborate and more efficient. In both cases, however, the parts of the space are the same. These are an initial state, a goal state, and between the two, a search space in which to construct a solution path. Paired constraints guide this search. In a well-structured or well-defined problem, all parts of the space are given. Think about a paint-by-number canvas, cartooned and numbered to indicate the color of the appropriate paint. This kind of problem precludes novelty. Novelty requires an ill-structured or ill-defined problem, in which not all the parts are specified. Given a blank canvas, novelty is possible.

Constraints

In problem-solving, constraints come in pairs. One precludes/limits search in some parts of the search space; the other promotes/directs search in other parts. Solution involves substitution: the more specific the pairings, the more efficient the solution process. As shown in **Table 1**, there are four constraint categories: goal, source, subject, and task.

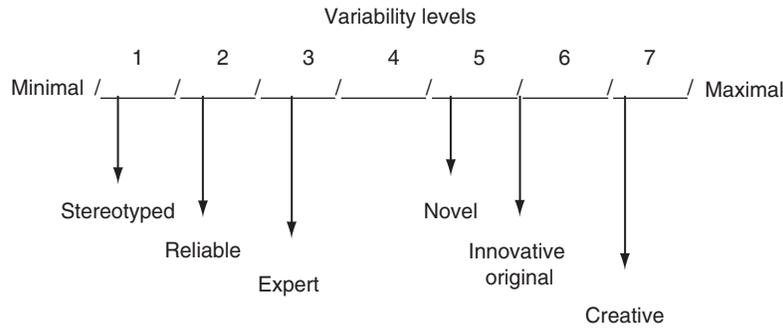

Figure 1 Variability continuum.

Table 1 Constraint categories

Category	Pairings
Goal	Preclude an existing style/solution → Promote a novel style/solution
Source	Preclude (work against) specific elements → Promote (work with) others
Subject	Preclude particular themes/motifs → Promote others (often opposites)
Task	Preclude traditional materials and manipulations → Promote alternative materials and applications

Goal constraints preclude an existing solution (the initial state) and promote an alternative (the goal state). Source constraints are elements available for selection and rejection, recombination, and restructuring. Larry Rivers, who was both a painter and a jazz musician called these constraints ‘first choruses,’ material on which the artist/performer improvises. I see them as providing both what you work with (promote) and what you work against (preclude). In some ways, choosing what to work against is the more critical. Subject constraints involve content or motif; task constraints, materials and how they are used. The goal constraint influences every other constraint. Source and subject constraints influence task constraints. Task constraints cascade, one influencing/generating another.

Novelty Problems

There are two kinds of novelty problems. One, the Domain-Specific Novelty Problem, is (in the case of experts) initiated by its solver. The other, the Generic Novelty Problem, is initiated by an outsider, typically a researcher investigating the conditions that facilitate novelty.

In a Domain-Specific Novelty Problem, the goal is a new style (or a variation on an existing style); the solution path is a set of procedures that define and realize the new style. In a Generic Novelty Problem, the goal is more general: variability of a particular degree and kind. Both problem types are solved incrementally via a series of substitutions. The substitutions are strategic (i.e., guided by the goal) and involve the selection of paired constraints. These constraints restructure the problem space by precluding repetitive, reliable responses and promoting surprising, often opposite substitutes.

Generic Novelty Problems

This section considers general, cross-domain constraints on a number of variability measures, including novelty *per se*.

There are several reasons for this focus. First (as shown in Figure 1), novelty and its progeny (originality, innovation, and creativity) increase when variability increases. Second, highly creative people tend to be highly variable in their areas of expertise (these are the habitual variability levels acquired along with skills). Third, although strict novelty criteria only reward responses that differ from earlier ones, most creativity testing and training measures use variability rather than novelty criteria. For example, the Torrance Tests of Creative Thinking (TTCT) assess aspects of divergent thinking. Fluency measures how many different responses are made; originality, how many unusual responses; elaboration, how much detail accompanies a response. We begin with constraints on novelty *per se*, then on specific kinds of novelty and finally, on variability *per se*.

Novelty per se

Novelty can be required either within or between training sessions. Within means that a response must differ from all responses in a single session; across, that the response differ from responses in all prior sessions as well.

In a famous study, porpoises were rewarded for swimming and leaping in ways that were outside the species’ normal repertoire Novelty was defined across sessions: to earn a fish, a response had to differ from all responses in all sessions. Did the porpoises notice what the fish were for? Yes. As training proceeded, new topographies appeared closer to, and even at, the start of a session. In a study with children, novelty was defined within sessions. Even if a response was seen in a prior session, its initial appearance in a subsequent session was rewarded. The children, like the porpoises, had to notice what kinds of painting or block-building responses were followed by a reward. Did children learn what praise or tokens (convertable into toys) were for? Yes. Reward increased both form diversity (first instance in a session) and novelty *per se* (first instance across sessions).

While both children and porpoises were successful at meeting implicit novelty criteria, this is not always, and not often, the case. The reason is that without explicitly stated criteria, performance reflects an individual's learning history. Since most of us are rewarded for reliable, conventional responding, it is not surprising that reliable, conventional responses occur early and often. (This is the reason why novelty involves high variability. Those reliable responses must be run through first.)

Particular Kinds of Novelty

The studies in this section targeted particular kinds of novelty: originality (unusual responses), innovation (useful responses) and flexibility (number of different response categories). The relevant response criteria were specified (made explicit) for some, but not all, participants.

One study showed that promised reward for completing a drawing task only increased originality when children were given clear instructions that the drawing be unusual, or when they had just been rewarded for coming up with unusual rather than ordinary uses for objects. In the latter case, the context seems to have cued the responding. That is, unusual responses very recently rewarded in, and thus associated with, the current context, included a new (and therefore noticeable) teacher, the experimenter. Another reported interesting mirror-image results. Instructions targeting flexibility increased flexibility but decreased originality. Instructions specifying originality had the opposite effect: originality scores went up, flexibility scores went down. A third series of experiments manipulated choice of inventive categories (subject constraints) and parts (task constraints). The explicit goal was to produce novel, useful objects, by combining the parts. The researchers reasoned that greater choice would promote conventional thinking; thus they predicted that limiting choice would preclude the conventional and promote the novel. This was the case. Compared to conditions where students chose either category (e.g., furniture or toys) or parts for combination (e.g. wheels, handles), the highest originality ratings were given when both category and parts were randomly specified rather than selected.

Variability *per se*

Variability can be measured in several ways. Two are reminiscent of divergent thinking measures: count the number of different responses, calculate the likelihood of a given response (the less likely, the more unusual the response). The second measure is called an uncertainty: the higher the uncertainty, the more unexpected or unusual the response. Several procedures reliably increase variability. Some involve explicit variability criteria; others, implicit criteria.

Explicit criteria

One procedure specifies what are called lags. A lag refers to the number of prior responses from which a current response must differ. For example, a lag of three means that reward only follows a response (or series of responses) that differs from three prior ones. Imagine three-response sequences made on right or left pointing arrow keys: the sequence RRR would be rewarded if it occurred after the sequences RRL, LLL, and LRL,

but not if any triad was repeated (e.g., RRL, RRL, LRL). Lags clearly preclude repetition and promote variation. They have been shown to increase response variability in pigeons, grade school, and college students. Pigeons have met lags up to 50; college students to 25; fifth graders to 10. Another procedure is known as frequency dependent selection. Here, less probable or less frequent responses are momentarily selected for reward. For example, with the same left-right key press pair, as R increases in frequency, reward decreases for R and increases for L. Depending on the relative probabilities specified by the reinforcement schedule, some stable (and more or less variable) alternation pattern will earn maximal reward.

Implicit criteria

Implicit criteria are embedded in all tasks; they differ depending on whether the task is easy or difficult, simple or complicated. An easy or simple task requires little variability: few things need be tried to master it, few to maintain it. Difficult or complicated tasks require higher variability: many things are necessary for mastery and maintenance. Ill-defined problems are, by definition, more difficult than well-defined ones, thus implicitly targeting and selecting higher levels of variability.

Whether variability levels are temporary or habitual depends on when a particular type problem is introduced. As discussed earlier, habitual variability levels – preferred performance ranges – are acquired early in skill acquisition. If easy/simple tasks are encountered then, the levels will be lower than if training involves difficult/complicated tasks. Computer maze games have been used to implicitly select and maintain high or low variability levels. For example, two groups of college students played two versions of a game with easier/simpler or more difficult/complicated sets of constraints. The easy set required exiting the maze at specific locations; the difficult one, exiting at the same locations by paths that differed from some number of prior paths (in other words, lags). As the number of locations decreased (from 3 to 1), the lags increased (from 0 to 5). The more difficult training task (combined locations and lags) generated higher variability both when the training conditions were in effect, and – importantly for this discussion – sustained it long after they were relaxed (i.e., when all paths to all locations earned points).

Domain-Specific Novelty Problems

In Domain-Specific Novelty Problems, the initial state is usually an existing, accepted style or solution type. The more radical goal state is replacement; the less radical, variants of the initial state. The initial and goal states together are the preclude-promote pairs of the goal constraint. This section summarizes two constraints (goal and task) in two domains – architecture and theatre; subject constraints are also included for the latter.

Architecture

Here we focus on one type of architecture (domestic) and one architect (Frank Lloyd Wright). The open, interconnected spaces of Wright's Prairie (palatial) and Usonian (practical) houses were highly influential, prototypes for single-level

ranch house, satellite spaces, and great rooms. As indicated in Table 2, his goal precluded the straight-sided box with its small, separate rooms (initial state), and promoted in its place, a radically new architectural style that he labeled 'organic' (goal state). For Wright, 'organic' was synonymous with 'continuity'. Continuity involved three relationships: between interior and exterior spaces; between interior spaces; between surface and decoration. To accomplish this, he borrowed horizontal elements (overhanging roofs, transoms, open spaces separated by sliding screens) from the traditional Japanese dwelling; balconies and verandas from the South; hearths and porches from the Midwest; simplified, stylized, and importantly – unbroken – surface decoration from his mentor, Louis Sullivan.

The site was critical in that the house conformed to, was an extension of, its topography. Most Wright sites were flat, which accounts for the horizontality of the Prairie and Usonian houses. The most famous exception is Falling Water, with cantilevers that overhang and mimic its waterfall. Critical to realizing a continuous, open plan was the modernness of materials at the time: reinforced concrete solved the problem of support. Multiple interior walls (which necessitated small, box-like rooms) were supplanted by fewer, lighter supports (piers, columns) beyond which Wright's organic, continuous plans could expand. Bridging the final separation (between surface and structure), decoration was derived from form: linear, geometric elements and patterns iterated the shapes of their supports. The house, in Wright's plans, was no longer divided.

Theatre

Commedia dell'Arte, itself a source for Chicago style improvisation (Saturday Night Live), cartoon characters (Donald Duck), and situation comedies (Seinfeld), is old, influential and extant in its original goal and form. As indicated in Table 3, the goal constraint promotes the formal exaggeration of reality, while precluding realism or naturalism. Among its obvious sources are physical comedy (Roman and Greek) and dexterity (street players). Its subject is (nonserious) survival in the face of cascading 'calamity.' The cascade results from comically misguided attempts at solving an initial problem, usually a romantic one.

Novelty in Commedia arises from its form (task constraints). The form is modular: the modules are 'prepared' parts. These parts are limited to a small set of types identified not only by masks, but also by idiosyncratic movements, motives, and lazzi (gags), all of which are well-practiced, that is, prepared. Novelty (spontaneity) is possible precisely because the types are so well-prepared: just as you or I respond to new situations in characteristic, recognizable ways, so do the Old Man, the Lovers, the Zanni (and Donald Duck). Improvisation emerges from the interaction of set types and changing situations.

Summary and Concluding Question

This summary has three parts: the first reiterates the relationships between novelty and variability; the second, the ways in which constraints help solve novelty problems; the third suggests ways to train for novelty. The question concludes the chapter.

Novelty and Variability

Novelty and variability are inseparable, and for a number of reasons. First, previously rewarded responses appear before novel ones, thus variability is high. Second, variability increases with difficulty: adding useful (innovative), unusual (original), or influential (creative) to a newness criterion augments variability. Third, influential creators as well as successful inventors and innovators, are highly variable in the domains of their expertise. This may be attributable to habitually high levels acquired during early, accelerated skill acquisition (a commonality for the gifted and talented). Finally, many novelty measures (fluency, originality, etc.) are actually variability measures. Variability is easily quantified, which makes it feasible to study.

Novelty Problems and Constraints

Novelty problems are ill-structured or incompletely specified. Paired constraints, strategically selected to realize a novel goal,

Table 2 Constraints for Frank Lloyd Wright

Category	Pairings
Goal	Preclude the 'box' → Promote the 'organic' (continuity)
Task	Preclude interior–exterior separation → Promote site-specific elements (cantilevers, strip windows, overhanging roofs, terraces)
	Preclude interior separation → Promote open, interconnected plans (piers, columns, screen walls)
	Preclude surface-structure separation → Promote structure-specific elements (decoration follows form)

Table 3 Constraints for Commedia

Category	Pairings
Goal	Preclude the realistic → Promote formal exaggeration of reality
Subject	Preclude the serious → Promote survival in face of 'calamity'
Task	Preclude prepared scripts → Promote prepared parts (the set types)
	Preclude predetermined outcome → Promote improvisation (interaction of set type and situation)

re-structure the problem space by precluding search among reliable, expected responses and promoting it among risky, surprising ones. The more explicit or more specific the constraints, the more efficient the solution process.

Constraints come in four kinds: goal, source, subject, and task. In Generic Novelty Problems, the goal is simply to augment variability; task constraints communicate the criteria. In Domain-Specific Novelty Problems, the goal is more complex: either to replace an existing solution/style (as in the case of Frank Lloyd Wright) or to continually produce variants of it (as seen in *Commedia*). With complexity, the initial pairing can be critical. For example, George Balanchine's re-structuring of classical ballet (the new style was called neoclassical) started when he precluded steps based on a story and promoted steps based on the score. The change necessitated others, for example, precluding elaborate costumes and promoting pared-down (albeit still elegant) ones. Balanchine was the Chanel of ballet: practice clothes became equivalents of the little black dress.

Training for Novelty

Two suggestions stem from this summary. The first is that skill acquisition should be early and accelerated so that students not only acquire repertoires replete with elements for recombination and restructuring, but also the high habitual variability levels necessary to do so. The second is that the use of constraints should be explicitly taught and practiced. There is no one more aware of constraints and their value than a professional; no one more unaware and averse to them than a novice.

In fact, in many professional schools, including the Pratt Institute (a well-known art, design, and architectural school in New York City), constraints are always in play, but implicitly. In others, like The Julliard School of Music (also well-known and in New York), they are also always in play, but explicitly. The difference stems from the discipline. Musical performance appears to be more constrained than painting or printmaking, but Monet was no less an expert at constraint selection than Stravinsky.

The Question: Is Novelty Undermining Creativity?

The kind of creativity at stake here is the influential sort, the novelty that expands a domain. This has always been rare, but the pressure to be 'new' has long been escalating, and in ways that work against the development of domain-changing creativity. The 'anxiety of influence,' to use Harold Bloom's prescient term, is omnipresent in art and in science. We open a first book of poems, Bloom wrote, expecting a 'distinctive voice,' and if disappointed, close it. We enter an art gallery, expecting a distinctive vision, and if disappointed, dismiss the artist as derivative. We peruse a professional journal, expecting a seminal finding, and if disappointed, dismiss the research as unoriginal, unimportant.

Michael Kimmelman, art critic for the New York Times, put the problem this way: "Novelty is one of the demands we make on living artists. An artist who sticks to a course for any length of time we tend to say has fallen into a rut." How long is "any length of time"? Long enough to develop a truly new point of

view? Would Braque and Picasso be allowed the eight years (1906–1914) they took to develop Cubism? Today, probably not. When the work of an artist (and less so, but only slightly, that of a researcher) has to consistently be new, both gatekeeper (critic, curator, editor) and creator suffer. The gatekeeper forgoes the exposure necessary for comprehension, much less evaluation. Our brains are made to sort information (conceptual and perceptual) into categories. The categories are not Platonic, preexisting. They are built experience by experience into sets with common properties. The truly new fits in no existing category, and requires repeated exposure to build its own. When Impressionism was new, when Abstract Expressionism was new, each was incomprehensible.

The fledgling forgoes more than the field. First to go is the ten-year plus developmental period required before or between real breakthroughs. *Broadway Boogie Woogie* followed ten years of static 'equivalents' to use Mondrian's term, and ten more of dynamic ones. It took Monet 20 years to move from easel-sized, middle-distant views to wall-sized, close-ups of water lilies. This kind of exploratory space is still allowed to well-established painters with highly priced, 'recognizable' styles. The same is true of well-established researchers. Fledglings, in contrast, are judged by how different they are from each other, and how different their current work is from the past, including their own.

Second is the willful (or worse ignorant) precluding of the past, the curbing or checking of critical 'first choruses.' In jazz, the first chorus is what the musician improvises on. In art, the first chorus is what the artist improvises on. Picasso's first choruses included the composition of Valesquez, the mannerism of El Greco, the structures of both Cezanne and anonymous Benin sculptors. In psychology, the first chorus is past research on which the researcher/practitioner improvises. I was fortunate in having Walter Mischel on my dissertation committee: Walter introduced me to the problem-solving literature, in which I 'discovered' the mostly-ignored work of Reitman on constraints. I am surprised at how often studies that were seminal, initiating whole areas of research, are unmentioned in current variants. Also, too often the wheel is reinvented. Perhaps if artists and critics, scientists and editors, were less anxious about influence, *influential novelty* would not be so hard to come by.

GEORGIA O'KEEFFE was a quintessential American painter. Born in the Midwest, she moved to New York City and became a central part of the New York art scene with her husband, the art dealer and photographer Alfred Stieglitz. She then established her home in New Mexico, becoming one of the founding artists in the Southwest art world.

Georgia O'Keeffe at an exhibition of her work "Life and Death." (Copyright UPI /CORBIS/Bettmann.)

The Early Years

On November 15, 1887, Georgia O'Keeffe was the second of seven children and the oldest girl born to Ida Totto O'Keeffe and Francis Calyxus O'Keeffe, owners of a prosperous 640-acre farm in Sun Prairie, Wisconsin. The O'Keeffe family was musical and encouraged creativity; there was a strong interest in reading and her mother promoted education.

Although O'Keeffe preferred her fun-loving father to her stern mother, it was her mother, grandmothers, and unmarried aunts Lola, a school teacher, and Ollie, who worked for a newspaper, who became her role models as capable, assertive, and focused women. Intense drive, independence, and a strong will characterized O'Keeffe since childhood. As she grew older, they formed the strengths necessary to maintain an artistic career, but in childhood they made her appear domineering to her siblings. Referring to a family photograph of the children where O'Keeffe was partly blurred, her sister Catherine, as noted by Robinson, said it was "probably because Georgia was giving orders."

O'Keeffe, who began drawing at an early age, was given art lessons on Saturday afternoons from a woman in Sun Prairie along with her younger sisters. Between lessons, O'Keeffe

would practice at home and by the age of 12 had decided to become a painter. At 13, she was sent to a Dominican Boarding School and then to a public high school in Madison. At both places, O'Keeffe concentrated on art, but it was a high school art teacher who made her aware of the details of nature through examining the structure of a jack-in-the pulpit.

Later, flowers became an important aspect of her iconography. When O'Keeffe was 15, the family moved to Williamsburg, Virginia, and she attended the Chatham Episcopal Institute, whose principal, Elizabeth Willis, was also an art teacher. It was Willis who encouraged O'Keeffe to apply to the Art Institute of Chicago, where in 1905–1906 she studied anatomy with John Vanderpoel. Afterward, she attended the Art Students League from 1907 to 1908, winning a prize in William Merritt Chase's still life class. During this period she began going to the 291 Gallery owned by Alfred Stieglitz (1864–1946) and saw shows by Rodin and Matisse. To help her family with its financial difficulties, O'Keeffe worked as a commercial artist until 1910 when she began a career teaching art in high schools and colleges in Texas and Virginia. During her time as an art teacher, she continued her own education, studying at the University of Virginia with Alon Bement and then from 1914 to 1916 at Columbia Teachers College with Arthur Wesley Dow. At Columbia, O'Keeffe became friends with Anita Pollitzer, a fellow art student, and continued to visit the 291 gallery, seeing shows by Braque and Picasso. When she left New York and returned to teaching art in college, O'Keeffe reviewed her work. Realizing that she needed to break away from her academic training, she decided to eliminate influences from previous teachers and make art she could call her own. Living and teaching first in South Carolina and then in Texas, O'Keeffe abstracted her impressions of nature and began creating works, such as *Special, No. 15* (1916), *Blue Lines* (1916), and the 1917 watercolor series entitled *Evening Star*, in what would become her mature style. O'Keeffe's independence and originality extended to her way of dressing. In a time when women wore ruffles, corsets, and pointed shoes, O'Keeffe wore simple dark garments, no corsets, and men's shoes. Interested in comfort and mobility, she said women's shoes pinched her feet. Looking at photographs of the young O'Keeffe, she appears contemporary, but when her style is compared to other women of her time, the contrast is marked. O'Keeffe also avoided jewelry but later in life wore a brooch with her initials made by the sculptor Alexander Calder.

The New York Years

O'Keeffe had been corresponding with Anita Pollitzer, and sent her friend works of art to critique. In 1916, Pollitzer showed several pieces to Alfred Stieglitz, the photographer and owner of the 291 Gallery. He was extremely impressed and presented O'Keeffe's art in two group shows that year. In 1917, just before closing his gallery, Stieglitz gave her a solo show. When O'Keeffe arrived in June just after the exhibition was taken down, Stieglitz rehung it for her to see. It was at this time that O'Keeffe began to model for Stieglitz. Returning to her teaching job in Texas, O'Keeffe kept up her correspondence with Stieglitz and in June of 1918, at his urging came to New York to paint. Stieglitz moved in with her in the 59th street studio and later that year they vacationed at the Stieglitz family summer home at Lake George. O'Keeffe and Stieglitz, who were married in 1924, made annual trips to Lake George until the 1930s when the family home was sold. It was there that O'Keeffe painted her studio, *My Shanty, Lake George* (1922).

Living together on 59th street, Stieglitz continued photographing O'Keeffe, a process that over the years generated an enormous variety of images. O'Keeffe was shown in different costumes, as facial portraits, as erotic nudes, and as a series of hand portraits. O'Keeffe said her hands had been admired ever since she was a child but 60 years later looking back at the variety of images of herself, she said she wondered who that person was; it seemed to her that in one life she had lived many lives.

O'Keeffe painted intensely and Stieglitz promoted her career, speaking to critics, walking with them through her exhibitions, and explaining the work. She showed at the Anderson Gallery in New York along with other well-known artists of the period such as Arthur Dove, Marsden Hartley, Charles Demuth, John Marin, and Paul Strand. In 1925 Stieglitz opened The Intimate Gallery and in 1930 The American Place Gallery, continuing to exhibit O'Keeffe's work.

In 1925, when O'Keeffe and Stieglitz moved to rooms on the 30th floor of the Shelton Hotel, O'Keeffe was so taken with the view of New York that she began to paint images of skyscrapers and industrial docks. The male artists in the gallery thought women incapable of doing cityscapes, but O'Keeffe, used to competition with her older brother, was also competitive in the gallery. In works such as *East River from the Shelton* (1927–1928) and *Radiator Building—Night New York* (1927) she demonstrated that a woman could successfully paint the City.

It was during this period that she also began exhibiting her large flower series containing works such as *Black Iris III* (1926) and *Two Calla Lilies on Pink* (1928). Although New York was an exciting place, O'Keeffe longed for the countryside; she said "distance has always called me" (Hogrefe, 1992, p. 369). In 1920 O'Keeffe began taking yearly trips to Maine and in 1929 made her first trip to the Southwest.

The Southwest

As a child, O'Keeffe's favorite stories were about the West, and visiting New Mexico was like an experience of coming home. On her second trip there, she sent back a barrel containing bones and fabric flowers, which enabled her to produce

Western themes such as *Cow's Skull: Red, White, and Blue* (1931) and *Summerdays* (1936) when she painted in the East. Eventually O'Keeffe divided her year between living with Stieglitz in Lake George and New York and her time in the Southwest. During her early trips to New Mexico, O'Keeffe stayed at Ghost Ranch, a dude ranch in the eastern part of the Jemez Mountains where the Mesozoic rock formations derive their intense color from iron oxide. In 1940, O'Keeffe bought Rancho de los Burros and in 1945 bought a second house in Abiquiu. She spent the summer and fall at Rancho de los Burros and the winter and spring at Abiquiu, which O'Keeffe considered to be her main residence.

Although she continued to make flower paintings, such as *An Orchid* (1941), the New Mexico desert was a constant source of inspiration both in its landscape and in the objects she found there. Walking in the desert the artist took pelvic bones bleached by the sun and used them in a series of paintings, such as *Pelvis With Moon* (1943) and *Pelvis III* (1944), where their holes let in the sky. After the death of Stieglitz in 1946 O'Keeffe settled her estate, delegating his large collection of art to museums. She was also active in organizing two exhibits of his collection, first at the Museum of Modern Art in 1947 and then at the Art Institute of Chicago in 1948. Beginning in 1949 the artist lived in New Mexico throughout the year.

O'Keeffe's career continued to expand. Even in the Depression she had sold work, but during the 1940s her fame increased. She had retrospectives at the Art Institute of Chicago in 1943 and at the Museum of Modern Art in 1946, and received an honorary doctorate from the University of Wisconsin in 1942. Later, in 1973, O'Keeffe received a second honorary doctorate from Harvard.

The 1950s were a decade of travel for O'Keeffe, who had until then spent her entire life in the United States except for brief forays into Canada. In 1951, she made her first trip to Mexico and in 1953 made her first trip to Europe, to which she returned in 1954. In 1956 she traveled to Peru and in 1959 took a three and a half month excursion around the world. Although O'Keeffe continued to paint images of the Southwest, such as *Ladder to the Moon* (1958), a new imagery entered her art as the result of her travels. O'Keeffe became interested in the cloud formations she saw from airplane windows and began her series of cloud paintings, which included the largest canvas of her life, the 8 × 24-ft *Sky above Clouds IV* (1965).

The Final Years

O'Keeffe remained active and retained good health until close to the end of her long life. She made her first rafting trip down the Colorado river when she was 74, her second one at 82, and her final trip in 1970 at 83.

In addition to rafting, she also returned to Colorado to paint. Eventually O'Keeffe's failing eyesight necessitated a change of medium in order for the artist to remain creative. Juan Hamilton, a potter and her studio assistant, showed her how to construct hand-coiled pots and O'Keeffe turned to pottery. Her pots echoed the shapes found in her late paintings such as *Black Rock with Blue III* (1972) and *Black Rock with Blue Sky and White Clouds* (1972). Before her death on March 6, 1986, at the age of 98, O'Keeffe had become the most celebrated

woman artist in America. She was elected to the American Academy of Arts and Letters in 1962, given the M. Carey Thomas Award from Bryn Mawr College in 1971, and in 1979 received the Medal of Freedom from President Gerald Ford. It is the nation's highest honor awarded to a civilian.

Georgia O'Keeffe and the Creative Process

Her Quest for Originality

After she finished school, O'Keeffe had an intense desire to find her personal method of expression, saying "I decided I wasn't going to spend my life doing what had already been done." She hung all her recent work on the wall and observed that each piece reflected the influence of one or another of the teachers with whom she had studied. Wanting to find her own voice, O'Keeffe (1976) said,

I have things in my head that are not like what anyone has taught me—shapes and ideas so near to me—so natural to my way of being and thinking that it hasn't occurred to me to put them down. I decided to start anew—to strip away what I had been taught—to accept as true my own thinking. . . . I was alone and singularly free, working into my own, unknown—no one to satisfy but myself.

Painting from Nature

One of her favorite ways to work from nature was by painting in her car. For this O'Keeffe said the Model A Ford was best. Its high windows let in the light and she could take out the passenger seat, and after unbolting the driver's seat, turn it around and have the car as her studio. This ingenious solution shows O'Keeffe used her capacity for what Ruth Richards calls "everyday creativity" in the service of her creativity in art. Sitting in the swiveled driver's seat, she could prop a canvas up to a size of 30 × 40 in. on the back seat and paint until about four in the afternoon when bees would invade the car. At that point, she had to close the windows and eventually the car became too hot to continue working. A very keen observer of nature, O'Keeffe would often remember events and images so clearly that she was also capable of painting them from memory. [See EVERYDAY CREATIVITY.]

Visual Memory

Artists are known for their excellent visual memories and O'Keeffe demonstrated the capacity at a very early age. She remembered, when she was 8 or 9 months old, sitting on a patchwork quilt and seeing her Aunt Winnie, accurately describing her aunt's blond hair and the details of her dress. Years later she told her mother, who also remembered that day. Her mother was at first incredulous, but then had to admit that O'Keeffe's visual memory was accurate.

O'Keeffe, who was very physically active, always liked the outdoors. All her life, she took long walks, and her observations formed the basis for later work. Her paintings *From the Plains I* (1919) and *Orange Streak* (1919) were memories of Texas, but created months later in New York. The habit of working from memory lasted her entire life. In her sixties, O'Keeffe began her *Cloud Series*, images of the world seen from the window

of an airplane. She did small charcoal drawings on the plane but filled in all the details for the large works from memory.

Early Evidence of Creative Ability

Evidence of early creative ability, common among artists, is also found in the life of O'Keeffe. She began to draw as a young child, first making images of her dolls. Because she sewed well, O'Keeffe made them clothing and then also built them a house. When she and her sisters were given art lessons as children, they learned by copying pictures of their choice in the teacher's collection. At home, O'Keeffe practiced by copying a picture of a lighthouse from her geography book. When she was unsatisfied with her first effort, she made another variation, this time with greater success. She then made a landscape drawing of the night view from her window, again working until it was made to the best of her ability. Writing in her late eighties, O'Keeffe noted that the two paintings—the lighthouse with the cloudy sky and the night with the bare trees and snow—must have been important to her because she kept them for a long time.

Abstraction versus Realism

For O'Keeffe even if a painting was realistic, it was not successful unless it worked as an abstract arrangement of color and form. She never separated the objective from the abstract and did not believe that subject matter alone produced a good work of art. For her it was the way lines and colors came together that formed the expressive basis of a painting. She altered the forms she saw in nature to heighten the abstract drama of her work, saying, "the abstraction is often the most definite form for the intangible thing in myself that I can only clarify in paint" (1976).

It was not her intention to copy reality exactly as she saw it, but rather to convey her response in the hopes that the viewer would share her impression about a place or object. She said, "the color used for the paintings had little to do with what I had seen—the color grew as I painted" (1976).

Positive and Negative Space

A strong point in O'Keeffe's work is the balance of positive and negative space. An example of positive space may be a wall, while negative space may be an open door in that wall through which a vista or other intimation of depth might be seen. Walls and doorways form a repeated graphic element in her work and it was a specific adobe wall with a doorway that made O'Keeffe want to buy the house at Abiquiu.

A further example of positive and negative space is found in her depiction of pelvic bones within whose holes the sky shines through. Speaking about the pelvic bones and her emphasis on their holes, O'Keeffe (1976) said that she was always the kind of child "that ate around the raisin on the cookie and ate around the hole in the doughnut either saving the raisin or the hole for the last and the best." She said that it was the holes in the bones that held her interest—the way they framed the blue sky in their contours. For O'Keeffe, the blue sky represented her idea of the eternal, lasting beyond the time of humans and bones.

Focus on Work

What characterizes successful artists is not only talent but their ability to work and their interest in working as a way of life. As O'Keeffe said,

One works because I suppose it is the most interesting thing one knows to do. The days one works are the best days . . . (you) can get at the paintings again because that is the high spot—in a way it is what you do all the other things for. . . . The painting is like a thread that runs through all the reasons for all the other things that make one's life.

Even with advancing years, O'Keeffe continued working and made efforts to break new ground. When she was 78 years old, she painted the largest canvas of her life, the 8 × 24-ft *Sky Above the Clouds IV* (1965). Because of its enormous size, the painting could not fit in her studio, so O'Keeffe worked on it in the garage. She mixed the paints in her kitchen Mixmaster and then brought them outside. Painting from 6 in the morning until 9 at night, she wanted to finish the canvas by winter because there was no heat in the garage. Still, in evening because the garage was warmer than the surrounding desert, O'Keeffe was afraid that rattlesnakes attracted by the warmth would come in behind her as she worked.

Painting Technique as Language

Early in her life O'Keeffe spoke about the various techniques, such as pastel, watercolor, and oil paint, as being languages. She saw the artist becoming proficient in the language of a given media and then being able to express herself creatively in that language. When she grew old and her eyesight failed, O'Keeffe could no longer see well enough to paint. She turned to pottery, saying "it could become still another language for me" (1976).

Symbolism and Communication

O'Keeffe insisted that her work was not symbolic, saying it just was what it was and that was an aspect of the world. Her flowers have been compared to female genitalia, but O'Keeffe admitted no such connection. When a seashell that she painted was also seen as sexual, O'Keeffe said it brought the ocean to her and that was its meaning.

Artists work on conscious and unconscious levels. An artist who consciously may not be aware of the symbolic content of a work may nonetheless be using symbolism on an unconscious level. For example, in her repeated imagery of skulls and flowers, there may have been an unconscious symbolism of death and rebirth, but O'Keeffe insisted on reading her work on a conscious level only. She saw her art not as symbolic, but rather as a depiction of the landscape of her world, an image of her perception and her method of communication. In speaking about the objects she painted—the flowers, rocks, trees, shells, pieces of wood, and bones—O'Keeffe said she had used these things to describe the wideness and the wonder of the world as she experienced it. And it is through these objects and her paintings that O'Keeffe transmits her world to us.

O

Organizational Culture

M Selart and V Schei, Norwegian School of Economics and Business Administration (NHH), Bergen, Norway

© 2011 Elsevier Inc. All rights reserved.

Glossary

Creation of meaning The process by which individuals or organizations develop an understanding of the situation and how it might evolve over time.

Creative knowledge environment Surroundings that exert a positive influence on persons engaged in the production of new ideas and innovations.

Empowerment The process of increasing the ability of individuals or groups to think and perform autonomously.

Shared vision A common imagination of the future of the organization or its tasks that give the basis for action.

Subculture Groups of people who share values which distinguish them from the values shared among the organization they belong to.

Introduction

According to Edgar Schein the essence of an organizational culture is a set of values that has a number of norms related to it. These norms define what is considered to be correct or incorrect behavior and what counts as valuable to the organization. Examples are power differentials between individuals, equality between men and women, and whether it is important to avoid risk or whether it is acceptable to take chances. The values are not always observable but are often taken for granted.

The organization's culture is an important aspect of innovation. All decisions are both affected by and also affect this culture. If the organization's culture is authoritarian and conformist, it is often tied to a bureaucracy. This results in limitations when it comes to making dynamic decisions. Where the organizational culture is innovative and progressive, leaders are expected to be more adventurous and to make decisions based on their own initiative. There are also examples of organizations that fluctuate between an authoritarian and innovative culture. Schein argued that a strong culture is characterized by an organization being so ideologically driven that individual action is affected and inhibited by the pattern of shared basic assumptions. Some theorists like Gareth Morgan argue that leaders can make use of a strong culture as a means of ideological control. According to this view, to lead an activity is equivalent to the reinforcement of the 'right' attitudes, values and norms of an organization. As a result, the employees are kept under control (see also Cameron Ford).

There are basically three perspectives on organizational culture represented in the research literature, according to Debra Meyerson and Joanne Martin:

1. The integration perspective implies that the organizational culture is seen as a unifying and inclusive force. Central

concepts are 'shared values' and 'common goals and beliefs.' The basic idea is that consensus is important for creativity and innovation.

2. The differentiation perspective involves a focus on cultural differences and the existence of subcultures. Individuals and groups are expected to have their own needs, perceptions and values, be they organizational or personal. Since cultures, by definition, are interpretative systems, variability must be expected between individuals and between groups. Mats Alvesson argued that a group can differentiate itself by standing in contradiction to the main culture or by representing something additional.
3. The fragmentation or ambiguity perspective is characterized by the organization being regarded as an arena in which social actors constantly negotiate and renegotiate what is perceived as meaningful in life. The focus is on how collective interaction and action lead to meaningful processes. Sensemaking, as well as individual and group-related cognitive processes, are therefore of key interest. Conflict is not seen as a bad thing for creativity and innovation but, on the contrary, is regarded as an asset.

The Integration Perspective

An organizational culture can be defined as the values that manifest themselves in an organization in the form of action. Intrinsic in all values are norms and expectations about how one should act in various situations. An organizational culture affects the extent to which creative solutions are encouraged, supported, and implemented. A culture that supports creative thinking encourages innovative problem formulations and solutions. In such a culture creativity is regarded as something both desirable and normal.

Of particular interest in this context is the behavioral pattern of the top leadership. The leaders of an organization are usually in the best position to influence the organization's own culture. In stable organizations the leaders are usually part of the culture. They must know the culture and express it in order to appear legitimate. The culture controls management as much as management controls the culture. This sets the limits of what is possible when it comes to changing attitudes and behavior. Leaders who come from outside or are strong reformers often encounter strong opposition.

An important way for leaders to influence creativity in organizations is to introduce creative goals. These have a positive impact on people's motivation, which in turn has a positive effect on creativity. By setting creative goals the employees are informed about what is demanded and valued by the organization. Several studies have shown that when employees are informed that creativity is important for the organization they also act more creatively. The goals introduced should not be too specific as this may prevent action. Instead, leaders should communicate relatively broadly defined expectations about the outcome. This will in most cases open up the possibility of various creative solutions. It is therefore important that leaders ensure that employees are able to display autonomy.

A consistent organizational culture is largely based on the organization's employees being able to share a common vision. A shared vision is different from an idea in that it constitutes an important force in the employee's heart. In many ways, this vision is the answer to the question; what do we want to create? Shared visions can therefore achieve consistency in an organization's various activities in several ways. A shared vision is often developed on the basis of a personal vision, and usually has its origin at the top leadership level in the organization.

Leaders can improve the conditions for visions being shared by employees by working actively with the communicative climate. A knowledge-based vision requires a strong commitment and can only be communicated effectively through social interaction. Key elements of this vision are new thoughts, ideas, phrasings, and actions. These provide a foundation for new forms of imagination in the organization. The vision must in addition communicate to all employees what kind of values and skills the organization requires.

A unitary culture has a vital creativity-related problem. The ideas shared by the organization's members have a tendency to decrease in value over time. There are several reasons for this. One is that organizations that have been successful for a long time usually become increasingly closed when it comes to accepting new ideas that are culturally legitimate. Another is that business models that once led to industrial dominance have a tendency to become outdated over time. For this reason, mature organizations are rarely active in industrial change initiatives.

The Differentiation Perspective

A consistent organizational culture expresses the core values shared by most members of the organization. When we speak of an organizational culture, we are thus referring to

the dominant culture. It is by using a macro-perspective that we can perceive an organization's special personality.

However, most large organizations are characterized by the fact that different subcultures evolved. These reflect common problems, situations or experiences that members have taken part in. Subcultures often occur as a result of an organization's division into sections. They can also be the result of geographical separation. An individual department can have a subculture that is unique for its members. Usually, such subcultures include the core values of the dominant culture and additional values that are unique to that particular department. Organizations can therefore be seen as collections of various subcultures that operate with different systems of meaning. This means that there is no monolithic culture. Different departments or professional groups have their own subcultures, and these are sometimes at odds with each other. These subcultures sometimes compete for power, control, and resources. The conflicts are normally resolved through adaptation and negotiation.

According to Deborah Dougherty, the reason for this division is that innovation often requires insights based on collective interpretation developed by various specialist groups. Within these groups people think differently and give priority to different types of information. Dougherty suggests four basic types of subcultures that characterize functional departments: (1) the engineering culture; (2) the market culture; (3) the production culture; and (4) the planning culture.

In recent years, the concept of creative knowledge environments has been launched by Sven Hemlin, Carl Martin Allwood, and Ben Martin. This refers to environments in which knowledge is produced by people in a work-life context. Creative knowledge environments may be small. They occur both at the individual level and the team level. In these environments, factors such as personal interaction and physical work conditions are important. Knowledge environments can also be large. They can consist of a research institution or a knowledge-intensive company where employees work. However, the basic idea with the concept of creative knowledge environments is that some form of differentiation of the dominant culture takes place.

The general principles of how a creative knowledge environment works apply at all levels of an organization, whether we are talking about a leadership or a production environment. Creative knowledge environments may be divided according to team and management responsibility. In many knowledge environments the common responsibility is to carry out the assigned work. This common responsibility is something that is special for a knowledge environment. We are talking about a creative knowledge environment that normally has a leader.

If the knowledge environment also leads, we obtain what is commonly called a self-governed knowledge environment. Where the knowledge environment in addition creates itself by selecting the members to be included, we obtain a self-designed knowledge environment. Such a knowledge environment is often made up of members with diverse skills and experience. They solve tasks for which knowledge and skills are required from different parts of their organization, and no single department can cover all areas of the field. It may for example be a case of product-, market-, quality-, or customer-focused knowledge environments.

The Fragmentation or Ambiguity Perspective

As has been shown, it is characteristic of researchers influenced by the differentiation perspective to assume relatively clear boundaries between the different subcultures in organizations. These subcultures are generally based on different departments or professional groups. However, many organizations are characterized by the fact that it is difficult to discern clear boundaries between defined subcultures. The reason is that organizational changes lead to borders shifting very quickly since they are constantly subject to different negotiations. This fact is important for the fragmentation or ambiguity perspective.

A central concept in understanding an organizational culture is meaningfulness. The individual development of reference frames does not take place in social isolation. Jill Perry-Smith pointed out that the creation of individual meaningful structures usually implies that the individual explores relationships with other individuals who are involved directly or indirectly in the same project. The interdependence of employees is often high in large-scale creative projects leading to development of a kind of collective reason emerging from collective interaction, as Karl Weick and Karlene Roberts showed. When people engage in interaction with others it creates an intersubjective meaning in the sense that a common understanding of the creative process emerges, according to Andrew Hargadon and Beth Bechky. Individual reference frames are thus linked together into intersubjective frameworks. When a mutual understanding emerges in this way Carl Martin Allwood and Marcus Selart argued that an organizational culture is developed.

Traditionally, research such as that of Teresa Amabile focused on the motivational and contextual factors influencing creativity in organizations. However, recent evidence suggests that cognitive meaningful structures also have a strong influence on how creativity unfolds. Such structures may have a major role in how organizational problems are defined and solved. They are thought to operate at many different levels of an organization, that is, at both the individual and the intersubjective levels.

Nevertheless, all creation of meaning is governed by perceptions that may be related to ideologies, paradigms, and organizations. It is therefore not unusual that various groups try to argue for their views in order to influence the development of the intersubjective creation of meaning. Sometimes differences in opinion may lead to the emergence of conflicts in organizations. However, as indicated by Carsten De Dreu there is a nonlinear relationship between the level of conflict in groups and innovation. Moderate levels have been observed to stimulate innovation while high levels appear harmful. Minority dissent can therefore prove to be beneficial to creativity, and thus to innovation. This is especially true for groups with a high degree of participation. For this reason, groups that are too homogeneous may lead to low levels of creativity, innovation, individuality, and independence. Conflicts about ideas can sometimes be beneficial. It is therefore important that minority views be ventilated and considered as an asset.

In many successful companies empowerment-oriented leadership is applied. In such organizations both rhetoric and economic resources are used to develop the intellectual resources. In these organizations employees are characterized

by qualities such as self-confidence, inner motivation and skill. Such properties are characteristic of individual creativity in organizations. Individual creativity is in turn thought to translate eventually into innovation and economic profit. As previously mentioned, a shared vision requires an integrated understanding of the organization's goals. However, a belief in empowerment allows a lot of fragmentation on how these goals will be achieved. In such organizations it is the management's task to set goals, secure resources, and then leave the arena.

Conclusion

There are three distinct perspectives on the characteristics of an organizational culture:

1. The integration perspective implies that an organizational culture is a unifying and inclusive force. Central concepts are shared values and common goals and beliefs. However, most scientists representing this perspective agree that subcultures exist. They see the unitary organization as an ideal, and regard political tactics and conflicts as harmful to the innovation process. It is through consensus that a creative environment that provides a basis for innovations should be built. The managerial challenge within this perspective is thus to direct the unitary culture toward creativity and innovation. This may be a great challenge given that many organizations feel forced by competition to focus on efficiency (exploitation) rather than innovation (exploration). Introducing clear-cut creative goals and establishing a communication climate that builds a shared vision are some options managers have in their toolkit.
2. The differentiation perspective involves a focus on cultural differences and the existence of subcultures. Individuals and groups are expected to have their own needs, perceptions and values, be they organizational or personal. Since cultures, by definition, are regarded as interpretative systems, variability among individuals and between groups must be expected. The focus is on the emergence of subcultures rather than on individual and intersubjective cognitive processes *per se*. The managerial challenge in the differentiation perspective is to handle the subtle conflicts that arise between different cultures. Subcultures may often adopt their own goals which may be at odds with those of the organization (suboptimalization). A possible solution might be to look for how creative knowledge environments of different sizes and at different levels can be created. Letting parties from different subcultures gain common responsibility might help the organization enhance creativity and innovation.
3. The fragmentation or ambiguity perspective is characterized by the organization being regarded as an arena in which social actors constantly negotiate and renegotiate what they perceive as meaningful in life. The focus is on individual and intersubjective cognitive processes rather than on the emergence of subcultures. Representatives of this perspective are interested in how meaningfulness emerges in the organization as a result of collective interaction. Conflicts and disagreements are not seen as something negative for the creative process, but on the contrary, are regarded as an

asset. It is by allowing groups and individuals to compete that creativity and innovation are developed. The managerial challenge within the fragmentation perspective is essentially to balance the level and type of conflicts so that it does not become counterproductive. Conflict and heterogeneity may spur creativity and innovations, but there is a limit.

In reality, across the perspectives, managers usually face the delicate task of trying to form cultures that build on the best of the various perspectives. Trying to balance the unitary and cohesive culture in the integration perspective with the need for heterogeneity and conflict advocated by the differentiation and fragmentation perspectives may prove difficult. However, the reward if one succeeds – a creative and innovative organization – is usually worth the effort.

Glossary

Adaptability An ability to change something (e.g., product(s); the process) or oneself to fit to occurring changes.

Efficiency The capacity of an organization to produce desired results with a minimum expenditure of energy, time, money, personnel, and material.

Innovation Innovation is a process of creation and application of new ideas resulting in the development of goods and services required for the success of an organization.

Job enrichment A way to motivate employees by giving them increased responsibility and variety in their jobs.

Organizational change Specific actions taken by the organization to transform internal structure or other characteristics/policies, apparently in response to environmental conditions and the need to survive and progress in a dynamic scenario.

Organizational learning Refers to the processes in which an organization makes use of information from past events to better adapt to future events.

Thinking organization Organizations which not only focus on acquiring and spreading knowledge but also utilizing it creatively when needed for giving a company a competitive edge.

Introduction

A visionary company doesn't simply balance between idealism and profitability: it seeks to be highly idealistic and highly profitable. A visionary company doesn't simply balance between preserving a tightly held core ideology and stimulating vigorous change and movement; it does both to an extreme. (Jim Collins 2002: 44)

Organizational development can be defined as a long-term effort to improve those aspects of an organization critical to survival and success. Wendell L. French and Cecil Bell's definition of organizational development includes the organization's vision, organizational learning, problem-solving processes, organizational culture, team configurations, and the theory and technology of applied behavioral science.

With the advent of globalization, organizational development can also be defined as an ongoing, systematic process that utilizes behavioral sciences for implementing effective change in an organization and for improving effectiveness. Thus organizational development is both a field of applied behavioral science focused on understanding and managing organizational change and also a field of scientific study and inquiry. It is interdisciplinary in nature and draws on sociology, psychology, and theories of learning and motivation as well as other fields.

Kurt Lewin, who is widely recognized as the founding father of organizational development, stressed organizational change. Following in his footsteps many theorists and practitioners have talked about the need for organizations to change and adapt in order to remain competitive. Another definition which captures the essence of organizational development was coined by Donald D. Warrick who referred to organizational development as a planned, systematic, collaborative, and primarily behavioral science-based process for understanding and changing organizations and improving their present and future health and effectiveness.

Efficiency, Adaptability, and Innovation

Efficiency, adaptability, and innovation are the three important aspects of an effective organization. Efficiency involves doing routine and standardized work in the best possible way. Efficiency was stressed in General Electric under the leadership of its then CEO, Jack Welch. He developed groundbreaking programs – including Six Sigma and Work-Out that helped transform GE into the global benchmark for maximized productivity and labor efficiency. Recently Welch, who is also regarded as father of the 'shareholder value' movement, said the obsession with short-term profits and share price gains that dominated the corporate world for over 20 years was 'a dumb idea.' Efficiency leads to higher productivity and consequently to higher profits, but the result is short-term benefits if it is not coupled with adaptability and innovation.

Adaptability is learning and being open to ways of changing routine and standardized job, in response to changes in the environment. Most organizations' response to change is 'reactive,' that is, after the change has occurred they take steps to adapt to it. To be effective it is vital that organizations be proactive rather than reactive and adapt to changes they foresee. Organizations must constantly check their environment, pick up cues, and anticipate problems and opportunities. They must recognize the influence of future markets, governmental policies, technological opportunities, competitor strategies, and a wide array of influencing factors. Organizations which are flexible, solution-oriented, and adapt quickly to changing conditions, not only survive but even flourish during turbulent economic times as their leaders capitalize on opportunities.

Finally innovation is dependent on the creativity of both individuals and teams, and must be an ongoing process. In some highly competitive fields such as technology; innovation is the first rule for survival. Creativity is considered to be the process by which new and competitive ideas are generated. Thus it is the foundation for efficiency and adaptability as well as innovation.

Creativity and Organizational Development: A Reciprocal Relationship

A creative organization is any business entity in which creativity is an integral part, affecting every aspect of the organization, and there is an ongoing and constant flow of novel ideas and innovative processes. Organizational creativity thus combines the two constructs of creativity and organizational development. In order to understand the essence of organizational creativity it is pertinent to understand the relationship between these two constructs (see Figure 1).

In the corporate setting practitioners have observed that organizational development and creativity have a reciprocal relationship. On the other hand organizational development can nurture or kill creativity at the workplace based on an organization's approach to creativity. Warren Bennis said:

There are two ways of being creative. One can sing and dance. Or one can create an environment in which singers and dancers flourish.

Thus organizations can create an environment in which creativity can flourish.

The Organizational Environment: Nurturing Creativity

In 2008 Jing Zhou and Christina Shalley examined theoretical frameworks which have focused not only on the contextual factors and antecedents of creativity, but also on factors enhancing or constraining creativity at the individual, group, and organizational level. Teresa Amabile proposed and tested a componential model of creativity which focused on domain and creativity skills as well as motivation. This model will be discussed in the next section. Richard Woodman, John Sawyer, and Ricky Griffin suggested an interactionist model of creativity (which was an extension of the model developed by Richard Woodman and Lyle Schoenfeldt). They found that creativity is affected by the interaction of (a) organizational or environmental factors; (b) groups (factors such as group composition,

Figure 1 Creativity and organizational development: A reciprocal relationship.

characteristics; and processes); and (c) individual factors (such as cognitive style/ability, personality, knowledge, and intrinsic motivation). Organization development activities influence the interactions of employees in vital areas including formal and informal teams, work ethics, characteristics of the job, culture and climate, and organizational structure.

Researchers identified organizational factors that impact the level of creativity in an organization. On the left side of Figure 2 are some of the key organizational factors (organizational climate, culture, structure, and policies) that can enhance or restrain creativity. Job autonomy and enrichment are determined by organizational policies and hence are factors governed by the organization. Discussing all organizational factors is beyond the scope of this article – interested readers are invited to look through the further reading suggestions.

Organizational Climate and Culture

Organizational climate refers to conditions that encourage or hampers employees' creative efforts. Climate may be broadly defined as the shared perception among employees of the organizational environment which they deal with every day. There is a rich interplay between organizational climate forces (structures, procedures, rules, and policies) and personal psychological forces (thoughts, fears; desires). To nurture creativity, the organizational climate needs to allow room for these forces to have a positive effect on employees. For example, the rules and policies should be flexible and lenient to allow employee risk-taking since the process of creativity often results in mistakes and false starts. Organizational leaders can encourage employees by letting them know that they are open to a little disorder or messiness in creative projects.

Organizational culture encompasses broader normative structures that shape employees' assumptions about appropriate or desirable behavior. Every organization has a unique culture; it may be weak (no specific cues) or dominant (clear signs of favorable and unfavorable behavior), but it sends a message to its employees.

Some companies like 3M are famous for their creative culture. At 3M, employees are allowed to spend as much as 15% of their time on their pet projects so they can be researched and developed. For example, the Post-It Note was developed by 3M because the company had allowed its inventor – Arthur Fry – to spend time working on the concept. When CEO Jim McNerney introduced the Six Sigma mindset, he unintentionally displaced the creative culture needed to innovate. To continue its 100-plus year history as the corporate innovator, present CEO George Buckley changed the focus from Six Sigma to more innovative breakthroughs restoring an environment where the creative juices can flow freely.

Organizational Structure and Policies

Organizational structure and policies play a vital role in affecting other organizational variables such as climate, culture, job structure, etc. Many companies have changed from a traditional hierarchical structure, where power was centralized in the hands of few, to a flat structure, where the employees are empowered and participative decision making is encouraged. In 2008, Shalley outlined the organizational supports for

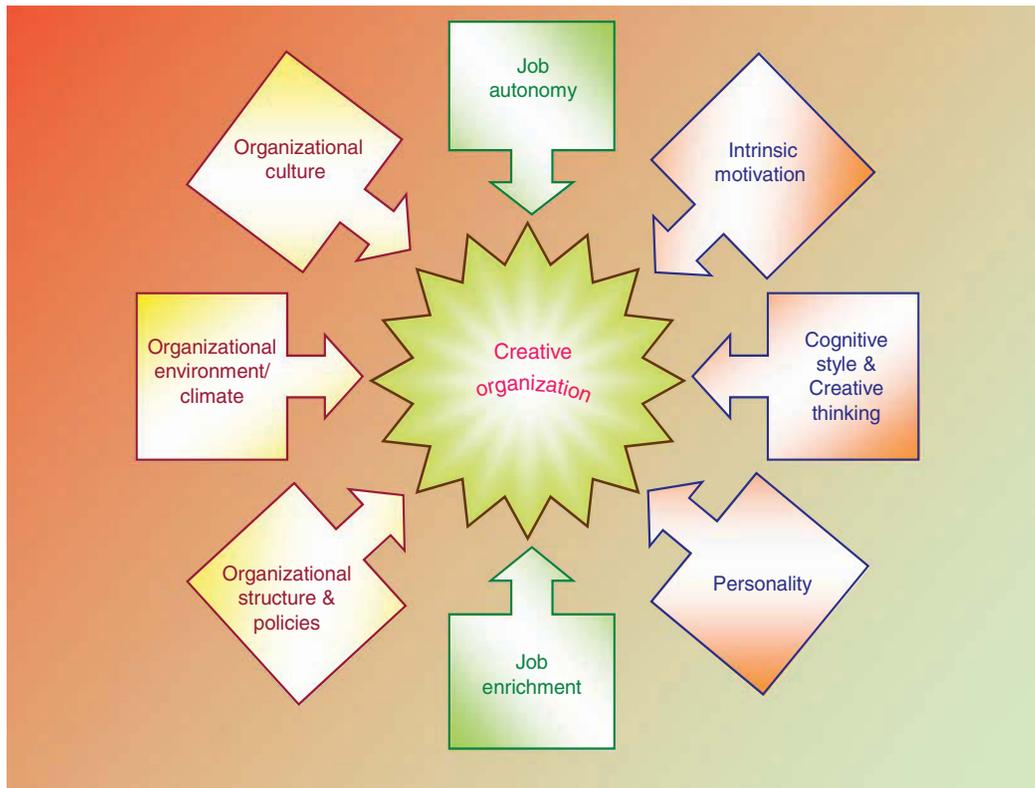

Figure 2 Organizational and individual factors contributing a creative organization.

creativity. Those included providing supervisors who model and encourage creative work and self-efficacy, an atmosphere where employees feel nurtured, and appropriate compensation packages and recognition.

Job Autonomy and Enrichment

Job autonomy refers to extended freedom at work including the power to make decisions and a feeling of responsibility for the job. When supervisors behave in a noncontrolling fashion they are empowering their employees and giving them more autonomy in their job. Greg Oldham and Anne Cummings found that employees produced the most creative work when they had appropriate creativity-relevant characteristics, worked on complex challenging jobs, and were supervised in a supportive and noncontrolling fashion.

The following example illustrates the importance of job autonomy. While working with the anthropologist Margaret Mead during the Second World War, Kurt Lewin was asked to help reduce civilian consumption of rationed foods, mainly meat. Even though traditional meats were scarce, families resisted trying nonscarce meats such as beef hearts, sweetbreads, and kidneys. Knowing that housewives were the shoppers and preparers of food, Lewin reasoned that if they were provided with new information and allowed to participate in deciding what to do, they would be more likely to change their shopping habits and prepare meals with nonscarce meats. To test his hypothesis, Lewin set up a controlled experiment with several groups of housewives. In one group, a nutrition expert lectured the group on the facts as well as the benefits of

cooking and consuming the nonscarce meats. In other groups, women were given the facts and asked to discuss and create their own meal plans. While 3% of the lecture group served nonscarce meats, 32% of the 'discuss and decide ourselves' group prepared the meats for their families. The latter group of women were given more autonomy; consequently they participated more and felt more responsible for their actions.

Job autonomy can be considered as a part of job enrichment which is a way to motivate employees by giving them increased responsibility and variety in their jobs. There are essentially five areas that are assumed to affect an individual employee's motivation and job performance: skill variety, task identity, task significance, autonomy, and feedback. Job enrichment involves addressing each of these areas in a positive way and therefore develops employee motivation and personal satisfaction.

The objective of job enrichment is to make the job challenging thereby enabling the employee to tap their potential and get the best out of them. Teresa Amabile stated that matching creative employees to assignments, based on their skills and interests, augments their motivation toward work and consequently favors creativity. Organizations can boost their employees' internal drive by helping them perceive projects as a new creative challenge.

The Employee: Source of Creativity

Today most CEOs and top leaders echo the belief followed by companies such as Southwest Airlines that employees are their

most valued asset. Southwest rose from being a small company to one of the largest in the airline industry even though it had the same airplanes as its competitors. The company had a very motivated staff that was encouraged by management to interact freely with customers and consistently rated among the highest in on-time performance and customer satisfaction.

Teresa Amabile's componential model of creativity posits that there are three key components of creativity: domain-relevant skills – which relates to the expertise in the given field; creativity relevant processes – knowledge about appropriate strategies, cognitive and work styles required for creative idea production; and task motivation – attitude toward task and perception of motivation. She found that while formal and informal education affected domain-relevant skills, training considerably helped to enhance creativity relevant skills. Following is a brief discussion of three important factors – intrinsic motivation, cognitive style, and personality (see Figure 2).

Intrinsic Motivation

Amabile defined intrinsic motivation as:

the motivation to engage in activity solely for the enjoyment, challenge, or personal satisfaction that arises from the activity itself. (1999, vol. 2: 251)

Intrinsically motivated employees are doing work that satisfies their personal needs and appropriately challenges them.

Supervisors can encourage motivation through goal setting. When workers were assigned both creative and productive goals rather than only productive goals, their creative performance increased.

Cognitive Style and Creative Thinking

Cognitive style refers to the manner in which we characteristically process information so it plays a role in creativity, problem solving, and decision making. Michael Kirton's Adaption-Innovation theory defined two types of managers based on his research. Adaptive style managers were able to initiate change but were unable to identify opportunities outside the system. Innovative style managers generated ideas that led to more radical change, but failed in getting their radical ideas accepted. The literature on creativity has concentrated on describing innovators but Kirton believes that adaptors possess equal levels of creative potential. Specifically it is the innovative creativity that breaks down old paradigms and creates new ones, while it is the adaptive creativity that improvises on the current paradigm. Hence effective organizations innovate and adapt.

Personality

Gregory Feist discussed the fact that both personality psychology and creativity focus on the uniqueness of an individual:

The essence of a creative person is the uniqueness of his or her ideas and behavior, whereas *personality psychology* is the study of what makes a person unique from others (i.e., individual differences). Both disciplines also focus on the consistency and stability – or lack thereof – of such uniqueness. (1998: 290)

The bulk of research on creativity over the years has emphasized various characteristics of individuals successful in creative endeavors suggesting a profile for creative individuals. Feist said that the research:

... makes a rather convincing case that creative people behave consistently over time and situation and in ways that distinguish them from others. It is safe to say that in general a 'creative personality' does exist and personality dispositions do regularly and predictably relate to creative achievement (1998: 304)

Creative individuals varying in age and working in different fields have been found to share common characteristics.

Harrison Gough's 30-item Creative Personality Scale gave insight into problem solving approaches, recognizing divergent information, possessing self-confidence, and tolerance for ambiguity. Openness to experience, reflecting characteristics such as imaginativeness, curiosity, originality, and broad-mindedness, has the most empirical support as being closely related to creativity. Openness to experience facilitates multiple perspectives building interest in the task itself. Strong self-efficacy, one's perceived capability for performing a specific task is also an important requirement for creativity. This ability influences performance through the adept use of inventiveness and resourcefulness. Although traits are inherent, if the culture of an organization is such that it is open and encouraging, to new ideas, some employees may become more open-minded and creative.

Conclusion

Creativity should be an integral part of an organization's everyday experiences. An important aspect of organizational creativity is organizational learning – processes in which an organization makes use of information from past events to better adapt to future events. Min Basadur suggested that organizations should go beyond being a learning and knowledge sharing organizations – they should strive to be 'thinking organizations' which not only focus on acquiring and spreading knowledge but also utilizing it creatively to gain a competitive edge.

In a borderless world, where change is constant, organizational creativity is vital for survival. Today's employees can be tomorrow's creative thinkers if organizations ensure that they nurture creativity at the workplace by providing an environment that nurtures and encourages creativity.

Glossary

Developmental potential Innate endowment composed of talents, intelligence, overexcitabilities, and the capacity for inner transformation.

Overexcitability An innate tendency to respond with heightened intensity and sensitivity to intellectual, emotional, and other stimuli. Also called psychic overexcitability.

Theory of positive disintegration A theory of personality development proposed by K. Dabrowski. Development is viewed not as a stage-wise progression through the lifespan,

but as inner transformation powered by the tension between the higher and the lower, the good and the bad, experienced within the self. Inner seeking, figuring out the world, questioning the meaning of human existence, experiencing anguish, testing one's values and ideals, growing in empathy and understanding of others constitute human development characterized by reflection, self-evaluation, and the urge for inner transformation. The theory emphasizes the role of inner conflict, moral sensitivity, compassion, and self-judgment in personal growth of creative people and spiritual seekers.

The Concept of Overexcitability and Its Origin

In 1937, the Polish psychologist and psychiatrist Kazimierz Dabrowski published a monograph entitled 'Psychological Bases of Self-Mutilation.' Examining clinical cases of gifted and talented youngsters and biographies of creators, such as Michelangelo, Dostoevski, Tolstoy, and Nietzsche, Dabrowski pointed to clashes of opposing tendencies that create enormous inner tension resulting in various forms of self-torment. He identified psychic overexcitability as a factor predisposing toward physical self-mutilation and emotional self-torment. This was the initial germ of his theory of positive disintegration.

Stimulation and stress create tension. When emotional tension becomes unbearable, self-inflicted pain through physical injury to oneself or through emotional self-torture brings release. The stronger the tension, the stronger the need to release it. Dabrowski saw that people prone to self-mutilation were more susceptible to being excited, tense, thrown off balance by their overstimulation and inner turmoil. In other words, they were highly strung and subject to nervousness. At the same time they tended to have a rich inner life.

The ability to sustain intense inner conflict was to Dabrowski a sign of inner strength because rather than injuring others the person injured himself. He observed that an emotional crisis and mental suffering, so great that it could bring on a psychotic episode, at times results in personality integration at a higher level. Consequently, various forms of neuroses and psychoneuroses acquire a positive value as part of the process of inner growth.

Strong overexcitabilities make for rich and vivid experiencing but they also produce a disequilibrating, disorganizing, and disintegrating effect on the self. Disintegration is positive when it fosters emotional growth, hence the name Theory of Positive Disintegration.

Overexcitability is defined by the following characteristics: (a) the reaction exceeds the stimulus, (b) the reaction lasts

much longer than average, (c) the reaction is often not related to the stimulus, and (d) emotional experience is promptly relayed to the sympathetic nervous system (accelerated heart-beat, blushing, trembling, perspiring, headaches).

As Dabrowski kept developing his theory, the five overexcitabilities became components of the concept of *developmental potential*, together with talents, intelligence, and the autonomous factor of inner transformation. It is the potential for emotional development to a higher level such as, for example, self-actualization. In fact, Maslow and Dabrowski began a friendship which was cut short by Maslow's premature death in 1970. The overexcitabilities are ways of experiencing with great intensity, aliveness, vividness, depth and richness in the sensory, intellectual, imaginative, and emotional realms. They are also the means of expressing and transforming emotional tension.

Each form of overexcitability can be looked upon as a mode of being in the world, or as a dimension of mental functioning:

- psychomotor – expressed through movement, restlessness, action, excess of energy seeking an outlet;
- sensual – expressed in love of textures, delight of touch, vision, sound, taste, and also luxuriating in comfort and hedonism;
- intellectual – favors analysis, logic, questioning, the search for truth;
- imaginal – generates analogies and metaphors, inventions, creative problem-solving vivid dreams, imaginary worlds, imagined experience visualized to the point of being 'as real as real';
- emotional – expresses itself in attachments and affectional bonds with others, empathy, the despair of loneliness, the joy of love, the enigma of existence and human responsibility.

Overexcitabilities are modes of personal experience and personal action. Each mode can be viewed as a flow of information in the form of sensations, feelings, experiences, images, ideas, hopes, and desires. The five dimensions are like color

filters or multichannel and interactive dish antennas through which the world is received and felt.

The response is specific to the person's most dominant form, or forms, of overexcitability. For instance, persons characterized by emotional overexcitability when asked what triggers for them the feeling of being incredibly happy, may answer that the love of family and friends moves them to tears, or that the feeling of oneness with all creation makes them ecstatic. If the answer is the speed and excitement of water-skiing, playing a hard game of racquet ball, or racing on a motorcycle to feel its roar, it indicates psychomotor overexcitability. In the latter case, although the question was asked in the emotional dimension (What makes you feel incredibly happy?), the response came in the psychomotor dimension.

These channels can be wide open, narrow, or operating at bare minimum. They are assumed to be part of a person's constitution and to be more or less independent of each other. If more than one of these channels have wide apertures, then the abundance and diversity of feeling, thought, imagery, and sensation will inevitably lead to dissonance, conflict, and tension. Consequently, experience becomes multidimensional – enriching, expanding, and intensifying the individual's emotional development and talent. At times the inner tensions and conflicts can be overwhelming.

The five overexcitabilities, plus specific creative gifts, talents, and abilities constitute the original equipment with which a child enters life. Parental, peer, school, historical, economic, and cultural forces all influence how this original equipment will fare.

Today we can say that individual differences, such as heightened versus average excitability, lie in the speed of information processing, in the developmental experiences that stimulate the brain to grow denser and more efficient neural connections, in the extensiveness of cognitive and other networks, and in the rate of emotional processing by the brain. With current advances in tapping the activity of the living brain, the overexcitabilities could be tested directly by comparing the responses of individuals who score high on a given overexcitability with those who score low.

Measurement and Cross-Cultural Validity

Early research depended on an Overexcitability Questionnaire with 21 open-ended questions. The OEQ-II, a 50-item Likert-scale inventory, has facilitated research and has been translated into a number of languages.

The concept of overexcitability has been shown to have cross-cultural validity in a study carried out by R. Frank Falk and his colleagues. Comparison of overexcitability profiles of American and Venezuelan artists found a close similarity. Comparison of overexcitability profiles of gifted students in Turkey, Taiwan, Spain, Mexico, and the United States showed strikingly similar patterns. Wieslawa Limont has extended this research to creatively gifted students in Poland.

Expressions of Overexcitability in Creative People

The following illustrative examples come from biographies and from overexcitability questionnaires obtained from

writers, poets, musicians, fine artists, film makers, and choreographers.

Psychomotor Overexcitability

Psychomotor overexcitability describes the surplus of energy characteristic of gifted and creative people as well as the funneling of emotional tension into psychomotor forms of expression. As shown in **Table 1**, the heightened energy erupts in speaking rapidly, outward gestures of excitement, intense athletic activity and physical work, the urge to act and to compete. Emotional tension can be funneled into actions that help to discharge it through compulsive talking and chattering, acting on impulse, nervous habits, working compulsively, or acting out destructively. The higher energy level of creative people is readily noticed though it is not universal.

Some creators were highly spirited and energetic when they were young but were not so in their adult years. Chopin did not have a strong constitution to begin with and it was later weakened by tuberculosis. Once she returned from boarding school, the once lively Emily Dickinson gradually became so agoraphobic and fearful of strangers that she never again left her family house. Richard Wagner, Antoine de Saint-Exupéry, Sergei Rachmaninoff, and Thomas Alva Edison are a few examples of the many creators who as children were impetuous, hard to control bundles of energy. Today highly spirited gifted children are often mistakenly labeled as hyperactive or having Attention Deficit/Hyperactivity Disorder (ADHD).

Saint-Exupéry as a boy was wild and fearless, fond of violent games in which he tyrannized over others. Edison was always getting into scrapes because of his inquisitiveness. One day, he attached wires to two large cats and then attempted to rub them vigorously to produce static electricity. The scratches and claw marks he got were deep. Rachmaninoff's favorite sport was to jump on and off horse-driven streetcars in motion, even in winter on icy pavement.

In response to the question 'How do you act when you get excited?' a poet in Jane Piirto's study of writers said "I wave my hands, stumble over my tongue & yak at hyperspeed «until my lips are ready to fly off»." A dancer said: "I feel the most energy in the a.m. Or during or immediately following dancing. I try to 'stay with it,' ride the wave as long as it lasts." The question 'What kind of physical activity gives you the most satisfaction?' evoked this response from a young actress: "Swimming but most of all water skiing. It's the most exhilarating sport I've done – the feeling of movement, water and wind against my body all at once." These examples illustrate high energy that finds ways to be discharged physically.

Sensual Overexcitability

Sensual overexcitability intensifies and enhances the delights offered through seeing, smelling, tasting, touching, hearing, sex, or any combination thereof in multisensory experiences. Persons so endowed immerse themselves in the delight of beautiful things, sounds of nature, sounds of words and music; they note the form, color, balance, and texture in anything around them. Specific aversions to certain tastes, smells, or touch and the like, are also common. Sensual pleasure tends to be relaxing and temporarily satisfying.

Table 1 Forms and expressions of overexcitability

PSYCHOMOTOR	
<i>Surplus of energy</i>	Rapid speech, moving when excited, love of fast games and sports, energy to do things (e.g., organizing), competitiveness
<i>Psychomotor expression of emotional tension</i>	Compulsive talking and chattering, acting impulsively, nervous habits (tics, nail biting), workaholism, acting out
SENSUAL	
<i>Enhanced sensory and esthetic pleasure</i>	Seeing, smelling, tasting, touching, hearing, and sex; delight in beautiful objects, beautiful people, sounds of words, music, form, color, balance
<i>Sensual expression of emotional tension</i>	Release through overeating, shopping for pleasure, sex, wanting to be admired
INTELLECTUAL	
<i>Intensified activity of the mind</i>	Thirst for knowledge, curiosity, sustained concentration, avid reading; keen observation, detailed visual recall, detailed planning; passion for precision
<i>Passion for probing questions and problem solving</i>	Search for truth and understanding; forming new ideas; tenacity in problem-solving
<i>Reflective thought</i>	Thinking about thinking, love of theory and analysis, preoccupation with logic, moral thinking, introspection (but without self-judgment), independence of thought (at times highly critical)
IMAGINATIONAL	
<i>Free play of the imagination</i>	Frequent use of image and metaphor, facility for invention and fantasy, facility for detailed visualization, poetic and dramatic perception, animistic and magical thinking
<i>Immersion in the world of imagination</i>	Predilection for magic and fantasy, creation of imaginary worlds, multiple imaginary companions; dramatization
<i>Spontaneous imagery as an expression of emotional tension</i>	Mixing truth and fiction, elaborate dreams or nightmares, illusions, persistence of imagery
<i>Low tolerance of boredom</i>	Need for novelty and variety
EMOTIONAL	
<i>Feelings and emotions intensified</i>	Extremes of emotion: positive and negative, awareness of a wide range of feelings, complex emotions and feelings, identification with the feelings of others
<i>Strong somatic expressions</i>	Tense stomach, sinking heart, blushing, flushing, pounding heart, sweaty palms
<i>Strong affective expressions</i>	Timidity, shyness (inhibition); enthusiasm, ecstasy, euphoria, pride; strong emotional memory; feelings of unreality, fears and anxieties, feelings of guilt, concern with death, depressive and suicidal thoughts
<i>Capacity for strong attachments, deep relationships</i>	Strong emotional ties to persons, animals, trees, plants, places; difficulty adjusting to new environments; compassion, responsiveness to others, sensitivity in relationships; loneliness;
<i>Inner dialog and self-judgment</i>	Dispassioned self-evaluation, taking steps toward becoming a better person

In contrast, when emotional tension is diverted to the sensual channel it may become excess in eating, smoking, shopping, sex, and a constant desire to be admired. For example Tchaikovsky began smoking for the pleasure it gave him but soon found that it pacified his high strung nerves – sensual pleasure that offered reduction of emotional tension.

Painters smell paint, feel the texture of their material, feel the brush strokes in a painting, just as potters feel the clay being molded in their hands, with heightened sensibility in their whole physical being. Many poets are acutely sensitive to the sound of words and their rhythms, the touch of paper, and the look of print fonts. Musicians are supremely aware of

timbres of instruments and the distinct color and timbres of voices, sounds of nature, and of their everyday surroundings (e.g., John Cage).

Chopin's description of Henriette Sontag's singing – one of the greatest sopranos of the early nineteenth century – is extremely sensual: "You feel as if she was blowing at you perfumes of the freshest flowers and caressing you with the delicious pleasures of her voice, but she rarely moves one to tears." Chopin is making a distinction between a purely sensual delight and sensuousness that also is deeply moving emotionally. Charles Darwin derived such intense pleasure from listening to music that his "backbone would sometimes shiver."

Intellectual Overexcitability

Thirst for knowledge, curiosity, capacity for concentration, and sustained intellectual effort, avid reading as well as precision in observation, recall, and careful planning describe a mind operating at a high level of intensity. Habitual or relentless inquisitiveness, questioning, puzzling over things, is one of the distinct characteristics of intellectual overexcitability. The person is driven to seek understanding and truth. Perceiving patterns and relationships, solving problems, finding it difficult to let go of a problem, and finding new problems to solve is typical. Another trait is reflective thought, watching one's own thought processes, delighting in analysis, theoretical work, and logic. On a more personal level we encounter moral thinking, introspection, and reliance on intuition. People strong in intellectual overexcitability are forceful thinkers and often highly critical of the shortcomings in the thought of others.

Intellectual overexcitability is not the exclusive prerogative of scientists and philosophers, but is also characteristic of artists and creative people in all domains. The more original an artist's work was judged by experts the more facility the artist had for asking questions. The Allport–Vernon–Lindzey Study of Values similarly defines 'theoretical value' as an interest in and pursuit of truth, a desire to gain knowledge, systematize it, and bring order to it.

Darwin described his curiosity, concentration, and the thrill of learning a logical principle. As a youth, he had much zeal for whatever interested him, and took keen pleasure in understanding any complex subject. Taught Euclid by a private tutor, he felt intense satisfaction from working the clear geometrical proofs. He remembered vividly the delight when his uncle (the father of Francis Galton) explained to him the principle of the vernier of a barometer.

In his autobiography, *Ex-Prodigy: My Childhood and Youth*, Norbert Wiener stressed that he was motivated by the ideal of service to truth rather than service to humanity even though his father exerted a strong moral influence on him to serve humanity. Wiener also described how when working on a problem "the unresolved ideas were a positive torture to me until I had finally written them down and got them out of my system." The excerpts from Darwin and Wiener show the crucial involvement of emotion in learning and solving problems.

These examples demonstrate several aspects of intensified activity of the mind that lead to ever more probing questions and search for understanding, shared by scientists and artists

alike though their questions and methods of inquiry may be quite different. There is a strong emotional component in the process.

Imaginational Overexcitability

The role of imagination in creativity is well documented. As a broad personal characteristic the concept of imaginational overexcitability looks at the creator's underlying predisposition, manifested in childhood, to engage in free play of the imagination, to fantasize and daydream, to generate unusual associations. The ability to convert experience into imagery depends on an exceptional ability to see analogies. For instance, Saint-Exupéry as a boy acted as a sunset caretaker when he explained: "Here are the chests where I lay dying sunsets to rest." In the *Pastoral Symphony* Beethoven created a visual image with sounds. By means of rapidly descending violin tremolos he conveyed the image of the wind slashing the rain in a storm.

The impulse to explore new possibilities and take what is given to change into something new is ever present. For example, in the film *Amadeus*, after hearing a court composer's piece Mozart goes to the keyboard, begins to play it and then starts to change it to make it more interesting, more dynamic, and forward moving.

Imaginational overexcitability is easily noticed as facility for visualizing elaborate imaginings, perceiving life experiences poetically and dramatically, and in animistic and magical thinking. Animistic thinking involves endowing inanimate objects with personality, character, and will of their own. Magical thinking rests on the conviction that to think something is as good as making it happen. The private rituals and formulas to ensure that everything works out all right are examples of such thinking. The capacity for living in a world of imagination requires that one spend certain amount of time daydreaming, watching movies, reading fairy tales and stories, creating private imaginary worlds, or engaging several imaginary companions in childhood, and sometimes even into adulthood.

Emotional tension is easily diverted into the theater of imagination where feelings and emotions find their form. For understanding one's emotional life finding an image to what is felt is enormously helpful. Words are inadequate and limited, but an image carries the energy and felt quality conveying the meaning of an experience. For people with overexcitability of imagination, spontaneous imagery is as natural as breathing. This does not mean that such persons are not capable of sorting out fantasy from reality. On the contrary, for them the difference is quite enhanced. The boundary may blur when intense emotions take over in a rush of vivid images. Frank Lloyd Wright once imagined that his mother was going to give a party for him. He told his friends in detail what will be served and how special this occasion was going to be. So they came, all dressed up. Wright's mother was surprised, but knowing her son she improvised a party. Because he imagined it, he actually believed the party was going to take place.

Richard Wagner was so fascinated by Beethoven and Shakespeare that he created in his mind a vivid image of each one: "I used to meet them both in ecstatic dreams, saw them, and spoke to them; on awakening I was bathed in tears."

His imagination was so graphic that whenever he thought of ghosts he was terrified. As a boy he visited relatives who lived in a big house. In their stately guest room were old portraits of young ladies "in hooped petticoats and white powdered hair" that seemed to him ghostly apparitions come to life. Every night of his stay he was drenched with perspiration, a victim to his frightening visions.

Absorption and imaginal experience

These examples demonstrate that it is possible to so become absorbed in an imagined experience that it becomes real. Sounds are heard as real sounds, smells are inhaled, tastes are savored, textures and sensations of warmth or cold are felt on one's skin. Auke Tellegen and Gilbert Atkinson examined the degree to which people are open to absorbing and self-altering experiences. They distinguished between reality and fantasy absorption. Involvement in an experience, such as listening to music, or acting out a role, being in character represents reality absorption. In fantasy, or imaginal, absorption the imagined scenes and actions may be experienced as completely real with full engagement of the senses. This ability first appeared to be related to the ability of being hypnotized, but on closer examination it was the ability to be absorbed in the experience that explained hypnotizability. Sheryl Wilson and Theodore Barber found that people with this ability experience their imaginings 'as real as real' or even as more vivid and palpable than the surrounding environment. This work was later confirmed by Steven J. Lynn and Judith W. Rhue.

The sensory cortex of the brain does not distinguish between a vividly imagined experience and one in tangible external reality. For this reason such experiences should not be called imaginary, in the sense of not being real, but *imaginal*, because they are experienced as truly felt. They are not hallucinations because the imaginer retains control over the experience. Nevertheless, strongly imagined experience can create changes in the body such as shivering with cold when watching movies with winter scenes, developing warts when believing being touched by a toad, or having an imaginary pregnancy with all the symptoms of a real one. Obversely, this enables healing by the power of the mind.

Recent reports show that the brain becomes active differently when real memories are recalled than when imaginary memories are recalled. In real memories the sensory areas light up, in imagined memories they do not. But people who report experiencing their visualizations as real, their sensory areas light up equally strongly. In other words, for people capable of full sensory engagement in their imagined experience, the brain does not distinguish between what is experienced when stimulation is external, from internal when it is imagined. Such an experience is not imaginary, meaning unreal, because it is real to the person. For this reason it is called *imaginal*.

Creative people do not tolerate boredom well. They don't enjoy routine and unimaginative practice. As a boy Rachmaninoff took up improvisation because the music he had to study was too dull for him. He told his naive listeners that he was playing Chopin or Mendelssohn and no one realized he was playing his own music. People capable of imaginal experience escape boredom by creating novelty to their own design.

Emotional Overexcitability

Feelings and emotions are frequently at a higher pitch, and the person has a keen awareness and sensitivity to nuances of feeling in oneself and in others. Because the vehicle for emotion is the body, blushing, getting flushed with color, perspiring, trembling, feeling tension in different parts of the body, feeling hot or cold, present psychosomatic signs of overexcitability. Positive as well as negative feelings are experienced with great intensity, openly by extroverts and inwardly by introverts. We live in a culture in which being emotional is criticized and tampered with. Children are often told what they should or should not feel rather than accepting what they do feel. When this happens children with high overexcitability are intensely miserable and confused. Consequently, emotional individuals have a tendency toward depression, suicidal thoughts, feeling of being out of place and not belonging. Feelings of profound alienation, even suicide, are often the result. Ways of recognizing and respecting children's overexcitabilities and protecting their sensitivities are described in *Living with Intensity*.

Highly emotional individuals become strongly attached to people, living things, and places. They experience great difficulties adjusting to a new location and a new environment. To pull up so many roots and strike them in new soil takes up much energy. Adjusting to a new place often takes a long time, or it fails to happen. Hence compassion toward others, their loneliness, and being out of place. Friendships are strong and enduring.

Being emotional often means to judge oneself, to carry on an inner dialog and self-evaluation on how well one does toward others, how well one carries out one's responsibilities toward others. In the first entry of her *Journal of Solitude*, May Sarton wrote: "I feel too much, sense too much, am exhausted by the reverberations after even the simplest conversation. But the deep collision is and has been with my unregenerate, tormenting, and tormented self." Such great intensity of feeling as well as an inner struggle and self-judgment used to be viewed as mental disturbance. Now they are understood to be essential to inner growth. The sculptor Malvina Hoffman said: "Language is a clumsy medium to express the pounding surge of intense feeling. . . . Music could drive my blood and suffuse my entire being."

Intensity, passion, and sensitivity to nuances of feeling are expected in creative people in the arts but not in science or mathematics. Herbert Simon, a Nobel Prize winner in economics, said that there was no emotion in his creative process – only hard cognitive work. Simon took for granted his wife's contribution to his emotional well-being and overlooked the obvious fact what drives his work is the powerful emotion of intense interest. Louis Pasteur and Norbert Wiener, to cite just two examples, were deeply emotional and highly sensitive people. Darwin and Einstein also had a strongly emotional aspect to their personalities. The spectrum of emotions and feelings is immense and exceedingly intricate. The portion of the emotional spectrum that is characteristic of each creator is undoubtedly unique.

In his autobiography Darwin made frequent observations on his friendships and their personal importance to him in contrast to his association with scientific colleagues. In

describing people he always noted the emotional impact each person had on him. Recalling his childhood, Darwin confessed to an act of cruelty. He beat a puppy and it troubled his conscience for a long time. "The exact spot where the crime was committed" was engraved in his mind. It was all the more troubling to him because he loved dogs and they often preferred him to their masters. Darwin also recalled that he was more affectionate in his youth when he had many friends among the schoolboys whom he said he loved dearly. When he attended the clinical ward of the hospital as a student some of the cases distressed him and left vivid imprints on his mind. Two surgeries he attended were performed without anesthesia – it was not yet introduced – he could not bear to stay and see them completed.

Einstein said about himself: "I am not much with people, and I'm not a family man. I want my peace." In personal relationships he kept a distance. He concentrated all his energy on solving the riddle of how God created the universe. And yet he was also animated by deep emotions and sensibilities. He was close to his mother and his sister Maja, and to his uncle Căsar Koch. He was deeply honest and abhorred German militarism so strongly that from the age of 15 he sought to give up his German citizenship; he became stateless at 16. Eventually he became a Swiss citizen. He cherished those few with whom he could discuss physics. Einstein said that he suffered nervous conflicts "at the very beginning when the Special Theory of Relativity began to germinate" in him. Similarly Max Planck described the 6 years of his own seminal work on the equilibrium between radiation and matter as 'a process of despair' because the solution was eluding him.

As a boy, Einstein had a great sensitivity to beauty and a deep religiosity. About the age of 12 he came to the conclusion that many Bible stories could not possibly be true. Religion lost its authority. He suspected that all institutional authority was intentionally deceiving the young and lying to them. The resulting emotional crisis made him distrust any authority. Einstein loved music and studied the violin but was making little progress with teachers who stressed mechanical practicing and accuracy without feeling. When he was 13 he fell in love with Mozart's violin sonatas: "The attempts to reproduce, to some extent, their artistic content and their singular grace compelled me to improve my technique . . . I believe, on the whole, that love is a better teacher than sense of duty."

Pasteur as a boy liked to fish but abstained from trapping birds – he couldn't bear to see a wounded bird. The contact with his family and friends was vital to the young Pasteur. Away from home he constantly begged for more frequent and longer letters. Pasteur was also deeply religious and it pained him to see in the practice of religion so much controversy, intolerance, and lack of peace and love.

Wiener's account of his boyhood and youth is very emotional. He remembered his first sweetheart from kindergarten – charmed by her voice he loved to stay close to her. He suffered fears of the dark, injury, violence, and death. The injustice and cruelty suffered by others affected him deeply. He was quite shaken when at the age of 13 he was told that his mother had a second child who died at birth. Realizing that his own family was not immune to tragedy, shattered his sense of security. Lacking religious upbringing he learned the story of Christ's

crucifixion from his Catholic friends. The image of the crown of thorns and of Christ's wounds filled him with pain.

Despite his extraordinary abilities and being radically accelerated in school – Wiener graduated from Tufts College at the age of 14½, spent a year at Cornell, and earned his doctorate at Harvard before he turned 19 – his self-confidence was undercut by his father's demand for perfection. Even worse, his father stated publicly in print that all the boy's accomplishments were due to the training he gave him and none to his abilities. Wiener was devastated; he felt that all his successes were his father's and the failures were his own. He dreaded graduation which forced him to leave the protection of childhood and face adult responsibility for himself. He seriously doubted he could succeed. "My achievement of independence during the year at Cornell had been incalculably retarded by the confused mass of feelings of resentment, despair, and rejection which had followed early in the year upon discovery of my Jewishness."

Studies comparing artists and scientists in regard to emotionality have shown that as a group scientists tend to be less emotional. But this comparison overlooks at least two things. First, the comparison is made of adults. The examples cited make it clear that as children scientists often are emotional and sensitive but later the involvement in research restricts their emotional range – recall Darwin saying that he was more affectionate as a boy. Second, there is a distinct difference in the artists' and the scientists' material. Scientists study phenomena outside themselves which are analyzed, experimented with, and explained in objective terms. And yet the process of working out solutions to problems is often described as despair or torture. The scientist's passion and agony do not enter the final result. Science tends to be seen as an unemotional and objective endeavor. In fact, objectivity is the outcome not of the individual but of the *collective* enterprise of science in which replication of results and confirmation of theories are carried out by different people checking on each other's work. The very substance of art is human subjectivity, the life of feeling to which an artist gives expression. Artists work with the complexities of human emotion and feeling. Before experience can be portrayed and expressed it has to be felt, whether in reality or in imagination.

In some cases emotional overexcitability is expressed negatively. For instance, Wagner was so self-centered that he believed that to be his friend a man had to be totally dedicated to him. Picasso, emotionally equally intense, was not far behind, being destructive in most of his intimate relationships. Somerset Maugham was often cruel to the boys procured for him. To understand what tips the balance toward a negative expression of overexcitability would require a close examination of the person's emotional development.

Conclusion

Overexcitabilities, according to Dabrowski's theory, are fundamental attributes of a creator's makeup. Without them a talent would lack richness and power. The model of developmental potential offers a way of examining the palette of expressions of overexcitability as its spectrum changes from individual to individual. Advances in brain research present the possibility of examining the nature of overexcitabilities directly.

As a property of the nervous system, each overexcitability contributes significantly to the creative process by not only heightening the experience but by making it also more complex, especially when the emotions are engaged as they always are.

Psychomotor overexcitability imparts a high level of energy and drive. Sensual overexcitability contributes a richer and more vivid sensory experience frequently in conjunction with emotional overexcitability. Intellectual intensity generates relentless questioning and searching for truth. Enhanced imagination brings the power to envisage undreamed of possibilities, to create new realities. Emotional overexcitability endows the creator with greater intensity, sensitivity, and complexity of feeling in all dimensions.

Scientists have greater emotional intensity than it is generally believed. We know today that intellectual processes divorced from emotion are ineffectual. Antonio Damasio described cases in which damage in a very small frontal area of the brain disrupted the connection between reasoning and feeling. One patient was perfectly rational on all psychological tests and yet could not bring his reasoning to any practical conclusion. Without feeling he was unable to decide which of two rational alternatives was the better one. It is therefore not surprising that creative scientists show clear evidence of emotional overexcitability, even those who would deny the role of emotion in their cognitive processes.

The problems of science are difficult. The gaps and the contradictions in our knowledge are never obvious, they have to be discovered first before they are solved. The problems of art are also difficult. The artist has to discover what experiences or humanly significant trends need to be expressed. The artist

may be aware of something pushing for expression yet may need years to express it just as a scientist working on a basic problem may go through years of despair and torment before the solution appears.

Glossary

Conceptual framework or conceptual scheme A set of basic categories, rules, and/or entrenched practices that organize experience, thought, and action; a paradigm (in one sense), a world view or a 'take' on a particular domain of inquiry or activity.

Convergent versus divergent thinking Psychologist J. P. Guilford's distinction of routine thinking, constrained by a set of norms or conventions, from unconventional, imaginative activity that disregards established rules to strike out in new directions. Convergent thinking raises standard questions and produces orthodox answers, while divergent thinking is iconoclastic, 'outside the box.' Brainstorming, free association, and planning retreats are common ways of generating divergent ideas.

Creative innovation A creative product, novel design, or increase of fit to an environment that 'sticks,' that is accepted and employed by a community.

Evolutionary change Slow, incremental change, as in Darwin's theory of biological evolution, in contrast to revolutionary jumps and rapid structural reorganizations, including paradigm shifts. A major issue is whether evolutionary change alone is sufficient to produce genuinely divergent outcomes.

Holism The doctrine that the whole is more than the sum or aggregate of its parts in the sense that the functional relation or structural organization of the parts determines the nature of the whole; and the holistic significance of a part derives from its relation to the other parts – from its place in the organizational structure – rather than from its own intrinsic nature. Holists deny that reductionist, analytic methods are adequate to understand the emergence or transformation of structures and phenomena in complex systems.

Incommensurable paradigms Thomas Kuhn's claim that there is no paradigm-neutral language and no neutral, objective standard against which competing paradigms can be compared. There is much disagreement about what incommensurability is and whether it actually exists in the history of the sciences and other disciplines.

Logic versus rhetoric An old dispute about how to conduct serious inquiry. Logical thinking, in the strict sense, must be clear and must conform to deductive or inductive inference

rules. Rhetoric, as the art of persuasion, is sensitive to context, audience, and our embodiment as emotional beings and makes use of nonlogical tropes or figures such as analogy, metaphor, and simile. Thinkers such as Plato and Descartes considered logic and mathematics to be constitutive of rationality and criticized rhetoric as a sophisticated tool for undermining rational deliberation. By contrast, many theorists today, including Kuhn, consider rhetorical stretching of current modes of thought and practice to be one key to creative imagination. The claim that logical thinking is convergent while rhetorical thinking is divergent is an oversimplification.

Paradigm A model, template, or matrix for making, doing, or evaluating something. For Kuhn a paradigm in the small sense is an 'exemplar' – a successful concrete problem solution that serves as a model for further work in the relevant, mature scientific community. A paradigm in the large sense is a 'disciplinary matrix' – an entrenched point of view and a corresponding set of practices that structure the efforts of such a community to emulate its exemplars. Others have extended the term to designate any organizing framework, major policy, or set of constitutive rules of operation, for example, as used in government or business.

Relativism The view that truth or correctness is relative to a culture, conceptual framework, or individual and that there is no objective way to resolve disagreements. What is true for me may be false for you.

Selectionist models of creativity and innovation:

Undirected variation plus selective retention The type of model discovered by Darwin and employed in his theory of biological evolution. A mechanism of undirected or partially 'blind' variation is coupled to a process of selection of those variants that happen to be favored by the selection criteria in play (e.g., the biological environment) and further coupled to a mechanism that transmits the favored features, to some degree, to the next generation (e.g., genetic inheritance). When the process is iterated over many cycles in an environment with relatively stable selection pressures, adaptive modification is almost inevitable. Today selectionist mechanisms are widely applied in many fields beyond biology, for example, to problem solving by computer. Universal evolutionists assert that selectionist

models are the key to understanding all forms of creativity and innovation, because something creative is basically a novel design and only a selectionist process can explain how more design can emerge from less.

Structuralism Originally the label applied to Ferdinand de Saussure's theory of language as a system of signs in which the linguistic units themselves are arbitrary and get their significance from their complex relations to the other elements in the system. Claude Lévi-Strauss and others extended the idea to the social sciences, literature, architecture, etc., contending that many everyday human activities are explainable by postulating the existence of deep

structures that generate common patterns – cultural genetic codes, so to speak. These deep structures are theorized to vary from culture to culture and from one historical period to another. Since the relations in question are typically rigidly synchronic, critics argue that structuralists are unhistorical and forced to postulate sharp breaks or ruptures in order to handle dynamical change – a charge that has also been leveled at Kuhn. Ontologically, structuralism takes relations seriously: systems of relations among items at one structural level of description constitute new, emergent levels of reality. Today, complexity theorists study networks and their sometimes-sudden transformations.

Paradigm Shifts as a Theory of Creativity

The physics-trained historian and philosopher of science Thomas Kuhn popularized talk of paradigms and paradigm shifts in his controversial 1962 book, *The Structure of Scientific Revolutions*. Paradigm shifts in Kuhn's technical sense are scientific revolutions. In the everyday sense a paradigm is a model or ideal, a standard of comparison, something to be emulated. Like its near synonyms 'archetype,' 'pattern,' 'template,' and 'prototype,' the word 'paradigm' is ambiguous, designating either a particular, concrete item or something more abstract and universal. A particular case may serve as a 'paradigm case.' An artwork or industrial prototype (a particular physical object) may serve as a model for replication. But a paradigm can also be a general type, pattern, template, matrix, or set of rules or specifications that the particular cases exemplify or embody. Since Kuhn regarded himself foremost as a philosopher, this article will emphasize the philosophical background and implications of Kuhn's work, while touching on contributions from other fields; and the focus will be on the early work for which he is best known. After the 1960s Kuhn took surprisingly little notice of the dramatic developments in the cognitive and complexity sciences that might have helped him articulate his position.

Kuhn employed several senses of 'paradigm' to describe and explain the development of mature sciences, that is, sciences such as physics (especially mechanics), chemistry, and evolutionary biology. During most of its history, according to Kuhn, the practitioners of such a science do 'normal science,' that is, science defined and guided by a paradigm. Occasionally, however, a crisis develops and a revolutionary paradigm shift may then occur. This 'paradigm change' language caught on in the politically turbulent 1960s and 1970s and was eventually uncritically extended to signify just about any major change in a policy or practice. The entry 'paradigm shift' appears in William Safire's dictionaries of American politics, and talk about 'breaking the rules' makes good advertising copy. There also have been scientifically serious extensions of Kuhn's work, as in theories of the cognitive development of children by Susan Carey and others. Among creativity theorists, Robert Sternberg's propulsion model (for example) extends Kuhnian insights to cover the range of movements through design space. On the other hand, those psychological and social theorists who believed they could quickly transform their enterprises

into mature, progressive sciences simply by deciding to adopt a paradigm had missed the point, Kuhn said.

The paradigm concept is important to studies of creativity at the personal, community/institutional, theoretical, and policy levels. Problem solving within a paradigm, according to Kuhn, requires conservative, convergent thinking, which other analysts have considered to be routine and hence modestly creative at best; while paradigm change signals bold, divergent thinking. Apparently, then, the best way to achieve creative innovation is to be divergent rather than convergent. A related view is that work within a paradigm is logical whereas paradigm changes involve nonlogical, rule-breaking, rhetorical moves. Some historically important thinkers and institutions have held that rhetoric has no place at all in serious intellectual enterprises. Kuhn challenged all of these received ideas.

Thomas Kuhn's Account of Paradigms and Scientific Creativity

According to Kuhn, an enterprise becomes a mature scientific discipline once it gains a paradigm that makes routine, consensual problem formulation and problem solving possible. The typical historical pattern of development of a mature science (one that has already achieved its initial, discipline-defining and unifying paradigm) is long periods of 'normal science' punctuated by occasional, short periods of 'extraordinary science,' that is, crisis situations that in some cases result in full-scale scientific revolutions. In those rare instances a new paradigm displaces the old and subsequently underwrites a new period of normal science strikingly different from the old one. Normal scientific problems are so well defined and highly constrained that Kuhn labeled them 'puzzles,' by analogy with crossword puzzles. The paradigm not only guarantees that the puzzle is solvable but also points fairly precisely toward its correct solution. Nonetheless, Kuhn insisted that even normal science is creative in its way. Extending the reach of the paradigm demands the best efforts of the brightest people. This is not drudgework. Moreover, disciplined normal science is essential in laying the groundwork for eventual crisis and revolution, for it is normal science's ability to focus on the most esoteric details that eventually produces the anomalies that resist all efforts to bring them into line with the paradigm; whence a crisis ensues.

Normal science involves highly convergent problem solving, whereas a revolution is so divergent that Kuhn introduced the term 'incommensurable' to describe the relation of the new paradigm (or lack thereof) to the old. The new paradigm points the science in a new direction, and work under the two paradigms is not mutually translatable. Since paradigms carry with them their own goals and standards, up to a point, scientists facing a revolutionary divide do not possess a single, coherent set of standards for evaluating the competing claims and practices. Kuhn emphasized that logic plus empirical data are insufficient to determine paradigm choice. (This is the most serious form of the so-called underdetermination problem.) Accordingly, members of the competing paradigm communities often reject each other's work as sloppy, out-of-date, or misguided. ("That's not the way to do good solid state physics!") Reliable signs of incommensurability are systematic communication breakdowns and failures to agree on what is a good problem and what counts as a solution. Lost is the "ease and fullness of communication" among practitioners and their "unanimity of agreement" over correct problem solutions – harmonies normally guaranteed by work within a common paradigm. Paradigm change is cultural change. A revolution splits the once tightly bound community of specialists.

According to Kuhn, revolutionary paradigm changes, although unpredictable, are inevitable, and we cannot expect them to become milder as a field matures and becomes even more tightly wound. This means that the growth of scientific knowledge, that is, scientific progress and scientific creative innovation, is not cumulative – a shocking conclusion that Kuhn claimed to find in his historical research as well as in his epistemological theory. Yesterday's scientific successes may be rejected or ignored today, and today's heretics may become tomorrow's heroes. However, the winners typically rewrite history to make the new paradigm appear to be the natural, rational, objective successor to the old. That, Kuhn wrote, is why paradigm shifts have been invisible to less historically sensitive analysts. (Moreover, the losers often rewrite their own history to make it seem to anticipate the change.) In advancing his controversial model of scientific development, Kuhn himself was attempting to overturn the old view of science as converging on the final truth by using a routine, scientific method. Most commentators agree that he succeeded in his critical aims but remain skeptical of his positive model.

As regards creativity, then, Kuhn seems committed to two varieties. The more modest sort of creativity involves working within a guiding framework that defines the research enterprise in that particular specialty area and thereby makes esoteric research intelligible. The divergent sort generates a new defining framework that sends the field in a different direction.

Educational psychologists from J. P. Guilford on have often operationally defined creativity as divergent thinking, as if divergence is part of the very meaning of 'creativity.' This view contains an important grain of truth; however, Kuhn largely rejected the view that creativity requires divergent thinking – although he would surely agree with psychologists such as Sternberg and Simonton that normal and revolutionary science feature different degrees of creativity. At least in mature, normal science, Kuhn claimed, innovation is normally the product of convergent thinking for the purpose of filling gaps in, and extending, the established paradigm. By contrast, the

human sciences and philosophy are too undisciplined, too divergent, to build consensual structures of theory and practice. They expend too much energy debating fundamental questions. Kuhn's paradox is that, in the mature sciences, convergent research is the most efficient means to divergent results. Convergent research is the fastest way to a revolutionary leap forward, since resistant anomalies can generate crisis and revolution. So divergent and convergent thinking cannot be decoupled in the way that some creativity experts have claimed, at least not in the sciences.

Kuhn's view also contrasts sharply with that of philosopher of science Karl Popper, who argued that the way to speed up scientific progress is to propose bold, conjectural hypotheses and then to criticize them as severely as possible by attempting to refute them. But to heed Popper's call for scientific revolution in perpetuity would have precisely the opposite result, Kuhn replied. It would destroy science as we know it. To label something a revolution only makes sense against a background of disciplined stability, for revolutions destabilize the constitutive framework that defines the activity in the first place. Popper's "critical approach to science and philosophy" is precisely what mature science excludes. For Kuhn a mature science is dogmatic. Mature, normal science shuns criticism of fundamentals and even discourages major innovation as disruptive.

It follows from Kuhn's view that a mature field must also be monolithic: it can possess only a one master paradigm at a time. To be sure, subspecialists within a larger field will work under their own smaller, specific paradigms, but these will articulate pieces of the overarching paradigm. This is a quite different situation from that found in the social and behavioral sciences, in which a large field divides up into loosely organized schools. Kuhn's year spent interacting with eminent social scientists at the Stanford Institute for Advanced Study in the Behavioral Sciences convinced him that social scientists are playing a very different game from that of physicists and chemists. The social sciences, he observed, remain too close to philosophy in inviting constant challenge to fundamentals.

Philosopher of science Imre Lakatos disagreed with Kuhn's monolithic claim, on both descriptive and normative grounds. Historically, the mature sciences have featured major, long-term research programs, he agreed, but usually two or three simultaneously, engaged in a quasi-Popperian competition. In this manner Lakatos attempted to strike a compromise between Popper's scattergun competition of isolated hypotheses and Kuhn's view that a single major research program characterizes each mature discipline. Meanwhile, Paul Feyerabend rejected both Kuhn's and Lakatos's view as too conservative. He advocated a proliferation of divergent theoretical claims ('methodological anarchism'), on the ground that testing one major theory against another is necessary to bring out its hidden empirical content. Kuhn found Feyerabend's celebration of divergent thinking absurdly impractical.

Kuhn's theme of an 'essential tension' between tradition and innovation affords a second perspective on his account of convergent and divergent thinking. Inquiry at the frontier of any creative enterprise involves a tension between convergent and divergent thinking. Every progressive field places a premium on creativity, which implies moving beyond the current frontier; but if a particular move is too divergent, it risks not

being recognized as a serious constructive contribution to that field. Margaret Boden's example is that an attempt to introduce atonal music in the seventeenth century would not have been recognized as music at all. Kuhn himself denied that the arts and humanities are as constrained as the mature sciences (a view since confirmed by extensive historico-psychological researches by Simonton and others). However, the general point seems to hold: insofar as a field permits less constrained contributions, it risks losing the coherence needed to recognize it as a rigorous scientific discipline at all. Esoteric research becomes pointless without a common basis of shared meaning and without a significant potential audience. That is why a crisis period is so traumatic for mature scientists. A full-scale revolution amounts to a culture change with the accompanying culture shock for traditional practitioners. Yet the revolutionaries typically insist that they are rescuing the discipline from crisis in such a way as to preserve its integrity.

Kuhn's account of scientific creativity differs from standard accounts of creativity in two additional ways. First, although highly routinized, Kuhnian normal science is not a rule-based enterprise that follows a 'scientific method.' It is misleading to regard Kuhnian paradigm shifts literally as changes in the rules of the game, although Kuhn himself sometimes employed such metaphors. Second, Kuhn denied that normal science is logical as opposed to rhetorical. He therefore rejected the traditional view, running from Plato down through Descartes and the Royal Society of London in the seventeenth to the twentieth-century logical empiricists, that serious inquiry must shun the corrupting influence of rhetoric and stick to logic. Kuhn was among those who insist that rhetorical tropes such as analogy, metaphor, and simile are crucial to creative conceptual and practical growth. He contended that normal research amounts to solving new puzzles by direct modeling on exemplars; and scientific education involves learning to use the exemplars as reference points in a network of 'learned similarity relations.' A paradigm carries the promise that its set of exemplars is sufficient to guide the process of solving any puzzle that can arise legitimately within that paradigm.

Normal scientists typically solve puzzles by rhetorically morphing the new puzzle and the old solution(s) until a sufficient match is obtained. One striking puzzle-solving genealogy that Kuhn provided begins with Galileo's realizing that a ball rolling down and then up a frictionless inclined plane is analogous to the motion of a point pendulum. Huygens subsequently transformed Galileo's solution of the problem of an idealized point pendulum into a solution of the physical pendulum problem. Decades later Daniel Bernoulli finally solved the apparently very different puzzle of the mechanics of fluid flow from the orifice of a tank. He did this by making his hydrodynamic phenomenon resemble Huygens' physical pendulum. The mechanistic paradigm under which he worked enabled him to see the two phenomena, and hence their mathematical explanation, as analogous. In this manner, a successful normal scientific paradigm integrates a variety of phenomena that don't appear at all similar to the layperson. And the integration is rhetorical rather than purely deductive or inductive, by contrast with the logical empiricist and Popperian conceptions of theoretical structures as deductive logical systems. In this respect, for Kuhn the overall structure of science is as rhetorical as it is logical. And the same is true for

his account of human cognition itself, a theme that Howard Margolis has developed. More recently, theorists such as Ronald Giere, Paul Teller, Nancy Nersessian, Paul Thagard, Hanne Andersen, Peter Barker, and Xiang Chen, building on the work of psychologists such as Eleanor Rosch and Lawrence Barsalou, have developed even more thoroughgoing accounts of the role of models in scientific work.

To sum up, a Kuhnian paradigm change (revolution) has five distinctive features. First, revolution implies successful revolt – overturning the old regime. Hence, a rapid advance, in itself, is not revolutionary. Relatedly, a paradigm shift does not typically result from a massive infusion of new empirical results. Rather, it amounts to a conceptual reorganization of the old materials. (Kuhn pointed out how thought experiments can function to alter basic structural intuitions.) Third, revolutionary overturnings do not occur in a vacuum, with the old regime simply giving way to anarchy. Rather, practitioners must be drawn to a new paradigm that they find more promising. The new one displaces the old, shoving it into the dustbin of history. As economist Joseph Schumpeter famously noted, as did Darwin before him, creative enterprises are also necessarily destructive. Fourth, in any progressive, creative, mature scientific discipline, revolutions are necessary, occasionally, to break free of the prison of the old framework. Fifth, paradigm change is wrenching cultural change that temporarily destroys community solidarity.

Some Questions and Criticisms of Kuhn's Account

Kuhn's model of scientific development has attracted a great deal of attention, both favorable and critical. It kicked off the 'battle of the big systems' that characterized attempts in the 1960s and 1970s to provide comprehensive models of scientific development. Few analysts now pursue this project, given the emphasis in social studies of science on the diversity of the various sciences and their shaping by socio-political and technological context – developments that Kuhn's work also stimulated. Kuhn was accused of relativism and irrationalism and vilified as a debunker of our more progressive institution. Donald Davidson argued that the idea of alternative conceptual schemes is incoherent.

Stephen Toulmin contended that Kuhn remained too close to the logical empiricists in positing an overly rigid and inflexible account of normal science and, as a consequence, was forced to introduce overly revolutionary breakouts from the old framework. Kuhn could claim to find such dramatic ruptures only because he attempted to project in the forward direction of scientific work the intellectual shock he experienced as a novice historian of science when he had to jump back across the centuries to make sense of the physics of Aristotle in comparison with that of Galileo and Newton. Working scientists at the research frontier are opportunistic pragmatists, the criticism runs, not sensitive historians – nor rigorous mathematicians either. Rigorous mathematics is for mathematicians, and history is for historians.

Toulmin, David Hull, and others proposed thoroughgoing evolutionary models of scientific development. Already in the late 1950s, psychologist Donald Campbell had proposed a universal evolution model of creativity, including scientific

advance. Richard Dawkins, Daniel Dennett, and others followed with their own versions. According to universal evolutionists, selectionist mechanisms suffice to explain not only all biological life, wherever in the universe it has arisen, but also all production of novel design, including that of human arts and technologies.

On this account, selectionist processes are the secret to creativity – the key to understanding creativity and innovation of all kinds, albeit a highly abstract or general key. Darwin discovered the power of selectionist mechanisms in the biological and behavioral realms. William James, B. F. Skinner, computer scientist John Holland, and many others since have greatly extended the scope of selectionist models to the degree that they are now routinely used to ‘evolve’ problem solutions on a computer under such labels as ‘evolutionary computation’ and ‘genetic algorithms.’ These variation-selection methods are generally not strictly analogous to biological evolution. The latter is just one (in fact, several) of a large family of selectionist mechanisms. All selectionist mechanisms, however, involve a highly iterated process of somewhat constrained but otherwise undirected variation plus a process of selection of superior variants plus a mechanism for passing the advantageous features, to some degree, to the next generation of variants.

Campbell argues that all innovation, all increases of fit to relevant environment, must, at least, be the product of BVSR: partially blind (undirected) variation plus selective retention of variants that happen to survive in the existing environment upon pain of commitment to providentialism, inductive instructionism, or a mysterious, nonnatural clairvoyance.

The BVSR models sound divergent, but the variation can be so constrained, so local and limited, that it is part of an overall convergent process in Guilford’s sense. In Kuhnian normal science, the variants produced amount to blind trial and error only within whatever search space remains for exploration after the known constraints have narrowed the search considerably.

If something like Kuhnian normal and revolutionary science exist, is an evolutionary account of creativity sufficient to explain both? Here one thinks of Stephen Jay Gould and Niles Eldredge’s account of ‘punctuated equilibrium’ to explain the long periods of stasis in the biological record, interrupted by periods of rapid innovation such as the Cambrian explosion. Complexity theorists such as Stuart Kauffman and Brian Goodwin also maintain that emergent structures that transform complex systems often have a more creative role in the biological world than Darwinian evolution does, a central issue of today’s evolutionary developmental biology (Evo-Devo). If these authors are correct, there are two major sources of emergent novelty, not one. Other complexity theorists such as Per Bak contend that no special explanation is needed for Kuhnian revolutions and other sorts of cascading failures such as mass extinctions, on the grounds that these systems are highly nonlinear. A quite ordinary development can occasionally trigger a major event.

Cognitive Economy: Categories, Sets, Schemas, Frames, etc.

At the most elementary level, it is obvious that we must lump and split into usable categories the ‘bloomin’ buzzin’

confusion’ of world input (as William James called it). Given our cognitive limitations, we cannot track each individual item separately but must organize experience, thought, and action into general kinds of things and standardized types of interactions. We must impose pattern on the world, and we thereby run the risk of stereotyping, or worse. Cognitive sets govern our interaction with the world and with each other, and Kuhn’s paradigms are cognitive sets or conceptual ‘boxes’ writ large.

The idea of a conceptual scheme or framework supported by a complex of cognitive processing rules originated with the philosopher Immanuel Kant (d. 1804), who was also, arguably, the first sophisticated cognitive psychologist. Kant held that all human beings represent their experience of the world in terms of a dozen underlying ‘categories’ plus two ‘forms of intuition’ – space and time – so that we perceptually project the world in terms of physical objects causally interacting with one another in space and time. This was a major improvement on the radical empiricist theories of associationist philosopher-psychologists such as David Hume, for it recognized the need for cognitive rules or regularized processes of some kind to account for the integration and coherence of our perception and thought. For Kant, Newtonian mechanics was the outward projection of our inward processing rules.

The cost of Kant’s ingenious account of cognition and of Newtonian science is that it presents us with the problem of skepticism about our knowledge of the universe. For if the world input must be transformed in various ways so that we can make sense of it, what reason do we then have to believe that ours is the correct representation of the universe as it really is? Isn’t the world as we experience it just a creative fabrication of our own minds or perhaps of our cultures and languages? Kant’s response was to deny that we could know the “things in themselves.” Our best science will always be the science of the world as we humans experience it. While the real world does make a contribution to the content of our experience, the constitutive form of that experience is imposed by the human mind. As Kant put it, the mind does not draw its laws from nature but imposes them on nature. This is one important version of the position known as idealism.

For Kant the system of categories was absolute and unchangeable, innately prewired, so to speak. But once he formulated the idea of a comprehensive conceptual framework, it was not long before the philosopher G. W. F. Hegel introduced the idea of alternative conceptual frameworks. In Hegel’s grand vision, the major epochs of human history are structured by different conceptual frameworks. However, the ultimate source of the frameworks themselves is neither nature nor the human mind but human social life – nurture, not nature – and historians have confirmed that social formations have undergone major historical changes. Thus Hegel postulated a kind of sociological reversal of the received views of mind and world: rather than society at large reflecting the structure of the individual human mind, we individuals acquire our cognitive apparatus from the social milieu into which we are born.

Informed by the deep, German historiographical work of his day, Hegel’s radically historicist position implied a completely new conception of creativity and its generation:

1. The creative projection that we call human experience is not innate but learned from the cultural system into which we are born.
2. Human history itself is radically creative in the sense that major new formations such as the modern nation-state, capitalist economic systems, and conceptions of human nature are not eternal entities but instead come into existence in historical time.
3. The most novel structures are not the product of intelligent human design, however, for such novel designs are beyond the horizon of imagination of people living during the time that those structures emerge. Rather, the latter are the unintended and unconscious consequences of a vastly parallel process of people going about their daily lives.
4. Therefore, people living in different historical periods literally "live in different worlds" of human experience.
5. Hence, there exists no permanent system of representation. Even the self-evident truths of one epoch may not be recognized as such in others.
6. This model, like Darwin's, implies that intelligence is not at all necessary for adaptive creativity. Creativity, and especially creative innovation, has more to do with distributed processes of complex systems.

No one doubts that imagination outruns our rational justification capacities, but Hegel broached the idea that non-conscious processes outrun in creative originality all forms of deliberate human design, even those based on the most active imagination. Later in the nineteenth century, Darwin also dispensed with intelligent design in explaining the emergence of novel biological design from the massively parallel process of natural selection, in which every single organism is a natural biological experiment.

This background provides a larger context within which to locate current discussions of creativity, including Kuhnian paradigm shifts, for Kuhn's paradigm concept owes much to Kant's formal framework of categories. Kuhn's move away from logical empiricism parallels Kant's move away from Hume, also parallels Hegel's subsequent move away from Kant – and raises many of the same difficulties. Kuhn frequently described his conception of science as "Kantian with moveable categories," and his most radical statement of the incommensurability of competing paradigms was that scientists on opposite sides of a paradigm shift "live in different worlds" – worlds historically created by research that constitutes the paradigm and the corresponding education regimen. The implication, from which Kuhn soon retreated somewhat, is that scientific revolutionaries and their followers are creators of new worlds. Kuhnian paradigms are 'moveable' and, in this respect Hegelian, since science students educated within different paradigms will acquire different cognitive programming. Beyond knowing what are the exemplary problems and solutions, this 'knowledge' of the world remains largely tacit, however (an idea that Kuhn apparently borrowed from the physical chemist Michael Polanyi). The programming is not available as an explicit scientific method any more than it was for Kant or Hegel. Present in Kuhn is also the idea that major innovation is largely the unwitting by-product of communities of scientists going about their normal scientific work, thinking that they are providing true descriptions and explanations of the world

while actually producing fuel for the next paradigm debate. For Kuhn there exists no true final theory of the world, since there is any number of ways in which we might successfully construe it. There is no end to future science. Nonetheless, Kuhn denied that he was a relativist and insisted that there is a clear sense in which scientific paradigm shifts represent genuine progress.

Work by francophones Ferdinand de Saussure, Gaston Bachelard, Georges Canguilhem, Claude Lévi-Strauss, Michel Foucault, and others anticipated or paralleled Kuhn's themes. Writing early in the twentieth century, Saussure treated language as a relational system. Particular words are arbitrary. They derive their meaning from their complex web of relations to one another. Change the relations and you change the meaning. The so-called structuralists took up this idea, and we find something similar in Kuhn. Insofar as the meaning of scientific terms is constituted by a relational system, a systemic reorganization alters meaning and thus, after all, injects new content of one sort into a Kuhnian paradigm.

Bachelard and Canguilhem held that the underlying organizational structures occasionally rupture to produce new forms of scientific life, and Foucault introduced large discursive formations or *epistèmes* that demarcated historical periods in terms of constellations of thought and practice far more pervasive than Kuhn's. Recently, Ian Hacking has built on Foucault's insights by promoting the idea of 'historical ontology,' according to which the conceptual grids of thought and practice that we lay down bring into existence a host of entities such as statistical averages, population cohorts, and diseases that did not exist before. Scientists themselves create many features of the reality that they study!

Recent work on the history of logical empiricism has revealed the surprisingly strong neo-Kantian influence even in that movement, calling into question the received view that it was simply old empiricist wine in new logical bottles. Particularly Hans Reichenbach and Rudolf Carnap anticipated Kuhn's conclusion that the science of a given period is underlain by an *a priori* structure of a sort. Michael Friedman terms this a "historically relative but constitutive *a priori*." He strongly defends one use that Kant made of the *a priori*, arguing that disciplined inquiry requires a stable framework or constitutive intellectual grid on which to operate. Friedman ends up accepting the existence of Kuhnian revolutions (although with greater continuity), especially those involving the profound mathematical changes in the history of space-time theories.

In artificial intelligence, too, we find attempts to organize inputs and outputs into larger structures. Schemas, frames, and scripts are three examples of structures postulated to explain how we (or computers) recognize and classify items and situations. There has also been much recent work on case-based and model-based reasoning, in which human beings or computer programs attempt to solve new problems by modeling them on one or more already solved problems stored in a case library, rather than using rules to derive a solution from scratch each time. This seems close to what Kuhn had in mind with his idea of exemplars. American law, business, and medical schools much use of the case method. Critics hold that human beings as well as computers must really be using rules at subconscious levels, for example, rules for finding similar cases. But as the philosopher Ludwig Wittgenstein noted, we must avoid the vicious regress of rules, rules for applying those rules, and so

on. At some point a more direct mechanism must take over. Psychologist Eleanor Rosch and associates have long contended that people recognize birds, chairs, and most everything else not by applying sets of necessary and sufficient rules or definitions of 'bird' and 'chair' but instead by matching the new item to a stored model or prototype. Rules tend to have an all-or-nothing character: something is either a bird or it is not, while human judgment seems to operate with something like a Kuhnian or Roschian similarity metric that admits of degrees of resemblance. Thus we judge a robin to be a more typical bird (and more easily recognized as a bird) than a penguin is, and legal experts judge a new case as resembling one precedent more closely than another. Once again, rhetorical matching and stretching turn out to be as fundamental to cognition as logic is.

Conclusion

The focus of this article is Thomas Kuhn's study of scientific revolutions in the mature sciences, but others have extended the term 'paradigm shift' far beyond Kuhn's intentions, especially to political and business contexts. Although problematic, Kuhn's work on paradigm change challenges previously dominant conceptions of inquiry and creativity by contending that scientific research involves major 'Kantian' framework presuppositions that are not directly testable but instead constitute the very intelligibility of the various fields of specialization. Both 'normal science' and 'revolutionary science' are creative, but in different ways. The article locates Kuhn's ideas in terms of intellectual history and briefly indicates connections of Kuhn's ideas to Darwinian conceptions of creative inquiry and their critics, including recent work in cognitive psychology, artificial intelligence, and complexity theory.

Perception and Creativity

E Nečka, Jagiellonian University, Krakow, Poland

© 2011 Elsevier Inc. All rights reserved.

Glossary

Allocentric perception The tendency to perceive nonhuman objects from their own perspective.

Laws of perception Universal, automatic, and inborn principles through which organisms perceive complex stimuli.

Perceptual learning Perceiving complex objects better and better thanks to systematic exposure to them.

Physiognomic perception The tendency to perceive feelings and motion in inanimate objects.

Visual thinking Thinking in images rather than words.

Perception is the process through which people acquire, interpret, and organize information coming from their sensory organs. It starts with sensory registration of the information and ends with construction of mental representations of the perceived object. Perception influences every act of creation because the way people perceive things determines how they think about things. If perception is inventive, it leads to creative thinking, but if it is mundane, the result cannot be especially amazing.

Creative Organization of Perception

Perception is not just passive reception of incoming stimuli, but involves active construction of mental representations. The classic viewpoint, rooted in philosophical associationism and introspective psychology but also typical of lay theories of the human mind, assumes that perceptual experience is the sum of simple, basic sensations, such as sounds, odors, or flashes of light. According to this standpoint, perception of a red square, for instance, amounts to summing up basic sensations of straight lines, angles, and redness. Objects are assumed to be perceived in the same way regardless of external conditions (unless these are extremely difficult or atypical) and notwithstanding internal states of mind (unless the mind is disturbed, as in the case of illusions or hallucinations). Their perception is also regarded as independent of individual differences: all people are supposed to see a red square in the same way, although they may differ in personality, values, life history, culture, and many other dimensions.

The classic view was first questioned by *Gestalt psychology*, particularly Kurt Koffka, Max Wertheimer, and Wolfgang Köhler. According to them, people perceive the world in a holistic way, that is, they see the 'forest before the trees.' The primacy of high-level structures over basic sensations is supposedly possible thanks to the so-called '*laws of perception*,' which are universal, inborn, and automatically triggered by incoming stimuli. For instance, the law of continuity makes people perceive separate elements (e.g., stones) as something more complex (e.g., a road) due to the fact that separate elements are arranged in a way that suggests spatial continuity. The law of similarity makes people perceive a set of objects (e.g., basketball players) as a unity (a team) thanks to their being dressed identically. And the law of closure is responsible for perception

of 'flawed' or 'incomplete' objects as if they were 'fixed,' that is, closer to their ideal representations. For instance, on being exposed to an incomplete circle people still see a circle, although they are aware of its imperfections.

If perception is organized according to Gestalt laws, it must be regarded as creative by nature. In other words, people demonstrate creativity in every act of perception, because they are able to compose complex and holistic mental representations before, if ever, they focus on details. The law of closure seems particularly important from this point of view. A human tendency to 'improve' in the mind objects which, in reality, are not perfect at all takes many different forms, some of which are not entirely perceptual in nature. For instance, an unsolved problem may be perceived as an incomplete figure that needs completion; a decision not made yet may be represented in the mind as something that needs improvement. Therefore, the need for closure postulated by the Gestalt school usually leads to enormous mental transformations, potentially resulting in new and valuable (i.e., creative) products, although if the closure is premature, the results may lack relevance and effectiveness, and thus creativity. Perception of the problem at hand is not synonymous with perception of relatively simple physical objects, in the sense that the former involves not only perceptual but also thinking processes, but the tendency to 'improve in the mind' objects that lack perfection seems very similar in both cases.

A question arises, though, whether this tendency to create complex, holistic representations has different levels of intensity depending on abilities, personality, temperament, and other individual traits. The Gestalt psychologists were not interested in individual differences; rather, they focused on general laws of perception. But if the Gestalt laws are universal, inborn, and therefore stable across individuals, perception may be called creative only in a very specific sense, namely, as a creative 'invention' of nature or evolution, but not from an individual person's point of view. If, on the other hand, these laws are common and universal but acquired through development and therefore much more differentiated among individuals than the Gestalt psychologists would like to admit, we can hypothesize that some persons are more skillful in the creation of holistic perceptual representations than others.

This problem was investigated by Morris Stein who exposed his participants to Rorschach inkblots for different durations, that is, 10, 100, 3000ms, or without any time pressure.

The task was to interpret every inkblot by saying what was shown in a given picture. Participants' interpretations were evaluated for consistency and integrity. Responses with some central organizing idea were ranked higher than responses focused on separate details. People who provided consistent and integrated interpretations in the case of very complex inkblots and were able to do so in spite of time pressure obtained particularly high scores. It appeared that the individual scores of integrity of perception correlated very highly ($r = + 0.88$) with peer rated creativity. It seems, then, that even though all people perceive the external world through complex, holistic, and meaningful ideas, some people are particularly good at this task and such people are judged more creative than others.

Physiognomic and Allocentric Perception

The classic view of perception was also questioned by the so-called New Look approach. According to Jerome Bruner, people perceive the external world through their internal states, particularly motivational factors, like needs and goals. For instance, hungry people are set to smell food easily, poor children tend to overestimate the size of coins, and anxious people usually notice signals of threat everywhere in the environment. These effects are first described under the labels of perceptual defense and perceptual sensitivity. Internal states of mind are regarded as essential factors in perception and the interpretation of external events. In general, subjective feelings influence perception to a great extent, particularly if perceived objects show incoherence or ambiguity.

If perception is affected by inner states of mind, mental states can be projected onto external objects. In particular, people can attribute feelings and emotions to non-living creatures, which is called *physiognomic perception*. The term comes from Heinz Werner who defined it as the ability to perceive affect in inanimate things, as well as a tendency to see dynamic movements in normally static objects. For instance, people say that a stone is angry, a book is dancing, or a house is missing its residents. Perceptions of this kind are creative in a sense, because they produce results (i.e., a mental representation of an angry stone, etc.) that are both novel and appropriate. Furthermore, they may lead to eminent creativity if transformed into pieces of art or poetry. Everything depends on the amount of novelty and appropriateness. If it is small, physiognomic perception is just an act of everyday creativity, that is, a kind of potential rather than actual achievement. But if the amount of novelty and appropriateness is large, this phenomenon results in eminent pieces of art.

Physiognomic perception has been demonstrated in experimental studies of creative visual perception. Participants were exposed to a series of drawings representing 'still life.' Exposure time was very short at the beginning of every series (10ms) but was made systematically longer and longer. Participants were asked to interpret the drawings by giving them meanings and titles. The authors were interested in the extent to which these interpretations violated the realistic, usual ways of perceiving objects. As the exposure time was increased, the interpretations became more and more realistic, which makes sense because an object shown for several hundred milliseconds is more

explicit and less ambiguous if compared with the same object shown for a much shorter period. The series would stop when a person used the 'proper' name of the object. The drawings were then presented in a series with systematically decreasing exposure time, which resulted in increasing frequency of idiosyncratic and unusual interpretations. The authors believed that the number of original and idiosyncratic interpretations represents the creative potential of a person.

Psychologists make use of the phenomenon of physiognomic perception in two ways. First, there are attempts to assess individual creativity by means of physiognomic perception ability. The Physiognomic Cue test consists of schematic drawings that may be interpreted in one of two ways suggested to a testee. The first interpretation is commonplace, such as 'sun,' the second is more original and 'physiognomic,' such as 'joy.' People are asked to indicate a preference for one of these two interpretations using a standard Likert scale. Second, physiognomic perception is widely used in creativity enhancement and training. Participants in such training may be asked to attribute feelings to bricks, or to imagine social interactions between pieces of furniture. Such exercises improve creative imagination and creative skills through deliberate manipulation of human perception.

A term very close to physiognomic perception is *allocentric perception*. Ernest Schachtel uses this term in reference to a tendency to perceive nonhuman objects from their own perspective. The opposite tendency, called *autocentric perception*, consists in perception of nonhuman objects from a purely human point of view. For example, the autocentric perception of a laptop computer would concentrate on its functions, the extent to which it is useful or useless for humans, or its potential to be improved as an even better tool for humans. The allocentric perception, on the other hand, would concentrate on the laptop's traits and attributes that surpass its human-centered functions. In other words, in allocentric perception people concentrate on the laptop as such, not on the laptop as a tool. This kind of perception may be difficult in the case of artifacts, that is, objects made by people for some specific purpose. In such cases, autocentric perception looks natural and easy, whereas nature can be perceived in the more allocentric way. According to Schachtel, allocentric perception is a key to creativity, particularly in fine arts.

Visual Thinking

Humans, in opposition to other species, can perceive the external world through images or through words. In consequence, they can think and process information in two modes: verbal and nonverbal. According to Allan Paivio, humans have two mental systems based on separate codes of information processing. The verbal system uses so-called logogens as forms of representation, whereas the nonverbal system is based on representations called imagens. These two systems can cooperate, meaning that a piece of information obtained through the nonverbal channel can be verbalized, while verbal information can be expressed in mental images. However, one of these systems has priority in given situations, which means that sometimes the processes of translation from words to images or vice versa results in error or inadequacy.

The dual coding theory has consequences for creativity. First, the question arises to what extent images can be equivalent to words or vice versa. Rudolf Arnheim is a persuasive advocate for the idea that people can think with images as efficiently as they can with words, if not better. An act of artistic creativity is just an act of thinking and reasoning with images. Artists can solve problems without words because images, not words, are primary components of their thinking. This idea of Arnheim's is close to the Freudian notion of primary processes, which – apart from being impulsive and unconstrained – were assumed to be imaginary in nature. Visual thinking is perhaps vital for artistic creativity and less common in other domains, such as scientific or technological creativity, although introspective data from eminent scientists, including Albert Einstein, do not leave any doubt concerning the importance of mental images in problem solving. The same should be said about literature and poetry; although writers operate with words, they must constantly visualize. The use of metaphor is an interesting example of how verbal and nonverbal codes cooperate in production of something that is called 'figurative language.'

Second, the question can be put whether mere exchange between verbal and nonverbal systems can increase the likelihood of creative outcomes. Conceivably none of these systems is more creative by nature, but their interaction may result in remarkable outputs. The use of metaphor in poetry looks again like a perfect illustration of such an output. Typically, culture relies on words; therefore, the mere change of code to nonverbal must produce original effects. Writing and reading is the dominant mode of cultural exchange and tradition. If the culture were rooted in images rather than words, verbalization instead of visualization would be regarded as a potentially creative action. Arnheim claims that all thinking, not only in artistic creativity, operates on visual representations, and this idea may look exaggerated, but a more moderate idea that creativity is stimulated by exchange between words and images looks acceptable.

Perception and Appreciation of Art

Perception is important not only for production of novel and valuable, or at least appropriate, ideas but also in understanding and appreciating them. Without sensitive and well-prepared audiences, creativity would be useless; one can even doubt if it would appear at all. The problem seems particularly important in the field of art education.

People can be taught how to listen to music or how to appreciate a painting, although 'naïve' and unprepared perception may have the value of fresh, uncontaminated experience. People may prefer listening to a piece of music without too much knowledge about the composer, his or her biography, or the particular musical genre. The same is true of visual arts: sometimes it is better not to know too much about the artist and his or her style of painting. One does not need to know the culinary details in order to be fond of food. However, we should not ignore the fact that knowledge influences the way people perceive pieces of art to an enormous extent.

There are two ways of studying perception in cognitive psychology and cognitive science. The bottom-up approach

to perception underscores the importance of basic sensory processes, deeply rooted in the physiology of vision, hearing, and other senses. The top-down approach to perception underlines the importance of psychological traits and states as factors determining the way objects are perceived. These factors include mental sets, expectations, feelings and emotions, values, abilities, personality traits, and complex models of the world. Any act of perceiving needs both bottom-up and top-down processes, although their proportion may differ depending on the object of perception and the overall context in which it is being perceived. For instance, listening to birds' singing is less dependent on acquired knowledge than listening to human speech, simply because the former does not involve semantics and the latter would be impossible without acquired knowledge of the meaning of words. If a person listening to birds singing is an ornithologist, his or her knowledge may be more important and more influential than in the case of lay listeners. Still, the amount of top-down processes is relatively small if listening to birds is compared with speech comprehension.

Previously acquired knowledge may affect current perception in a negative way. First, it accounts for the perceptual constancy effect. For example, people perceive grass as green regardless of light conditions, although sometimes grass reflects light in a way that produces the color of blue or violet. People know that normally grass is of green color; therefore they usually cannot perceive it as blue or violet. Similarly, they know the actual size and shape of well-known objects and therefore perceive them correctly, regardless of disproportions that may arise from seeing them from a distance or at a specific angle. Perceptual constancy is beneficial in standard situations requiring 'normal,' mundane perception, but it may hinder appreciation and acceptance of particular styles of expression in visual arts. The impressionists painted grass in many different colors, usually not in green. Second, previously acquired knowledge is likely to cause perceptual set. People are likely to see (hear, sense, etc.) what they expect to see, and the opposite is also true – they are unlikely to notice things that they do not expect to exist or appear in the particular circumstances. Perceptual set is so strong that people can swear they did not see objects that were shown to them but did not fit the scene. For instance, if shown a photograph of a professor's study they are sure that they saw many books on the shelves although, as it happened, there were no books whatsoever in this particular photo. They know that professors have many books and this knowledge is likely to disturb reliable perception of a particular image. Such effects, clearly demonstrated in laboratory experiments, influence the way people listen to music or appreciate paintings.

Previously acquired knowledge may also be useful in art understanding and appreciation. First of all, knowledge makes people sensitive to those aspects of a piece of art that are less salient than others but still very important. For instance, listening to a Bach fugue requires at least basic acquaintance with the structure of this particular musical form, that is, the idea of different transformations of the same motive pursuing one another. Moreover, knowledge helps perceive similarities between an object of perception and other objects, and therefore stimulates thinking by analogy.

Perception is influenced not only by explicit knowledge that can be acquired through art education but also by implicit

knowledge rooted in one's own experience. Frequent exposure to a complex stimulus, such as a painting or musical composition, makes people more and more sensitive to many concealed aspects of this stimulus. This is the phenomenon called *perceptual learning*. Typically, people are not aware of being better and better prepared for analysis of a complex structure, because these processes take place automatically. Perceptual learning improves sensitivity to previously concealed aspects of stimulation thanks to attention weighting, imprinting, unitization, and differentiation.

Attention weighting involves a change in the amount of attention paid to different aspects of a stimulus as a result of learning. If people 'inspect' a favorite painting many times, they can learn to direct their attention to those aspects of the painting that were entirely concealed from them at the beginning of the learning process. Imprinting amounts to development of specialized receptors or modules of the mind that can capture previously concealed aspects of a stimulus. Unitization is the process of combining previously separated aspects of stimulation, and differentiation is the opposite – it is the process of dividing what used to be perceived as a whole. These four mechanisms of perceptual learning can produce enormous change in people's sensitivity to various aspects of stimulation. They are particularly important in art education because pieces of art are usually very rich in stimulation.

Repeated exposure to an object results not only in perceptual learning but also in changes in its esthetic appreciation. This phenomenon is called the 'mere exposition' effect. A melody heard for the first time may not be appealing, but it tends to gain artistic value if played repeatedly. Of course, there are limits to such increases in attractiveness, meaning that the melody soon becomes 'worn out.' This is rarely the case with Beethoven's or Bach's compositions, but happens quite frequently with pop music and pop art in general. It seems that high-level creativity is less dependent on the mere exposition effect but also more resistant to depletion of artistic power due to the process of familiarization.

Conclusions

Perception is an ambiguous term. In a broad sense, it refers to every instance of mental assimilation of an object, not only physical but also social or symbolic. In this broad sense it is possible to speak of perception of the social climate or perception of US policy around the world. In the narrow, technical sense, perception means construction of mental representations on the basis of sensory processes, mostly auditory and visual. This article focused on the narrow sense of the word. However, perception is important in creativity in the broad sense too. In particular, the way people perceive a problem is of utmost importance for creative problem solving. Inadequate or stereotyped problem perception may result in adoption of inappropriate problem solving strategies or general inability to tackle the difficulty. Although very important, these issues refer to thinking and problem solving rather than perception per se.

Personal Creativity

M A Runco, University of Georgia, Athens, GA, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Discretion Knowing when to be creative and when to be conventional instead.

Intentions Usually a reflection of a value system and may lead to mindful efforts and are thus often apparent in what the person is motivated to do.

Interpretation The result of cognitive processes, and in particular those involved in the construction of meaning.

Personal creativity Original and effective thinking and behavior that may have no social expression and may not lead to manifest product.

Self actualization The highest form of psychological health that allows true spontaneity and the expression of authenticity.

Introduction

Scientific theories are not static. They develop and change. Some things are added, some are refuted and taken away. Hopefully there is progress, which means that a better understanding of ourselves and our world is constructed. What is unique to the sciences is that the methods, standards, and goals are maximally objective.

Creativity studies have adopted objective methods, standards, and goals and have thus become quite scientific. Yet creativity studies are in some ways unique. The topic, creativity, is different from all other human behaviors and potentials, for example, and this translates into unique difficulties for scientific research on the topic. Few other research topics are as unpredictable as creativity. Indeed, creativity is by definition unpredictable because originality is required. If something is original, it is unlike everything that came before it and is therefore unpredictable.

An enormous stride toward scientific respectability was made when J. P. Guilford, President elect of the American Psychological Association, argued so convincingly for empirical studies of creativity. He described creativity as a natural resource and pointed to the pressing need to invest in both its study and its encouragement. He also described various methods for the study of creativity, or at least for the study of creative potential. His own structure of intellect model has proven to be quite useful and, although it has been around for decades, is still cited with regularity. Another large step was taken at the *Institute for Personality Research and Assessment* (IPAR), not long after Guilford's Presidential address in 1949. Objective information about architects, writers, and various other professional groups was collected at IPAR, mostly with reliable personality inventories and tests of cognitive skill and style. In this manner a great deal was learned about domain differences, and all kinds of objective information about those creative professions was reported in the psychological literature.

Personal Creativity and Optimal Objectivity

The theory of personal creativity is much newer than the work at IPAR and those other seminal efforts. It differs from them

because it views the highly objective work to be incomplete. It suggests that we can be too objective about creativity, and if we are, we lose the most important part of creativity, which is in fact personal and is therefore not entirely objective. This may sound like an extreme claim about what is most important but it is based on the fact that personal creativity is required for everyday and ordinary creative problem solving, as well as world class creative achievement. World class creative achievement certainly requires more than personal creativity, including persistence, determination, large and diverse knowledge bases, and social impact, but it starts with the same personal processes that characterize everyday and ordinary creativity. Personal creativity is in that sense a prerequisite to all creativity. This article briefly describes the theory of personal creativity. Since it was developed largely as a response to social and product views of creativity, it begins with a summary of them, to put personal creativity into context.

Product Views of Creativity

Products represent one of the primary strands in creativity studies. The other strands, according to the 4P framework, include process, person, and press (or place). There really are several product strands. One focuses on tangible results of creative work. There is, for example, a detailed 'matrix' for assessing products which can be used with all kinds of things, from chairs to new tools for writing. Robert Weber has also presented detailed analyses of individual products, though his interest seems to be more in invention than in isolating the characteristics of creative products. Inventions certainly represent a good example of creative products. A list of creative products would also include works of art (e.g., paintings), compositions, publications, presentations, performances, copyrights, patents, motion pictures, films, or videos, computer software, 'apps' for cellphones, designs, and video games.

Many of these imply that product research involves only the work of adults, but checklists of productivity have also been used successfully with adolescents. These tend to be used as criteria in studies of predictive validity or longitudinal research. Almost always the score provided by such checklists reflects the quantity of creative work (the number of products, and

perhaps the number of awards and the like as well) rather than their quality. In fact this leads us to the second way that products are used in creativity research. Sometimes the kind of product is entirely disregarded and the issue is on *productivity*. Here the products themselves are not important at all; the only concern is with the count or quantity of things produced. Research using productivity may not even identify the products; it may just analyze some number that represents how many things each participant produced. Not surprisingly, this kind of research is often archival. It may involve an analysis of age, for example, and thus look to encyclopedias or other records to see how many things tend to be produced when the creator is in his or her twenties, in comparison to how many are produced when the creator is in his or her thirties, forties, fifties, and so on. This kind of developmental comparison is interesting, but the connection between productivity and creativity is dubious at best.

Social theories of creativity do not make the same mistake. They take quality into account by examining judgments or attributions of creativity, originality, aesthetic appeal, and effectiveness. Some of this work is still historical, in which case some of the issues mentioned above are still apparent. But sometimes judgments are obtained in experimental research and used as data. Judges in the consensual assessment method, for example, are explicitly asked to rate poems, collages, or the like for creativity, in which case there is still a reliance on the product.

Systems theories of creativity, which are quite popular, assume that attributions by judges are required of all creative work. In the best known systems theory of creativity, an individual produces an original idea, and if its value is recognized (which assumes that the domain and culture value work in that domain), the idea may become known by others working in the field. If it is truly a good idea, it may change the way they think, and thus become part of the shared knowledge base and assumptions of the domain. Individuals entering the domain at that point will therefore be exposed to that idea as a part of the existing dogma, in which case the idea has gone the full cycle, from a person, to the field, to the domain, and then to other individuals. In the extreme view of this kind of systems theory, a creative idea is only creative when it survives the entire system and has interpersonal impact.

There are several problems with product, social, and systems views of creativity. Some are circumvented by the theory of personal creativity. Indeed, the theory of personal creativity was developed in direct response to what was seen as an exaggerated and unrealistic use of products and social attributions and judgments in theories of and research on creativity. Put differently, the theory of personal creativity was proposed to insure that the scientific study of creativity does not go too far in the direction of objectivity. Social and product theories of creativity are highly objective – products can be counted, interrater reliability easily determined – but too often they exclude much of what is most important about creativity.

The most notable problem with product and attributional theories of creativity may be that they focus on the results of creative work – the products that result from creative efforts or the reactions by some audience to the creative person or the products. They dismiss the process used. This is unfortunate because if we really want to understand creativity in a way that will allow its encouragement, the process and underlying

mechanism must be defined. Product and social theories do not allow that. They focus on reactions rather than on creation.

A second problem involves historical shifts and revisions. The basic idea here is that attributions of creativity change. They vary from era to era. This kind of variability indicates that social judgments are unreliable. Indeed, reliability is defined in terms of consistency and stability. How can we rely on social judgments if a person is deemed creative at one point in time but not creative later? Examples of this are easy to find (e.g., Rembrandt). Clearly social judgment is indicative of more than creative talent. It reflects many factors that are extraneous to creative talent (including luck!) and are much more indicative of fame, reputation, impact, and the like.

Defining Personal Creativity

The theory of personal creativity focuses on the individual. No impact or reputation is required, which separates personal creativity from social and systems perspectives. Personal creativity is, on the other hand, congruent with the humanistic view. As exemplified by Carl Rogers and Abraham Maslow, humanistic views of creativity emphasize self-expression and self-actualization and de-emphasize products, attributions, and the like. Both Rogers and Maslow eventually concluded that creativity and self-actualization are inextricable from one another. That suggests a divergence of the theory of personal creativity and the humanistic approach. The latter is tied to a definition of psychological health that is not a part of the former.

Probably more important is that the theory of personal creativity makes precise predictions about the mechanisms that are required for all creative achievements. As implied above, this mechanism is involved not only in children's creativity and the everyday creative problem solving of noneminent persons as they go through their day to day lives. It is the same mechanism that is used by eminent creators as they strive to solve large-scale problems or produce world-shaking work.

Personal creativity involves (a) the construction of original interpretations of experience, (b) the intent to construct and use those interpretations, and (c) the discretion to recognize when to rely on original interpretations and when to rely on rote and conventional thoughts and actions instead. On a behavioral level it is discretion that is necessary for the individual to know when to be creative and when to act in a conventional fashion instead.

The first of these – constructions of interpretations – can be understood by considering how *sensation* differs from *perception*, on a cognitive level. Sensation is entirely dependent on the five sensory systems. Each of these (sight, smell, taste, touch, or hearing) brings experiential data into the cognitive system. The sensory systems do not alter data in any way; they merely detect information and bring it in, where it can then be processed. The information brought into the cognitive system via one of the sensory systems is therefore raw data. At that point the cognitive system can attempt to make sense of it. This is where perception begins. At that point information is analyzed, translated, transformed, considered, compared, and so on. All of this allows the individual to understand his or her experience. The key point is that sensation differs dramatically

from perception in that the first uses only raw data and the second transforms that into meaningful information. The transformation may occur in various ways, but it allows the construction of interpretations. Indeed, an *interpretation* is synonymous with the construction of meaning. That is the process that supports personal creativity. If the construction of meaning – the interpretation – is original and effective, it is creative. It is creative only on a personal level, but it might later be made social or elaborated into some sort of product. At first, it is personal creativity.

The process used to construct interpretations can also be viewed as *assimilation*, as defined by Jean Piaget. It is not the same as adaption, which, for Piaget, also involved accommodation and changes in cognitive structures. In fact, creativity is distinct from adaptation in a number of ways. Creativity can be proactive, for example, while adaption is by definition reactive. Creativity can even be maladaptive, as is suggested by the dark side of creativity and the destructive tendencies of some creative individuals. Assimilation is only one part of adaptation. It is defined as a manipulation of information. It is what is known as a top-down process in the cognitive sciences and is manifested whenever a personal interpretation is constructed. Interpretations are constructed; they are not merely representations of the external world.

None of this implies that all thinking is creative. As we age we develop assumptions, routines, and habits, and much of our behavior depends solely on them. They are not original. Occasionally we do mindfully construct an original interpretation if it is also effective. That is a creative act. We may then elaborate on it, refine it, apply it, and perhaps even share it, and it might eventually make itself known in the form of a product or performance. But at first it is just a new interpretation.

There is research on individual differences in the use of creative interpretations. Gudmund Smith developed a technique to assess interpretative tendencies, or what he calls *percept-genesis*. This technique involves presenting ambiguous figures to individuals and asks them for possible interpretations. Since the stimuli are ambiguous, varied interpretations are possible. Results from several studies confirm that creative persons are able to construct meaning with less information, when the stimuli are more ambiguous. There are age differences, with less creative performances at age 7 and 12. Another drop occurred in middle age. Smith and colleagues have reported good reliability and several kinds of validity in the *Creativity Research Journal*.

Recall here that personal creativity is not identical with self-actualization. Personal creativity is not necessarily tied to sound psychological health, nor is it dependent on the fulfillment of lower level 'needs' as is assumed by humanistic theories. Still, the originality that is expressed by psychotic individuals is not creative. It is not an attempt to understand the world and not intentionally constructed, as is required by personal creativity. As stated above, the original interpretations of experience that contribute to personal creativity are intentional.

Contrarianism, blind nonconformity, and other forms of unconventional behavior are also distinct from creativity. They might lead to originality but they are not at all good indicators of creative talent. Truly creative individuals tend to the unconventional, but the vast majority of them also fit well into society. They are able to do so, even though they have original

insights, because they exercise their *discretion*. They know when to be original and when to fit in. They are not blindly original, out of control in their originality. Frank Barron described it nicely, in 1995, as 'controlled weirdness.' All of this reinforces the idea that creativity is not equivalent to originality, and that sometimes original individuals are not creative.

Enhancement

The fact that discretion is a part of personal creativity suggests a method for enhancement. That is because techniques have been developed to encourage and exercise discretion. These techniques have been used with the hopes of facilitating the development of moral reasoning skills, but since they focus on discretion, there is every reason to believe that they could be adapted to creative thinking as well. If they are effective, individuals should recognize that it is good to be original, but only some of the time. This would parallel the recognition that it is good to fit in, some of the time, or to use the terminology from the research on moral reasoning, it is good to be conventional, some of the time. It is also good to be *postconventional*, which is the most mature level of moral reasoning. Postconventional individuals understand rules and conventions, and to take them into account when making decisions, but they think for themselves. It allows mindful action rather than either blind conformity or blind originality.

Another approach to enhancement emphasizes (a) providing opportunities for self-expression and originality as well as (b) appropriately rewarding and (c) modeling those same two things, self expression and originality. The last of these is especially relevant to personal creativity because modeling has a twofold impact: it provides actual examples of creative behavior, which can be imitated, and it demonstrates that creativity is a valuable thing. It thus communicates appropriate values. These values are critical for intentionality. If individuals do not value creativity, they will not put any effort into being creative, nor try to develop creative skills. They will not invest in their own creativity. They simply will not appreciate it and thus not care about it. But if individuals see the value of creativity, they will try to be creative and try to become more creative. They will appreciate it in others as well. The value of creativity can be communicated via creative models, including parents, teachers, or supervisors.

Conclusions

The most important part of personal creativity is that it is universal. It is not just a part of the creative efforts of ordinary people and everyday actions, but also plays a role in eminent levels of creativity. It does not just describe what an individual does, but it also describes the efforts that precede and are required for socially recognized creativity. Recall here that personal creativity precedes attributions of creativity and the completion of creative products.

A second important part of the theory of personal creativity is that it attempts to get at the actual mechanism that is involved in all creative work. This mechanism is hypothesized as interpretive and assimilatory. Given that everyone can assimilate, this underscores the universal nature of personal

creativity. Admittedly, many people put less and less effort into originality as they age, but that simply means that some people rely more and more on habit and routine as they age and exercise their creative self-expression less and less. With that in mind the practical implications outlined above are especially noteworthy. They offer techniques that may counter the tendency toward habit and routine and encourage discretion and the intention to be creative and to develop creative skills.

Personality: Autonomy and Independence

G Oztunc, University of Georgia, Athens, GA, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Autonomy The inclination to be free from and independent of other people.

Creativity A person's ability to produce new ideas or to display original behaviors that are unique and useful.

Independence The state of being free from other people's influence or control.

Meta-analysis The method of synthesizing the results of existing but relevant empirical studies and calculating an order to generate an overall index of effect size.

Personality A specific person's distinctive behavioral or dispositional qualities and traits that are stable over time.

Introduction

Expanding upon the article by Gregory J. Feist on autonomy and independence in the previous edition of the Encyclopedia of Creativity, this article discusses the relationships among personality, autonomy, and independence. When studying creativity and personality, it is essential to regard the individual as having a set of unique ideas or characteristics. The term 'unique' is central to understanding the creativity and personality of an individual because what matters are the originality of the ideas and the behaviors displayed by the person. Not surprisingly, empirical studies that have been conducted to date on the uniqueness of ideas and personal characteristics have focused on creative individuals.

The interest in creative individuals can be traced back to Plato and Aristotle. However, empirical studies on creativity and creative personality have been mostly conducted since the 1950s. Although, for many years, the concept of creativity has been considered difficult to operationally define, research conducted in the creativity literature over the last 50 years has revealed that originality and usefulness are the two essential traits of creativity. Accordingly, in order for any thought or behavior to be regarded as creative, it must demonstrate both originality and usefulness. In other words, contrary to the predominant belief that originality and creativity could be considered identical or synonymous, it is possible and important to keep these separate. Originality is required for creativity, but creativity requires more than originality. It requires some sort of usefulness.

Rather than reviewing research literature on the characteristics of creative individuals, this article discusses autonomy and independence as the vital qualities of creative personality. They support originality of creative thought and creative behavior. Creative individuals differ from their counterparts in that they frequently express strong desire for being isolated from typical social environments when working on their creative products. That is to say, creative individuals demonstrate considerable tendency to become autonomous and independent of other people. At this point, clarifying the differences among autonomy, independence, and introversion will be helpful in understanding the sections to come.

Independence refers to the actual state of being free from other people's influence or control. Autonomy refers to one's

strong inclination to reach such a state. Introversion, in contrast, refers to one's desire to be away from social interactions that generally occur in a variety of social environments. It is also very important to illuminate the fact that autonomy generally occurs as a result of one's willingness to free him or herself from the psychologically binding influence or constraints of others. Therefore, unlike individuals with typical personality characteristics, creative people express greater interest in autonomy and independence, ultimately leading them to generate original and useful ideas through various creative endeavors. This article discusses the relationship among autonomy, independence, and creative personality.

Developmental Dimensions of Autonomy, Independence, and Creativity

Introversion could be defined as one's desire to be removed from social interactions and be regarded as strongly relevant to autonomy and independence. In keeping with this close relationship, the following sections address some facets of introversion as a personality trait underlying autonomy in individuals.

Neurophysiology of Introversion and Creativity

Hans J. Eysenck, a well-known personality researcher, proposed that every essential dimension of one's personality involves a biological basis. Of these essential dimensions, including extroversion, neuroticism, and psychoticism, the primary emphasis in this section will be placed on the extroversion-introversion dimension. Research on the biological basis of personality has revealed that introvert and extrovert individuals differ remarkably in their physiological reactions to different stimulations. That is, introvert individuals have been found to have lower thresholds for and to be more reactive to stimulation. Moreover, this greater reactivity is evident in the central and autonomic nervous systems of introvert individuals. Research, for example, has reported significant increases in the cortical (electroencephalography - EEG) reactivity, papillary response, heart rate, and skin conductance of introvert individuals when they are exposed to stimuli at a moderate level.

In many respects, there is a strong tendency in creative people to be more introverted than extroverted, with a great number of personality characteristics supporting this trend. Therefore, it would be reasonable to suggest that both creative people and introverts demonstrate the same kind of physiological reactivity to different stimuli. In attempts to explore such a connection, Colin Martindale and his colleagues studied creative individuals and found that there is a higher resting arousal level in creative people. This is, of course, not to say that a simple relationship exists among physiology, introversion, and creativity. Examining the EEG activity during the process of creative problem solving, Colin Martindale and James Armstrong reported that there is a significant difference between creative people and less creative people in terms of the resting cortical arousal levels, with the creative people having higher levels than their less creative peers. At the same time creative individuals have lower cortical arousal levels than less creative individuals during the inspiration stage of creative problem solving. This supports the notion that low cortical arousal is considered to be strongly related with an increase in defocused attention which is among the correlates of creative problem solving.

Birth Order and Creativity

It was first proposed by Francis Galton in the nineteenth century that an individual's personality development is strongly influenced by birth order. Among the researchers and theorists having pursued this idea, Alfred Adler proposed that firstborns, compared to the laterborns, are more likely to have stronger desires and feelings for power and superiority. The impact of birth order on people's personality has been more recently explored by Frank Sulloway in his book entitled *Born to Rebel: Birth Order, Family Dynamics and Creative Lives*. Frank Sulloway draws particular attention to individuals' tendency toward nonconformity, rebelliousness and unconventionality, and asserts that laterborns, compared to the firstborns, have much more inclination to challenge and reject social norms while also demonstrating rebellious and nonconformist behavioral characteristics. Moreover, according to Sulloway, firstborns are more likely to pursue or maintain power for their privileged positions, resist radical and unconventional ideas, have tendency toward power, authority and status quo, and express their creativity through the intellect dimension. On the other hand, laterborns, as opposed to the firstborn individuals, are more likely to react against power and authority, accept radical and original ideas, show greater interests for new experiences and ideas, and express their creativity through the unconventional and nonconformist dimension.

On the contrary, many other researchers who have examined the relationship between creativity and birth order have found that there is an overrepresentation of firstborn individuals among the highly creative people. For example, in her classic study of creative scientists, Ann Roe found that firstborn scientists were overrepresented in her sample. Similarly, a study conducted by Gregory Feist revealed that there was an overrepresentation of firstborn and lastborn individuals among highly creative scientists. Although this is the most apparent contradiction between the results of Sulloway and other researchers regarding the impact of birth order on creativity and personality

characteristics, Sulloway's main focus is on the tendency of creative people for accepting or rejecting new and radical ideas, rather than the influence of birth order on their creativity and inclination toward autonomy and independence.

Personality Traits as the Basis for Autonomy and Creativity

Any discussion of autonomy and creativity must take into consideration several personality traits, including introversion, internal locus of control, intrinsic motivation, self-confidence/arrogance, nonconformity/norm-doubting, desire for solitude, and asocial and antisocial leanings. Conceivably, one reason for the need of such consideration is that these are some of the crucial personality traits contributing to the emergence and subsequent development of one's creativity.

Introversion

Among the consistent findings of the personality literature of artists and scientists, is the tendency toward introversion. An example is found in a classic study concerning scientific creativity: Ann Roe showed that the scientists who are more creative are also more achievement oriented and less affiliative compared to scientists who are less creative. Bernice Eiduson, Jack Chambers, and Ravenna Helson found much the same. Additionally, J. P. Rushton and his colleagues recently found some difference between creative research-oriented psychologists and teaching-oriented psychologists, and suggested that the former group was higher in independence but yet less extraverted than the latter group.

Internal Locus of Control

As with introversion, the internal locus of control offers an important insight into understanding the relationship between autonomy and creativity. In the 1950s, Julian Rotter argues that the locus of control is related to someone's ideas about who or what is the source of reinforcement for someone's own behavior. We see many studies that look to the relationship between creativity and internal locus of control over the last 20 years. According to those studies, it should be appropriate to say that creative people are more internally oriented than less creative people.

Intrinsic Motivation

As a result of being internally oriented, creative people demonstrate a tendency to be intrinsically motivated. According to Teresa Amabile, an individual's intrinsic motivation, as demonstrated through enjoyment, pleasure and satisfaction, could boost the level of his or her creativity. Another characteristic of her theory is that people become less creative if they are motivated by external factors such as evaluation, competition, reward, surveillance, and restricted choice. Even though some of the empirical evidence regarding intrinsic motivation comes from research on children, there are some other studies that look at adults in general and college students in particular. For instance, Amabile experimentally created intrinsic and extrinsic

motivational states using students of English or creative writing. The participants completed a questionnaire based on intrinsic or extrinsic motivational state. After also having a participant group complete a neutral questionnaire, they were asked to write a short haiku-style poem. Professional poets rated these poems on the level of creativity. The poems written by writers in the intrinsic and control groups were more creative than the ones written by extrinsically motivated writers. Amabile argued that creative performance can be increased by reward and competition in education. Given that evaluation, reward, and competition are used as motivators in classroom settings, this argument makes important implications for education. The reason that so many children have test anxiety and do not achieve the desired levels may be considered as the result of pressure coming from that kind of evaluation. In this regard, Amabile's argument may give an idea to educators that they should motivate students by intrinsically motivating conditions.

Mark Runco suggested that in order to motivate a person to be creative, some degree of negative affective state may also be important. In order to create something new and better, someone should be dissatisfied with the current situations. Robert Eisenberger and his colleagues went further and gave the evidence that some kind of rewards can increase the creative performance of children if they can be directed with explicit instruction to be creative. Amabile also argued that intrinsically motivated creative people can be positively motivated by extrinsic factors. Looking at all these results and findings, we can say that relying solely on extrinsic motivation in achieving creativity may weaken it in the absence of intrinsic motivation.

Self-Confidence and Arrogance

Self-confidence and arrogance represent another set of traits that involve internal locus which are related to autonomy. The argument is that people are more confident in terms of expressing their ideas if they do not have to think about others' influence, and most of the time they may even be more superior to others. In our world, where competition is an important factor in achieving success, accomplishment depends highly on the level of dominance, arrogance, and self-confidence of any given person. In this respect, the paper of Raymond Van Zelst and Willard Kerr shows that there is a statistically significant correlation between being productive and describing oneself as 'argumentative,' 'assertive,' and 'self-confident.'

Nonconformity and Norm-Doubting

It is very common that people who demonstrate different traits of creative personality tend to be against social norms. These people are generally regarded as societal misfits. Behaviors seen in those people do not always receive a warm welcome from the remaining part of society. Several studies examining the influence of society and societal pressure on individuals were conducted in the 1960s. For example, Solomon Asch conducted a very simple experiment in which the participant was placed in a group of people who were asked to find out the length of a target line by comparing it to another three lines. The participant was asked to evaluate the length of the target line, which corresponded to only one of those three lines, after

all of the group members had given their judgments. Results revealed that 76% of the participants complied at least once when other group members deliberately had a wrong agreement on the length of the target line.

The results of Asch's study drew the attention of social and personality psychologists. Social psychologists, on the one hand, became strongly interested in the potential reasons leading the 76% of the participants to rely on the group judgment. On the other hand, personality psychologists became more concerned with the factors preventing the 24% of the participants from being influenced by the group judgment. For example, Richard Crutchfield, using Asch's method, examined the same question and found that the decisions of highly creative people in that 24% group were never affected by conditions. According to Crutchfield, this can be explained by "intrinsic, task-involved motivation for creative thinking."

Many artists show great reluctance toward any kinds of group influence. In a sense, they can be defined as a group that questions and challenges the limits of society. The nonconforming and rebellious nature of artists is supported by the empirical literature on personality and artistic creativity. For example, according to the studies conducted by Wallace Hall and Donald MacKinnon, the most creative architects are conflicted, impulsive, nonconformist, rule-doubting, skeptical, independent, and not concerned with obligations or duties.

Solitude, Asociability, and Antisociability

Highly creative individuals are generally characterized as having a strong desire to be isolated from the society in order to avoid the influence of others and environment. In his book entitled *Solitude*, Anthony Storr discussed how people view interpersonal relationships as the only means of happiness, leading them to overlook the importance and necessity of intellectual and creative development. It appears, at this point, to be helpful to distinguish between creative skills and interpersonal skills, with the former necessitating solitude that brings discomfort to many people. But, since creative people actually require solitude to a certain extent, it is not an issue for such people. As Storr says:

Yet some of the people who have contributed most to the enrichment of human experience have contributed little to the welfare of human beings in particular. It can be argued that some of the great thinkers ... were self-centered, alienated, or 'narcissistic'; more preoccupied with what went on in their own minds than with the welfare of other people.

There is also a tendency among creative people to be asocial as well as resistant to the norms of any given culture. For example, through a meta-analysis of the literature on personality and creativity, Gregory Feist found artists to have low scores on the responsibility, socialization, good impression, and achievement via conformance subscales of the California Psychological Inventory that assesses individuals' personality. In addition, they were found to score higher on the Eysenck Personality Questionnaire's psychoticism subscale that comprises a variety of personality traits including aloofness, impulsiveness, coldness, and antisociality. Of the various domains that require high levels of creative ability, artistic creativity has been particularly considered to be

associated with a great deal of personality dispositions that require asocial and antisocial tendencies. Looking specifically at the relationship between artistic creativity and personality, John Drevdahl and Raymond Cattell studied writers, visual artists, and science fiction writers, and found all three groups to have considerably lower scores on the warmth subscale. In the same way, Jacob Getzels and Mihaly Csikszentmihalyi reported that successful art students have significantly low levels of warmth as measured by the Sixteen Personality Factor Questionnaire. Additionally, another study by Gregory Feist on scientific eminence revealed a direct and significant path between eminence and observer-rated hostility as well as an indirect but significant path between eminence and arrogant working style. Finally, according to Hans Eysenck, artists have higher tendency toward aggression, aloofness, tough-mindedness, and egocentric behavior than their non-artist peers.

Conclusion

Research to date has revealed an obvious relationship among creative ability, creative achievement, and various autonomy-oriented personality dispositions. As well, there is a biological basis for the fact that creative individuals have a strong desire to be away from others, giving rise to the ultimate development of autonomy and independence. As a result, it has become clear that the autonomy-oriented personality involves such traits as introversion, intrinsic motivation, nonconformity,

solitude, asocial/antisocial behavior, self-confidence, and internal locus of control, with each nurturing individuals' creative performance to a considerable extent.

This article is a revision of the previous edition article by Mark A Runco, volume 2, pp. 373–376, © 1999, Elsevier Inc.

Glossary

Creative license Analogous to artistic license but not limited to the arts. Behaviorally, the strength and willingness to bend rules, question assumptions, break with tradition, and act in an unconventional fashion in order to insure originality.

Egocentricism Being stuck in one's own perspective; being unable to take another's point of view.

Fixity Occurs when an individual views a problem from one perspective and is unable to break a routine or change perspective.

Incubation Time away from a problem which allows a relaxation of effort and eases shifts of perspective.

Paradigm shifts Dramatic changes in world views and assumptions which occur periodically in the sciences.

Sociocentric thinking The ability to take someone else's point of view. It is a mature capacity; young children are egocentric.

Tactics Intentional efforts to increase originality and creativity.

Introduction

Changes of perspective are related to creativity in many different domains. Many artistic styles develop, for instance, when an artist or group of artists recognizes the need to change the way the world is viewed. The new style, in this sense, presents an alternative perspective.

Dramatic shifts also characterize the sciences. In Thomas Kuhn's well-known model, *normal science* involves the accumulation of factual information, which is collected with theories and methods that reflect a similar perspective of the world. At some point, however, existing theories are found to be inadequate to explain certain observation. A dramatically new perspective results from a paradigm shift. These are dramatic in the sense that they do not merely extend the thinking that came before but instead introduce a completely new way to view the world. Examples include the scientific revolutions of Copernicus, Darwin, and Einstein.

Albert Einstein seemed to have developed some of his most significant insights using thought experiments. He imagined himself riding a beam of light, for example, or on a train moving in the opposite direction to another train. These thought experiments gave Einstein a unique and useful perspective on the relativity of our physical world.

Picasso has often been quoted as saying that he learned to paint only after he remembered how to think like a child. Picasso was well aware of the assumptions and routines adults too often develop. More often than not an adult's perspective will differ from that of a child.

One of the most dramatic changes in literature occurred when Dorothy Richardson and James Joyce developed stream-of-consciousness styles. They shifted the perspective within the novel, away from the observer or third person and to the individual or protagonist.

As I described this in an article on problem finding,

Richardson, author of *Pilgrimage*, seems to have been the first to use stream-of-consciousness in literature. Her insight was that a new perspective in literature was needed. This led her to reorganize her

thinking and writing about the protagonist of *Pilgrimage*, Miriam Henderson. Rather than describing the character and her actions, Richardson began to *take the character's point of view* and describe the 'inner psychic existence and functioning' for the reader. (Runco, 1994: 374)

I am quoting Doris Wallace on this issue of 'inner psychic existence and functioning.' Wallace concluded that the organization and reorganization in Richardson's writing

reflects a type of problem finding, for no one before Richardson saw the need for a new perspective. Wallace also described the history of insights, arguing that they are constructed over a long period of time. This is apparent in the work of Darwin and Richardson, and other creators who had insights only after they considered a problem for a long period of time. (Wallace, 1991)

Perspective Shift as Fundamental to Relation Processes

As this discussion of paradigm shifts may suggest, shifts in perspective, like those of Copernicus, Einstein, and Darwin, can lead to dramatic changes in world views. In this sense the shift is the mechanism which leads to the insight. Shifts of perspective may underlie other processes related to creative work.

Recall here that shifts in perspective may be literal or metaphorical. Consider the tactic (often used in the research and in programs designed to enhance creative potential) to 'stand the problem on its head.' The idea here is to turn the issue upside down – to obtain a different view. Programs sometimes suggest magnifying or minifying a problem. In the former the problem or its representation is enlarged. In the latter the problem or its representation is reduced. Again, this requires a shift of perspective.

Another recommendation for finding creative ideas is to stand back and change one's 'level of analysis.' Related to this is the suggestion to alter the medium being used to represent the problem. Use words instead of numbers or pictures instead of words. There may be several benefits to these changes, but certainly one of them is that a change of perspective is involved.

There are various explanations of the *incubation* that is often tied to creative insight. There may be a preconscious relaxation of constraints, allowing alternatives to be found. Incubation may be effective precisely because it allows one individual to find a new perspective and to break away from an existing viewpoint. Most of us have probably had the experience of taking time away from some difficult problem, only to return and solve the problem easily because we saw something that was obvious after the break (the incubation) that we were overlooking or taking for granted before it.

Mood Swings and Perspective

A large amount of attention has been directed to the affective disorders of creative persons. Typically these are bipolar disorders, which are characterized by mood swings. Such mood swings may be functionally tied to creative work; and here again it is possible to speculate that there are relevant changes of perspective. Put briefly, the mood swing may provide the individual with more than one perspective of his or her own work.

This hypothesis is supported by anecdotal reports by creative persons that they are (a) highly productive but not critical when they are experiencing the mania of a mood swing, and later (b) highly critical – an effective editor so to speak – when they experience the depression which characterizes the opposite extreme and other polarity of the mood swings.

Developmental Trends

Individuals may intentionally change their perspective in order to increase the likelihood of a creative insight. There may, however, be developmental trends in the capacity for shifting perspective. These would suggest that changes of perspective are more difficult for younger individuals and perhaps should not be encouraged early on.

Most obvious here is the tendency for young children to be *egocentric* in the sense that they cannot take someone else's perspective. Only in adolescence do individuals recognize that others hold different perspectives from one's own. To the degree that these general cognitive tendencies relate directly to creative problem solving, we would expect age differences in the capacity for using changes of perspective in a tactical manner to increase one's originality and creativity. This certainly would be consistent with theories of metacognition, with younger children not recognizing that tactics and intentional efforts are necessary for problem solving.

Cognitive and Extracognitive Influences on Shifts of Perspectives

Shifts of perspective require particular cognitive capacities. Some shifts may require visualization or other sensory capacities, as would be the case when the individual literally imagines what another perspective would look like. Higher order abilities are also required. The shift may, for example, take the individual to a hypothetical perspective; and this requires formal operational thinking. The shift may require that the

individual imagine him- or herself in someone else's shoes. That is a special kind of hypothetical reasoning that reflects *sociocentric thinking*. This too is cognitively demanding. Young children, for example, are egocentric rather than sociocentric and unable to shift to someone else's point of view. This is not a matter of choice but is instead a reflection of the maturity (or lack thereof) of the nervous and cognitive systems.

Extracognitive capacities are also required for shifts. Open-mindedness is required, for example, because the individual must acknowledge that there are other possibilities. A courageous attitude may be necessary so the individual is willing to try something new, and perhaps take a risk with it. Ego-strength will certainly be necessary. This provides the confidence to actually use one's personal creative license. Ego-strength may be especially important because creative ideas and insights are often unconventional; and if they are found by shifting perspective, that shift may be away from conventions, norms, traditions, and expectations. It is analogous to what has been called *artistic license* but it may not involve art; hence the term *creative license*.

Beauty is in the Eye of the Beholder: Perspective Differences Influence Judgments of Creativity

To the degree that creativity is a social phenomenon, it is dependent on interpersonal judgments – and these will very likely vary depending on the perspectives held by the different persons involved. As a matter of fact there is a principle in social psychology that predicts that two people will tend to form different hypotheses to explain their actions. The person doing the action will tend to explain it in terms of the immediate environment and context. An observer of the same action will focus his or her explanation on the person involved. This follows from the divergent perspectives of the two individuals. The person doing the action will tend to look away from him- or herself. Their physical perspective will be oriented outward. The observer, on the other hand, will probably see the person doing the action as salient and spend most of the time viewing that actor. This may apply to creative work, and a creator may explain his or her work contextually while an audience will emphasize the creator. The most important point is that discrepant perspectives lead to different opinions.

No wonder that (a) different judges often disagree about the qualities of creative work, or even about the level of creativity in the work, and (b) opinions of creators often differ from those of audiences and judges.

This line of reasoning about interpersonal judgments implies that implicit theories are relevant. Implicit theories are held by parents, teachers, or any group of nonresearchers. Scientists and researchers hold explicit theories, which are explicit in that they are articulated, shared, discussed, presented, published, tested, and so on. But nonresearchers also have stable views of creativity. They are not shared nor articulated, so they are implicit instead of explicit. They are quite important since they can lead to the expectations that in turn have a notable impact on development and behavior.

Simply put, implicit theories probably assume a particular perspective. Consider the example of a teacher whose perspective on creativity is that it is domain specific. He or she may not

look for an artistically creative student to do much in science or some other domain. Conversely, if a teacher's perspective on creativity reflects the implicit theory that creative talent is general rather than domain specific, he or she might expect the artistically creative child to also perform in an original fashion in science and other domains. Much the same applies to the explicit theories of creativity held by researchers and individuals actually studying creativity. Their perspectives will lead them to expect certain things and ignore others (i.e., those traits that are thought to be irrelevant to creativity). The point is that there is probably a strong relationship between implicit theories and particular perspectives on creativity.

Conclusions

Shifts of perspective are fundamental to several facets of the creative process. Some tactics may work effectively because they force the individual to shift perspective. Even though perspective is not mentioned in many programs which present recommendations to individuals who hope to maximize their creativity, a change of perspective may be implied in some of the recommendations that are suggested, and its occurrence (a shift of perspective) may explain the benefits.

A change of perspective may have several benefits. A shift of perspective may, for example, break the individual's routine and allow him or her to find an approach that is uncommon or novel. Novelty is of course a correlate of originality; and originality is in turn vital for creative insights. Shifts of perspective may thus have their effect because they lead directly to novelty. The breaking of routine may be sufficient for the finding of creative ideas and solutions. Much research has demonstrated that fixity precludes originality, and that avoiding fixity or breaking one's mental set can lead to original problem solving. The benefits of changes in perspective are numerous.

FERNANDO ANTÓNIO NOGUEIRA PESSOA was Portugal's major 20th-century writer. Over the span of his lifetime, he produced a vast array of poetry and prose that included commentaries on literature, aesthetics, philosophy, religion, and politics. In addition to his wide range of subject matter, Pessoa was extraordinarily original. This originality manifested itself not only in the form and content of his work, but in the manner in which it was conceived. Pessoa devised a creative universe with and through the use of what he referred to as "heteronyms"—72 in all. Heteronyms were personas, devised by Pessoa, from which to write. Although it is not unusual for writers to make use of a *nom de plume* or pen name as a creative device, Pessoa's creation of heteronyms extended well beyond this approach—particularly with four of them under which the bulk of his work fell: Alberto Caeiro, Alvaro de Campos, Ricardo Reis, and Bernardo Soares. These four were assigned biographical details, physical descriptions, specific aesthetic sensibilities, ideological inclinations, and relationships to each other. The creation of Bernardo Soares possessed a further distinction—that of being a "semiheteronym"—part autobiographical, part fiction. It was under this particular semiheteronym that Pessoa wrote his most autobiographical work, *The Book of Disquietude*.

Fernando Pessoa. Used with permission.

Background

Fernando Pessoa was born on June 13, 1888, to Joaquim de Seabra Pessoa, a civil servant in the Ministry of Justice who wrote for Lisbon's leading daily newspaper, *Diário de Notícias*, and Maria Madalena Pinheiro, a well-educated woman who was well versed in music, languages, and the written word. Pessoa's young life, however, was soon to be disrupted by the death of his father in 1893—when Pessoa was only 5 years old—and by

the death of his brother 1 year later. It was in 1894 that Pessoa invented his first heteronym—one Chevalier de Pas.

Pessoa's mother remarried in 1895. Her new husband, João Miguel Rosa, was a Portuguese consul in Durban, South Africa. In 1896, the family moved to Durban. Upon arrival, Pessoa was enrolled in the West Street Convent School. Three years later, he continued his education at Durban High School. Pessoa proved to be a successful student and proceeded to learn English and French in addition to his native Portuguese. This ability in languages allowed him to read extensively and to be influenced by British, American, French, and Portuguese authors such as Milton, Shakespeare, Shelley, Keats, Tennyson, Carlyle, Poe, Whitman, Baudelaire, Verde, and Pessanha, respectively.

In 1901, due to the death of his half sister, Henriqueta Madalena, Pessoa returned with his family to Lisbon. He was 13 years old at the time. One year later, the family returned to Durban, and Pessoa entered a commercial school where he learned business English and bookkeeping. Two years later, back in high school, he published an essay on the historian Thomas Babington Macaulay. In addition, he was awarded the Queen Victoria Memorial Prize for his performance on his university examinations. Already proving to be an excellent student, Pessoa had to decide where to continue his studies. In 1905, at the age of 17, Pessoa decided to return to Lisbon, where he would remain all his life. However, despite the return to Portugal and a brief stint at the university, Pessoa had little or no formal academic training. His plans to attend a university were thwarted by a student strike against João Franco, who at the time was the dictator of Spain. Throughout his life, Pessoa would rely primarily on his previous commercial business training for his livelihood as a bookkeeper and translator of foreign correspondence. This work would provide him with nearly sufficient income to write.

The Writing Pessoa

And write he did. Pessoa wrote nearly all the time and on nearly anything he could find, including scraps of paper. Although some of these "scraps" were published during his lifetime, most of them remained in a wooden trunk he left behind. Recent inventories have established that well over 25,000 items remain—still to be sorted and published.

Although many persons live to write, only a select few write to live. Pessoa was one such person. Certainly, he lived an

everyday life—eating, drinking, working, sleeping, and interacting with friends, relatives, and associates. However, for the most part, he spent his time writing. This approach to living and writing has earned him such enigmatic titles as “The Man Who Never Was”—precisely because it often appears that, despite the engagement in the gestures of everyday life, Pessoa seemed to have lived predominately through an imagination that unfolded in and through his writing (this title is from the title of an essay written by Jorge de Sena. See Bibliography for source.) Also, given that he wrote very little under his own name of Fernando Pessoa, a question emerges as to the precise relationship between the author and the written text. Even his most autobiographical work is written as a semiautobiography by a semiheteronym—as if his life’s story was, in part, a fiction.

The Writing Pessoa as Social Entity

No person creates in a vacuum. Human beings are inextricably linked to a multitude of intricacies that constitute their social world. These intricacies, in turn, formulate the very person and the world in which they create. For this reason, it is important to examine the social, historical, and ideological circumstances of any person’s day—creative or otherwise—that constitute the person’s very world. In Pessoa’s case, his writing—both thematically and stylistically—gave voice to a historical time full of change and misgivings about present and future circumstances.

Modernism, the period in which Pessoa wrote, was formed by the changes that took place in the late 19th and early 20th centuries such as the impact of industrialization, world war, advances in technology, communism, fascism, and the spread of Western imperialism. One of the results of events such as these has been an increased disparity between inner and outer worlds. In previous historical periods, such as the Middle Ages or the Renaissance, people are said to have experienced more congruity between their inner lives and outer worlds. Lives were organized typically around their God, ruler, community, and family. The work that was done was continuous with the satisfaction of everyday needs such as providing food, shelter, and clothing for themselves and their families. However, with modern developments such as the increased use of technology, for example, and the resulting period of industrialization, the machine replaced work that human beings had once done. Although this transition made work more efficient, it also altered the relationship between human beings and the fruits of their labor. Mass production ensued, and with it a new era of reproduction through replication. Urban areas became centers of a new, technologically driven, modern age. Individuals and families often were forced to relocate from rural areas to urban centers to benefit from new job opportunities. Suddenly, there was a demand on persons to relate to their work, themselves, and others in a very different sort of way than they had been previously accustomed. This demand was to contribute to a need to negotiate life in an alternate way—one that would include a stance toward the newfound circumstances being presented. In short, urban life called for an unprecedented pluralism.

Modernism was also somewhat idiosyncratic in that its shape and impact was contingent on the particulars of the

context in which it flourished. In Portugal, for example, certain conditions were present as a result of specific social, historical, and ideological circumstances that contributed to the exigencies of modern times, including the threat of war by Britain unless Portugal abdicated rights to what is now Zimbabwe, the financial and economic crisis of 1890–1891, and the 1910 revolution against the Portuguese monarchy. These specific, culturally bound events are important to the understanding of the factors that constitute the context in which any person—creative included—develops. Although the effect of global changes may have been felt by people throughout, writers and artists typically depicted the effects in their artwork. Many writers and artists, situated in the urban centers of the day (e.g., London, Paris, Berlin, Vienna, New York), began to explore new forms and themes in reaction to the rapidly changing social and political world in which they found themselves.

One such theme was that of representation. Writers, in particular, used language to experiment with the issues of representation, including authorship. Pessoa devised two strategies in keeping with the modernist project. First, he created a universe of heteronyms from which to write that necessarily called into question the notion of authorship. Second, he wrote his most autobiographical work as a self-reflective text. Both these strategies suggest a play with representation, specifically, the relationship between who one is and what one writes—previously assumed to be a continuous relationship—in keeping with the previous view and experience of the world and lived life. It was through the use of both of these strategies that Pessoa also addressed the pluralism called for in persons as a result of the magnitude of changes being experienced at the time—changes that contributed to an increased fragmentation of reality, one of the fundamental characteristics of modern consciousness.

The Writing Pessoa as Excess to His Social World

The creation of a multitude of personas as a creative universe in which to write is certainly one response to a call for pluralism. However, despite Pessoa’s creative response to the social, historical, and ideological circumstances of his day, there was a uniqueness about his approach that was not shared by many of his fellow countrymen and women. Differences such as these point to the way in which the individual, along with being formulated in and through the context in which she or he creates, can come to formulate a vision or perspective that relies on, but clearly exceeds, the very context in which it has been formulated. This excess—along with the finely tuned relationship between the creator, her or his medium, and her or his world—are just a few of the elements that come to constitute a creative person’s life.

Portugal was and continues to be somewhat of a paradox. On the one hand, it manifested a certain sophistication during the Age of Discoveries in the 15th and 16th centuries when it participated in the exchange of goods through trade with China and India. On the other hand, it was, and remains, a largely homogenous population with cultural traditions and practices that, for the most part, have remained untouched to this day. In his day, Pessoa commented on a certain Portuguese

provincialism—one sensibility he did not share with his fellow countrymen and women—perhaps due to the influence of having lived, learned, read, and written in two, very diverse worlds (Portugal and South Africa). As a result, he developed a sensibility uncommon among most others from his country, which, in turn, has earned him the credit of nearly single-handedly bringing modernism to Portugal.

Conclusion

This article has attempted to demonstrate the continuous relationship between the creative person and her or his social world. However, even with this continuity, a creative person, regardless of the shared experience of social, historical, and ideological conditions, brings her or his participation in these conditions to light—through her or his medium and

imagination—in a unique and original way. Pessoa was one such person who, through both his writing and the creation of his universe of 72 heteronyms, demonstrated the way in which one person—an extraordinarily creative person—gave voice to the times in which he lived.

JEAN PIAGET was one of the two or three outstanding psychologists of the 20th century. He was most widely recognized as a developmental psychologist. But his lifelong effort was guided by biological and philosophical concerns about the nature, origins, and transformations of knowledge. For this reason he coined the term genetic epistemology to characterize his vocation. His published output was enormous, some 60 books and monographs and well over 1000 articles.

Background

Jean Piaget was born on August 9, 1896, in Neuchâtel. He had two younger sisters. His father, Arthur Piaget, taught literature and history. His mother, née Rebecca-Suzanne Jackson, had no profession and was considered, at least by her son, to be quite neurotic. But she was active in socialist causes and during World War I, although outspokenly pro-French, she went to the aid of German refugees and prisoners. In Neuchâtel, during Piaget's early years, there was considerable interest in science, especially natural history. Piaget's first publication, a paragraph describing an albino sparrow, appeared in 1907,* before he was 11 years old, in *Le Rameau de Sapin (The Fir Branch)*, published by one of two local natural history societies in

*In this article publication dates are given for the first appearance in French. Titles of works are given as published in English translation, except where there is none.

which he was active. During his boyhood and adolescence he studied the mollusks of the region assiduously and passionately. He received his first doctorate from the University of Neuchâtel, with a thesis on mollusks. Piaget went on to study at the University of Zurich and Paris, moving away (but not completely) from his early interest in mollusks to studies in philosophy, theology, psychology, and psychiatry. Beginning in 1921, he taught and did research at the University of Geneva until his death in 1980. From 1929 to 1939 he was professor of psychology, sociology, and philosophy of science at the University of Neuchâtel. From 1929 to 1939 he was also professor of history of scientific thought at the University of Geneva. Among his other parallel appointments at the University of Geneva, he was professor of sociology (1939–1971), director of the Institute for Educational Sciences (1933–1971), and professor of experimental psychology. Meanwhile, he was professor of developmental psychology at the Sorbonne in Paris (1952–1963). Although he retired from his professorships in 1971, he continued as director of the International Center for Genetic Epistemology (1955–1980). Recognition came early and continued long. Among his many honors were more than 30 honorary doctorates, the Dutch Erasmus Prize, and the Distinguished Psychologist Award of the American Psychological Association. Although he wrote relatively little about education, he was director of the International Bureau of education from 1929 to 1967, and on the international stage his ideas have been very important in shaping thought about child rearing and education. The direction of his influence on educational thought has been to advance the conception of the child as a self-constructing knowing system and the conception of the teacher as a person who understands the process of cognitive development and the structure of knowledge according to the tenets of genetic epistemology.

No single work of his can be cited as most representative because his interest was in the cognitive system as a whole, at all organismic levels. Although he considered himself to be also a philosopher and a biologist, the article primarily focuses on his work as a psychologist. Taking his work as a whole, we can say that his network of enterprise was distinctly multidisciplinary but not eclectic. In every field he touched—psychology, biology, philosophy, history of science, and logic—he expressed a consistent and unified point of view. Various facets will be discussed later, but here we might bring out the particular form his biopsychological interactionism took, the elaboration of the idea of an “epigenetic landscape,” borrowed in part from the British biologist Conrad Waddington. Briefly

put, this means that, although the organism is self-constructing, it functions in a setting that provides various constraints on development, thus guaranteeing that all knowing systems will share certain cognitive characteristics. Although this position is certainly genetic, it is not the deterministic genetics of Mendel and his intellectual descendants. For Piaget every developmental step opens the way to new possibilities: Human knowledge has an ever-receding frontier.

Taking his work decade by decade, as a youth he was much concerned with the relation between science and religion and the relationships among the sciences. These preoccupations were expressed in a long prose poem, *The Mission of the Idea* (1915), and in an autobiographical, philosophical novel, *The Search* (1918). As already mentioned, during the same period he continued his work, mainly fieldwork, on mollusks, receiving his doctorate from the University of Neuchâtel in 1921. His first book, *The Language and Thought of the Child* (1923), gained wide recognition. In the 1930s he published a pioneering trilogy about the mental development of his own three children. In the 1940s and 1950s much of his work was centered on elaborating the stage theory of mental growth, with a major focus on the period of concrete operations (i.e., from about 5 to 12 years of age). Toward the end of this period he and Bärbel Inhelder published *The Growth of Logical Thinking from Childhood to Adolescence: An Essay on the Construction of Formal Operational Structures* (1955). In this work he characterized the well-functioning adolescent as being capable of abstraction, thinking not only about things but about thought itself; capable of formulating and testing hypotheses systematically and with considerable combinatorial skill; and capable of distinguishing between the conceptually possible and the real as a special case of the possible. In one experiment it was shown that adolescents could construct an experiment about the period of a pendulum to demonstrate that, among a number of variables, only the length of the cord made a difference. It is striking that adolescents could do that much. In the history of science, it took many centuries until in about 1600 A.D. Galileo made his celebrated observations about pendulum motion. These somewhat paradoxical findings suggest the need for careful reflection on the relations between empirical psychology and the history of science. Between 1955 and 1956 Piaget founded the Centre International d'Épistémologie Génétique, which held its first international symposium in 1956. This led to a long series of monographs constituting a protracted effort to integrate the empirical and theoretical works of Piaget and his collaborators. Subjects taken up included the epistemology of space, time, causality, and chance; also included were works on child logic and on the relation between learning and development, and—going beyond childhood and adolescence—the history of science. Among many elaborations and overviews perhaps the most comprehensive and accessible in English is *Biology and Knowledge: An Essay on the Relations between Organic Regulations and Cognitive Processes* (1967). In the 1960s and 1970s Piaget and others in his entourage moved away from the earlier emphasis on stages and structures toward a more functional concern with intellectual processes and the strategies and procedures subjects actually use. Perhaps the most important work of this period is *The Equilibration of Cognitive Structures: The Central*

Problem of Intellectual Development (1975). It should be mentioned that Piaget was primarily interested in the *epistemic subject*—that is, the characteristics that all knowing systems must develop. In contrast, most psychologists have been interested in the psychological subject—that is, the particularities of individual persons. These two perspectives are not contradictory but complementary. Piaget has often been criticized for his omissions: having neglected the study of affect and the study of interpersonal relations. In reply it might be said, first, that one person cannot do everything and, second, that the criticism is based on an incomplete knowledge of Piaget's work, especially the following: *The Moral Judgment of the Child* (1932), *Play, Dreams and Imitation in Childhood* (1945), and his lectures in 1954 at the Sorbonne on "Intelligence and Affectivity," published later.

For his analysis of different forms of knowledge, Piaget borrowed descriptive categories from philosophers, such as Kant, and from the history of science. Thinkers in these fields either took these categories for granted a priori or explicitly attributed them to learning and association. On the contrary, Piaget believed that these categories develop through the child's interaction with the world, both in its physical and social aspects. Piaget and his collaborators found ways of observing and documenting this development. There are thousands of articles and monographs reporting this work. We can consider only a few examples here.

Conservation

The idea of conservation permeates scientific thought. Nothing is destroyed: Change consists entirely in processes of transformation. In the history of science this perspective was not freely given but hard won, discovered and rediscovered in many settings. Each such rediscovery was a great intellectual victory. Sometimes the search for what was conserved was undertaken deliberately, to solve a particular problem. Sometimes the discovery occurred in the course of trying to solve some other problem. A few key examples follow. William Harvey, in his studies of the functioning of the heart and the circulation of the blood, had to refute the notion that each pulsation of the heart expelled blood from the body so that the blood had to be continually replaced. He calculated the amount of blood that must pass any point on each pulsation and was able to show that if it had to be replenished the amount of blood required would weigh thousands of times the weight of the body, a *reductio ad absurdum*. Thus, by assuming the conservation of the weight of the blood as it circulates, he was able to support his general position that the blood moves through the body in a closed cycle. Around the same time, 1600 A.D., Galileo was able to demonstrate the fruitfulness of the idea of the conservation of momentum. About 200 years later Lavoisier was able to demonstrate the conservation of the weight of matter as it is transformed through burning. About 50 years later several scientists were able to demonstrate the conservation of energy across a variety of transformations, both biological and physical. In modern science the conservation principle is so well established that it can guide the search for understanding of puzzling phenomena. Faced with an unexplained

transformation, the physicist may be heard to mutter, “Something must be conserved—what is it?” Piaget drew on this history for his studies of children’s thinking. At one point, around 1930, he asked one of his students to show a child a lump of sugar dissolving in a glass of water. When the sugar disappears, the question becomes “Where did it go? Does it still exist? Did the level of the water rise when the now-invisible lump was dropped into the glass and if so did it stay up as the sugar disappeared? Children of different ages give different answers to these questions as their conceptual development proceeds. These observations were followed, over the next 2 decades, by some of Piaget’s most famous experiments. Let the child make a ball out of clay, then squash it down into a pancake: Does the amount of clay remain the same? Likewise, if you pour water from a tall thin vessel into a short wide one—or vice versa—does the amount remain the same? The person who worked with Piaget on this problem, and on many others, was Bärbel Inhelder. They became lifelong collaborators.

This work has been repeated in many countries and forms the basis for Piaget’s account of the stage of concrete operations. By operations he meant the mental acts by which the child copes with problems of the type described. For conservation of matter three main operations have been discerned: identity, reversibility, and compensation. That is, “You didn’t add anything or take anything away.” “You could pour the water back again and it would reach the same level.” “It’s taller, but it’s thinner.” To the uninitiated it comes as a great surprise that it takes about 5 to 10 years to move from grasping the elementary conservation of matter to grasping the conservation of volume (i.e., displacement volume when an object is submerged in a vessel of water). The work on the development of concrete operations was done mainly with school-age children. Development within this period has been richly documented in varied social settings and variegated tasks focusing on a wide range of concepts. The preoperational period and the period of formal operations are less well understood. On the other hand, the sensorimotor period was beautifully elaborated in Piaget’s study of his own three children, which remain irreplaceable classics. Piaget liked to describe one child who was spontaneously exploring the idea of number. This boy had about a dozen objects, which he would arrange in some spatial configuration and then count. Then he would rearrange them in another configuration and count them again. After each observation, of course, he got the same result. Finally he exclaimed, “Once you know, you know forever!” This child’s optimistic attitude toward the growth of knowledge resembles the scientist who, committed to the task of discovery, persists in this work in the face of all obstacles. The person who worked with Piaget on the child’s conception of number—a subject that can get very subtle and sophisticated—was Alina Szeminska, a Polish woman who spent many years in Geneva. When World War II threatened, she went home and was eventually imprisoned in a concentration camp, but survived.

In many areas, then, Piaget found that intellectual development moved forward in a stagelike way. There has been some confusion resulting from Piaget’s use of *stage* in somewhat different ways. On the one hand, he speaks of the four great stages: sensorimotor, preoperational, concrete operations, and

formal operations. Movement through these stages is thought to take about 12 years. On the other hand, because in describing the first 2 years of life, Piaget discerned six stages, it will simplify matters if we refer to the stages of infancy as substages. In *The Origins of Intelligence in Children*, Piaget recounted his observations of his own three children in the first 2 years of life. Some phrases from this account give the general flavor: the Third Stage—procedures destined to make interesting sights last; the Fifth Stage—discovery of new means through active experimentation; the Sixth Stage—the invention of new means through mental combinations. The similarity of these concepts used for describing the baby to things we might say about the sciences is apparent. In *The Construction of Reality in the Child*, Piaget’s emphasis is less on the process of thought and more on the content. Piaget takes up the development in the baby of four basic concepts: object, space, time, and causality. Here again we encounter six substages in the development of each of these concepts.

Piaget rarely discussed the concept of stage. Rather, he used it to organize his observations. He took the position that stages are not general. Uneven development, or *décalage*, occurs often in Piaget’s empirical work. Indeed, for disequilibrium to be a powerful force in development, widespread *décalage* is essential. Although Piaget referred frequently to stages in his empirical work, his emphasis changed over time to ideas of process, such as exploring the possible, discovering the necessary, coping with contradiction, and moving toward wider and more stable equilibrations. Piaget has often been criticized for his supposed neglect of two important areas: the psychology of affect and social processes. In reply it can be said that this “neglect” was by no means total. With regard to affect, several of his early works are pertinent: *Language and Thought of the Child* and *The Moral Judgment of the Child*. Moreover, the idea of intense interest as a motivating force permeates Piaget’s work. The twin ideas, that there is a universal thirst for knowledge and that disequibrated cognitive structures are disturbing, are hardly devoid of affect.

With regard to social processes, the criticism is unjust. In addition to the works mentioned earlier, a collection of his sociological essays, which finally appeared in English in 1995, belies the objection. Also, his celebrated experimental work on perspective taking in children showed that the child must learn to grasp the consequences of looking at a scene from more than one position, in other words, how the other sees the world and how different points of view can be synthesized. More generally, Piaget’s work shows the child as moving away from domination by authority and arbitrary convention and moving toward freely chosen, self-constructed social ideas. If so, it can truly be said that in each generation children rediscover the social contract. Obviously, this statement is idealized, even utopian. Among other things it provides no place for leaders or for other exceptional people—and for that matter, no place for evil. Piaget’s whole oeuvre depicts an unbroken series of cognitive victories, a forward march of knowledge, always graciously inclusive, assimilating old knowledge into new schemas. The picture reminds one of the exchange, perhaps apocryphal, between the English painter Turner and a woman who objected that the sunsets she saw were nowhere near as glorious as the ones he painted. Turner’s reply ran, “But, madam, don’t you wish they were?”

Glossary

Comparative studies Investigations in which two or more eminent individuals are studied together to determine similarities and differences. Such studies can have both nomothetic and idiographic aspects.

Historiometric research Investigations in which biographical and historical data are subjected to quantitative measurement and analysis in order to test generalizations about creativity or leadership. These studies are almost always nomothetic.

Idiographic studies Investigations that focus on attributes or behaviors that are unique to particular eminent

individuals. An example would be an inquiry into why Van Gogh cut off part of his ear to give to a prostitute.

Nomothetic research Studies that concentrate on testing generalizations that apply to large numbers of individual cases. An illustration would be an inquiry into the relation between intelligence and creativity.

Psychobiographical studies Investigations that scrutinize a single eminent individual. Such single-case studies are often psychoanalytic, but they need not be so. The goals are almost always idiographic rather than nomothetic.

Biography

Pablo Picasso is widely considered to have been one of the foremost artists in the history of Western art. Picasso is also unique in popular culture, having an image comparable to Albert Einstein. Where Einstein was the greatest modern genius in science, Picasso was the greatest modern genius in the arts.

This article starts by narrating his life and work, and then reviews empirical studies of his life and work.

Life

Pablo Ruiz Picasso was born on October 25, 1881, in the Andalusian city of Málaga, at 15 Plaza de la Merced, not far from the port. His father, José Ruiz Blasco, had a relatively distinguished ancestry, and his family had been in Málaga since 1790. Unlike his older brothers, Diego, Salvador, and Pablo who held respectable positions as a diplomat, a medical doctor, and a doctor of theology, respectively, José was undisciplined and unwilling to dedicate himself to a secure job, so he decided to become a painter. In 1880, José married Maria Picasso Lopez, whose family, potentially of Italian origin from her father's side, had lived in Málaga for two generations. A year into the marriage, Pablo was born, and later, his sisters Lola and Conchita (who died a few months after her birth).

In order to support the ever-increasing needs of his family, José accepted a post in the School of Arts and Crafts of San Talemo, and in 1891, a teaching job at the La Guarda Institute, a school in Coruña, a cold city on the Atlantic coast of Galicia. Although José was saddened by this move, for little Pablo this was quite an adventure. Ever since he was very young, Pablo seemed fascinated with drawing. According to his mother, his first word was 'piz-piz' to ask for a 'lapiz' (a pencil). In Coruña, Pablo attended the school where his father taught and as a result, enjoyed a great deal of freedom that allowed him to go to his father's studio and paint rather than stay in class. To the detriment of his regular school studies, Pablo was constantly

absorbed in his drawing. One evening, when Pablo was not yet 14, Don José turned the work over to his son and went for a walk. When he returned, the pigeons that Don José was fond of painting were finished and so astoundingly realistic that he gave Pablo his palette and brushes, announcing that his son's talent was superior to his own, and therefore, he would stop painting.

In 1895, Don José accepted a professor post at the School of Fine Arts in Barcelona, and moved there with his family. Here, Pablo, once again distinguished himself as a prodigy: although not yet of age, he was allowed to take an exam to enter an advanced art course. The examination consisted of drawing from a model, and the time allowed was one month. Picasso finished in one day with astonishing results.

Pablo's eventual fame as an academic painter now seemed assured, so the next obvious stop on his path of attaining recognition was the Royal Academy of San Fernando in Madrid. Aged 16, Picasso passed all the required academic tests; however, the academy setting did not attract him as much as spending hours at the Prado Museum and working on his own projects. His decision to stop attending the academy seemed like a betrayal to his family, and as a result, his uncle Don Salvador stopped paying his monthly allowance. Although his father strived to continuously support him, Picasso started to experience the pains of poverty, which he nevertheless accepted in exchange for his artistic freedom.

Unfortunately, he soon became ill with scarlet fever, and was forced to return to Barcelona. Picasso spent most of 1898 convalescing in the Catalan village of Horta de San Juan in the company of his friend, Manuel Pallarès, a fellow artist from Barcelona. The countryside was a revelation for him and it helped him gain psychological freedom and strength of character. Later he was to say: "Everything that I know I learned at Horta de San Juan."

As a result, when Pablo returned to Barcelona in early 1899, he had made the decision to break with his art school training and to reject his family's plans for his future. Instead, he continued exploring his own ideas, and became a regular

customer of *Els Quatre Gats* (The Four Cats), a tavern modelled after the Parisian *Chat Noir*, a meeting place for intellectuals. Here, Picasso befriended other artists and poets, such as Carlos Casagemas and Jaime Sabartès, and started contemplating the idea of travelling to Paris.

He embarked on a trip with his friend Casagemas, and their final stop was the French capital, where they rented a studio in Montmartre. Here Picasso met other Spanish artists who introduced him to the Parisian art scene. A few days after his arrival, he visited the gallery of Mlle Berthe Weill (who later became Matisse's first dealer), where he sold three paintings and met the Catalan industrialist Manach who decided to pay him a monthly salary in exchange for all his work. However, after only two months, the two painters went back to Spain, and after trying to unsuccessfully entertain a love-hurt Casagemas in Málaga, Picasso moved to Madrid where he worked as an art editor for a new journal, *Arte Joven* ('Young Art'), and later that year he headed back to Barcelona where he had an exhibition at the Sala Parés, a modern art gallery.

Following Casagemas' suicide in 1901, Picasso traveled back and forth between Barcelona and Paris, until 1904 when he decided to move permanently to Paris. His first apartment and studio, nicknamed *Bateau Lavoir*, where Gauguin had lived before, was almost uninhabitable, and Picasso struggled in poverty for the next two years. Despite these hardships, Picasso met his first mistress, Fernande Olivier, an art student, and his studio became an attraction for Spanish and French artists who respected him: among them were Matisse, Braque, as well as the writers and critics Max Jacob, Cocteau, and Apollinaire. During this time he also met Gertrude Stein an American writer who helped the development of modern art.

By 1912 his financial situation had greatly improved, and he moved to Montparnasse with his new mistress Eva (Marcelle Humbert). In 1914, the First World War broke out, and while his friends Apollinaire and Braque enlisted, Picasso stayed in Paris continuing his work oblivious to the war. Following Eva's sudden death due to illness, the artist started a project with Cocteau and the Russian Ballet Company, where he met the ballerina Olga Koklova whom he married in 1918. Three years later, his first son Paul was born in Paris. Olga's high society life style eventually became tiring for the artist, and in 1935 they separated. Picasso moved on to his next mistress, Marie-Thérèse Walter, who was to give him a daughter Maya; nevertheless, Marie-Thérèse was soon replaced by Dora Maar, a French photographer of Yugoslavian descent, who later documented Picasso's work on *Guernica*.

Unlike the First World War, the Spanish civil war and the Second World War left Picasso deeply marked. The brutal bombing of the village of Guernica, the Nazi occupation of France, and his friends dying in concentration camps (Max Jacob among them), turned Picasso vehemently against war. As a result, he joined the communist party. He continued living in Paris during the occupation, but due to his political views, he was not allowed to go to Spain or publicly display his work.

In 1945, after the liberation, Picasso relocated to Côte d'Azur with Dora, and a year later he moved to Vallauris with his new mistress Françoise Gilot. She gave him two children, Claude and Paloma, but left him due to his infidelities in 1953. Picasso was not alone for long, and a year later he had a

new lover, Jaqueline Roque. She became his second wife, and they shared the last 20 years of his life in a large villa above Cannes, 'La Californie.'

Work

Everyone who had ever met Picasso was impressed by his tremendous energy for work. Deeply immersed in his art and highly prolific, Picasso left over 50 000 works, including paintings, drawings, sculptures, ceramics, prints, tapestries, and rugs. He had a curious experiential creative style, constantly exploring not only new techniques and motifs, but also his own feelings.

Although his father was a rather mediocre painter, he did encourage Picasso to boldly combine different materials. As Picasso himself later noted, his childhood experience in Don José's studio might have inspired his interest in mixing materials that eventually took the form of cubist collages. Another influence of his Spanish home is the motif of the bull and the toreador. Picasso's first painting is *The Matador* (1889), and this motif can be found throughout his work.

Under Don José's influence, Pablo produced academic style paintings, such as *The First Communion* (1896). However, by 1900, with the discovery of Paris and its rich art museums, Picasso's style changed drastically. The slavish realism and religious subject matter of his early paintings were forever replaced by the modernist influences of Toulouse-Lautrec, Degas, Van Gogh, Gauguin, and Matisse. His painting *La Moulin de la Galette* (1900) as well as his illustrations in *Arte Joven* (1901) are reminiscent of Lautrec's nightlife scenes, and his pastels exhibited at the Sala Parès in Barcelona (1901) are reminiscent of both Degas and Lautrec.

Following the suicide of his friend Casagemas, between 1901 and 1904, Picasso started using predominantly cold colours (blue), dramatic subject matters, and stylized linear forms. This was Picasso's *Blue Period* and it included works such as *La Vie* (1903) and *The Old Guitarist* (1903), incorporating influences from El Greco and Matisse. Having met Fernande in 1904, Picasso started using warmer tones and lighter themes (*The Rose Period*), as exemplified by *Young Acrobat on a Ball* (1905). Although throughout his work the artist incorporated themes and techniques from a variety of revered painters, he did it with originality and with a sense of exploration that always pushed him toward a new breakthrough.

In 1907, Picasso finished a painting that was to irrevocably change the world's concept of art: *Les Femmes d'Alger (O.J.)*. Depicting the female body with an almost grotesque insight, the mask-like faces (inspired by African art) defiantly stare at the viewer, marking the beginning of analytical Cubism. Picasso's idea was to break preconceptions of form and aesthetics, and to provide the world with a new visual perspective. Initially, all his admirers were shocked and disappointed by his stylistic violations. However, he persisted in his ideas, and together with Braque developed analytical and synthetic Cubism. The *Portrait of Kahnweiler* (1910) is a good example of analytical Cubism. With a restrained colour palette, the main goal of this style is to penetrate into the nature of form, and understand space below the mere surface of objects. Familiar contours and natural opaqueness disappear as the subject undergoes a process of analytic crystallization of form.

Exploring even further the metamorphosis potential of the subject matter, Picasso and Braque began to incorporate elements of *papier collé* (coloured surfaces cut out of paper) in their paintings. This added three-dimensional patterns, texture, and was the beginning of synthetic Cubism. One example of synthetic Cubism is *Woman in an Armchair* (1913).

Picasso's later works include a multitude of portraits depicting his mistresses, such as *Portrait of Dora Maar* (1937). At the pinnacle of his career is, of course, *Guernica* (1936–1939). Motivated by the fascist bombing of the ancient capital of the Basques, *Guernica* has a candor of expression that gives it a strong emotional impact. The sharp angular patterning, the strong contrasts between light and dark, the unbalanced composition, all suggest the chaos brought by the bombing. These universal means of conveying emotion made this painting a transcendental image of war and human suffering.

During his late period, Picasso departed considerably from his own figurative style. Instead of continuing his quest of challenging form through the dissolution of perceptual preconceptions, he started obsessively producing images of musketeers and matadors or other heroic figures inspired by obvious art-historical references. While some critics argue that Picasso's creativity had waned toward the end of his career, others claim that Picasso had reinvented his art once more. To give an example, *Tête de Matador* (1970), where the clothing reminds of Goya, may seem like a technically naïve reinterpretation of the emblematic bullfighter figure. However, given that this is also a self-portrait, one could see this work, along with others, as the artist's ardent desire to defy death just like a Spanish *toreador*. At the same time, perhaps intending to leave one last mark on the world's art history, the artist might have attempted to assimilate and *Picassify* such celebrated elements of the Western figurative tradition. In time, it is conceivable that these works might be someday viewed in the same way as the late-life works and swan songs of other great artistic creators, such as Titian or Michelangelo.

His Life: Empirical Studies

Because Picasso is widely recognized as one of the greatest creators of the twentieth century, his life has sometimes become the subject of psychological research on creativity. This research uses one of the following three standard methodologies for studying historic figures: psychobiographical, comparative, and historiometric.

Psychobiographical Methods

Originally inspired by Sigmund Freud's classic psychobiography of Leonardo da Vinci, many great artists have become the subject of this approach. This method can be characterized as single-case studies that use qualitative analyses to draw idiographic conclusions. By 'idiographic' is meant that the inferences concern explanations for unique characteristics of the psychobiographical subject. For example, a large number of psychobiographies have been written about the Dutch painter Vincent Van Gogh, their purpose being to explain why he cut off part of his ear to give to a prostitute. Although these interpretations often rely heavily on psychoanalytic theory, they do not have to do so.

Probably the best example of a psychobiography of Picasso was published by Mary M. Gedo, an art historian. She compared the chronology of the artist's work with what was going on in his personal life. In doing so, she argued that his creativity was highly autobiographical. The connections were more than just the observation that some lover or friend became the subject of a painting. Sometimes the composition appears to have a deeper significance. As an example, Gedo argued that the 1903 *La vie* reflected the conflict the artist experienced between "his desire for a suitable sexual object and his duty toward a sorrowing, unyielding mother" (p. 50). Sometimes particular stylistic shifts could be connected to specific episodes or conditions in Picasso's life. It was no accident that his famed Blue Period took place when his material and emotional circumstances were usually dire.

Comparative Methods

The comparative approach is also qualitative in nature, but uses multiple cases rather than a single case. Because of this difference, comparative studies tend to be more nomothetic than idiographic. That is, comparative researchers will look for general characteristics that apply to all of the cases rather than the peculiarities of any one case. This approach is extremely old. In fact, Plutarch's *Parallel Lives*, which compares ancient Greeks and Romans, may be viewed as a classic example.

The most important modern instance using Picasso among the cases is undoubtedly Howard Gardner's *Creating Minds*. The book's subtitle provides a clue to its aims: *An Anatomy of Creativity Seen through the Lives of Freud, Einstein, Picasso, Stravinsky, Eliot, Graham, and Gandhi*. These seven individuals each represent one of Gardner's original intelligences. Despite that divergence, Gardner showed that they all share certain dispositional traits and developmental experiences.

For example, all seven were highly self-absorbed. This self-absorption ranged from disregarding others (Einstein and Eliot) to being difficult toward others (Gandhi, Stravinsky, Graham, and Freud) to being "frankly sadistic" (Picasso!). The artist could be extremely cruel to even his closest intimates.

Likewise, all seven displayed Gardner's version of the "ten-year rule," namely that some major breakthrough or creative shift takes place every decade or so. In Picasso's case, these are identified as *Les demoiselles d'Avignon* and the development of cubism, then the emergence of his Neoclassical style, and finally *Guernica*, which is seen as a 'comprehensive work' rather than a 'radical breakthrough' (as in *Les demoiselles*).

One very positive feature of this approach is that Picasso is put in the context of other highly creative individuals operating at roughly the same time. He was not only similar to the other great creators, but also strikingly different. For instance, of the seven subjects Picasso had the best claim to status as a child prodigy. Facilitated by the fact that his father was an art teacher, Picasso was able to acquire very precocious mastery of artistic techniques and expression.

Historiometric Methods

Like comparative studies, historiometric research uses multiple cases, only even more so. A typical investigation might consist

of dozens if not hundreds of cases. However, unlike either psychobiographical or comparative approaches, historiometry is strictly quantitative. Furthermore, although historiometric inquiries, like comparative studies, are inclined to nomothetic conclusions, that inclination is even more emphatic in historiometry, which engages in formal hypothesis testing using statistical techniques. Indeed, most often the cases that make up the sample are never completely identified by name. Instead, the names are only mentioned to illustrate how a variable might be defined or to prove a specific illustration of some nomothetic result. Accordingly, Picasso might be one of the cases in the investigation without ever being explicitly mentioned.

A case in point is a historiometric study that Dean Simonton conducted of 772 Western artists who were born between 1042 and 1918. This study was designed to test the hypothesis that artistic creativity is contingent on the artist being enmeshed in a complex social network of fellow artists, including older and younger creators as well as those who more properly count as contemporaries. This hypothesis was amply confirmed. Yet, despite the fact that Picasso was counted among the 772 cases, that inclusion was never made explicit. Only a handful of cases, such as Michelangelo and Leonardo da Vinci, are ever identified, and then only to make some narrow methodological or substantive point (e.g., that Michelangelo was the most eminent of the 772).

Nonetheless, it is worthwhile noting that Picasso exemplified the central finding of this historiometric investigation. More specifically, given that he was probably the most eminent artist of the twentieth century, we would expect that he would have been richly linked with other artists. That was in fact the case, those artists including such fellow (even if sometimes lesser) luminaries as Jean Arp, George Braque, André Derain, Juan Gris, Paul Klee, Fernand Léger, Henri Matisse, Amedeo Modigliani, Henri Rousseau, Gino Severini, and Maurice de Vlaminck. Naturally, some of these artistic linkages were more substantial than others were. The Braque and Matisse connections were especially critical, the former as a collaborator in the advent of Cubism, the latter as a key competitor and influence.

Although psychobiographical, comparative, and historiometric approaches are quite distinct, all three converge on one crucial fact: Picasso was certainly not a lone genius. His relationships with others, both artistic and personal, exerted a powerful impact on his creativity. In that respect he is typical not only of other artistic geniuses but also of creative geniuses in general.

His Work: Empirical Studies

Rather than concentrate on Picasso's entire life or work – or the relation between the two, some researchers have turned their attention to single creative products. For example, Robert Kastenbaum used Picasso's 1903 *The Old Guitarist* (in conjunction with Alfred Tennyson's poem *Ulysses*) to examine how young artists – Picasso was in his early 20s at the time – envision old age, with the idea that such time-transcendence would shed light on creativity. Other psychologists have used other Picasso creations to fathom other aspects of artistic creativity.

By far, the product that has received the most scrutiny is Picasso's 1937 *Guernica*. As noted earlier, this painting cannot be considered one of his key artistic breakthroughs. That distinctive status is reserved for his 1907 *Les Femmes d'Alger (O. J. Version O)*. Even so, it can still be viewed as his most iconic creation in the sense that it likely constitutes the work most strongly connected with his name. The painting is also one of the few of Picasso's works that deals with an actual historical event, namely the brutal bombing of the Basque town Guernica by Italian and German warplanes during the Spanish Civil War. This event clearly affected Picasso deeply, for the painting displays far more dramatic and dynamic power than his other major works, which are often austere and static. Yet from a research perspective, the most significant reason why this painting has attracted so much attention is that Picasso left 45 sketches. Because these sketches are numbered and sometimes even dated, they provide clues to the work's development.

These sketches fall into two categories. First are the various sketches that treat the entire composition, or at least the relationships among two or more figures. Second are the sketches that are devoted to the central figures in the final painting. These principal figures (with their approximate location) are as follows: (a) the menacing bull (in the upper left hand corner); (b) the weeping mother with her dead child (just below the bull); (c) the fallen and dismembered warrior with his outstretched hand and arm (bottom left corner), his head (to the right of former), and his arm holding the broken sword (bottom center); (d) the wounded and screaming horse (dominating the center); (e) the frightened woman looking out an upper-story window holding a lamp (to the right of the horse's head); (f) the wounded but still walking woman laboriously dragging her leg (lower right corner); and (g) the woman apparently falling in a burning building with arms thrust upward (in the upper right corner). Interestingly, the sketches include some figures that never ended up in the completed work, such as a winged horse.

Rudolf Arnheim, the Gestalt psychologist, conducted the first scientific study of artistic creativity based solely on these sketches. The resulting 1962 book *Picasso's Guernica: The Genesis of a Painting* has become a classic on this subject. Upon careful examination, Arnheim concluded that the sketches do not exhibit a progressive advance toward the final version. In particular, "the work of art cannot unfold straightforwardly from its seed, like an organism, but must grow in what looks like erratic leaps, forward and backward, from the whole to the part and vice versa" (pp. 131–132). Indeed, some of the sketches seem well wide of the mark, hardly seeming to belong to the same painting even when they concerned the same figure. Most conspicuous are the dramatically different versions of the horse and the weeping woman.

Dean Keith Simonton, in his 1999 book *Origins of Genius*, argued that these abundant "false starts and wild experiments" (p. 197) provided evidence for a Darwinian theory of creativity – a theory assuming that creative thought depends on blind variation and selective attention. Simonton's assertion then kindled an empirical and theoretical debate on what the *Guernica* sketches actually revealed about the creative process. This debate began with Robert Weisberg, who in 1995 had argued that the sketches reveal straightforward 'reproductive'

thinking in which graphic ideas already found in Picasso's 1935 etching *Minotauromachy* were simply extended and developed into those found in *Guernica*. As a consequence, Weisberg published a book review of *Origins* that was highly critical of Simonton's position. Later in 2004, Weisberg published an empirical study of the sketches that showed how the figural developments were highly structured. In the same year, Subrata Dasgupta published an article criticizing Simonton's interpretation on theoretical grounds. After responding to Dasgupta's critique, Simonton decided to conduct a comprehensive empirical study of the sketches. This investigation was published as a target article in a 2007 issue of the *Creativity Research Journal*, with comments by Weisberg and others, plus a reply by Simonton. A year later, Charlotte Doyle published her own independent criticisms of Simonton's interpretations. Because Simonton has yet to respond to the last article, the best conclusion to draw is that the jury is still out about whether the sketches illustrate Darwinian creativity. At this point, it is probably best to stick to the empirical facts. These facts represent something of a paradox.

On the one hand, it is manifest that the sketches are by no means utterly random. In the first place, the imagery in *Guernica* has undeniable antecedents in Picasso's prior work. It did not emerge de novo but rather most of the images have recognizable versions in previous products, especially the aforementioned *Minotauromachy*. In a limited sense, *Guernica* is nothing more than a recombination of previous visual ideas, even if an unusually successful recombination. To be sure, these earlier ideas did undergo considerable development. Thus, the naive and passive little girl holding the lamp in *Minotauromachy* is far removed from the fully aware and emotionally wrought adult holding the lamp in *Guernica*. Moreover, it is also quite clear that the succession of sketches did not randomly jump around from one graphic subject to another. Rather, Picasso would often pursue one line of thought for a few sketches before turning to another – trying out the range of possibilities in one figure before trying out a complementary range of possibilities in another figure. This sequential exploration was especially important in getting adjacent figures to become compatible in the overall compositional representation.

On the other hand, it is equally obvious that the sketches are far from being systematic. Their haphazard quality is especially impressive given the tremendous amount of artistic expertise the artist had acquired by this time – almost 40 years worth. With that amount of accumulated skill and knowledge, Picasso could have begun with a rough sketch of the composition with all the figures roughly in place, and then gradually refined each figure in conjunction with the others until the final composition emerged with the parts congruent with the whole. In fact, with lesser works Picasso could conceive a satisfactory product in precisely this way. Yet in a masterpiece like *Guernica* his procedure was extremely messy and inefficient.

The latter statement was demonstrated in Simonton's 2007 empirical investigation. Here five independent raters were asked to rate all of the sketches according to how similar they were to the final painting. Significantly, two of the raters – Subrata Dasgupta and Robert Weisberg – were already on record as claiming that the sketches displayed a highly systematic progression. Even so, all five raters exhibited a strong

consensus on their ratings so that they could be consolidated to produce a highly reliable 'progress score' for the sketches. These scores were then plotted as a function of the sketch's order. **Figure 1** shows the outcome. It should be apparent that after the initial sketches, the progress scores become chaotic, sometimes moving forward and other times moving backwards. Picasso was definitely not engaged in honing his initial sketches toward the final product. On the contrary, he was clearly engaged in exploring diverse possibilities. As Picasso himself put it, "I do not seek, I find."

It can be argued that the "false starts and wild experiments" seen in **Figure 1** merely reflect the fact that most of the sketches focused on single figures. As a result, Picasso might advance one graphic component (e.g., the horse) to a certain stage and then return to another graphic component (e.g., the bull) to bring it up to the same stage of development. However, if this argument is correct, then the backtracking will vanish when we look at each graphic component separately. This separation is accomplished in **Figure 2**.

The sketches for the bull, mother with dead child, warrior, horse, and weeping woman all exhibit significant zig-zag patterns indicative of backtracking. Often the final image in the painting is closest to one of the earlier sketches in the corresponding series. For instance, the second sketch in the mother with child series turned out to be the most proximate to the final product. The same was true for the weeping woman. The only sketch that shows a roughly positive monotonic function is the woman with the lamp. Yet even in this case the penultimate sketch in the series is the one that comes closest to the final image.

It is essential to emphasize that Picasso's exploratory experiments did not stop with these sketches. Even after he transferred his graphic ideas to the large canvas that was to become the final product, he continued to make major alterations. This fact is apparent in the series of photographs that were taken of the painting in progress. For instance, the photograph of the earliest version of the canvas depicts the fallen warrior with his arm thrust up with a clenched fist. Because this arm and fist dominated the center of the painting, it made the warrior one of the most dominant figures in the composition. Yet this

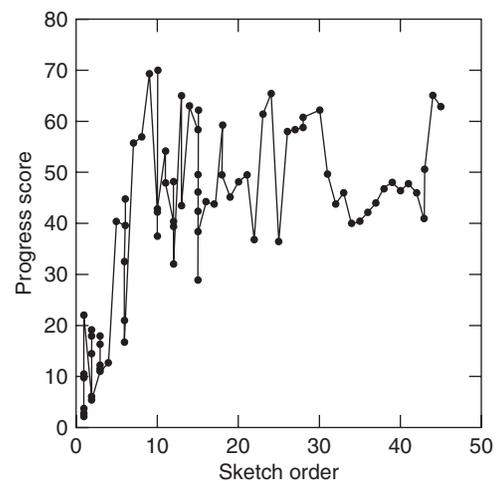

Figure 1 Estimated progress scores for the *Guernica* sketches plotted as a function of actual sketch order.

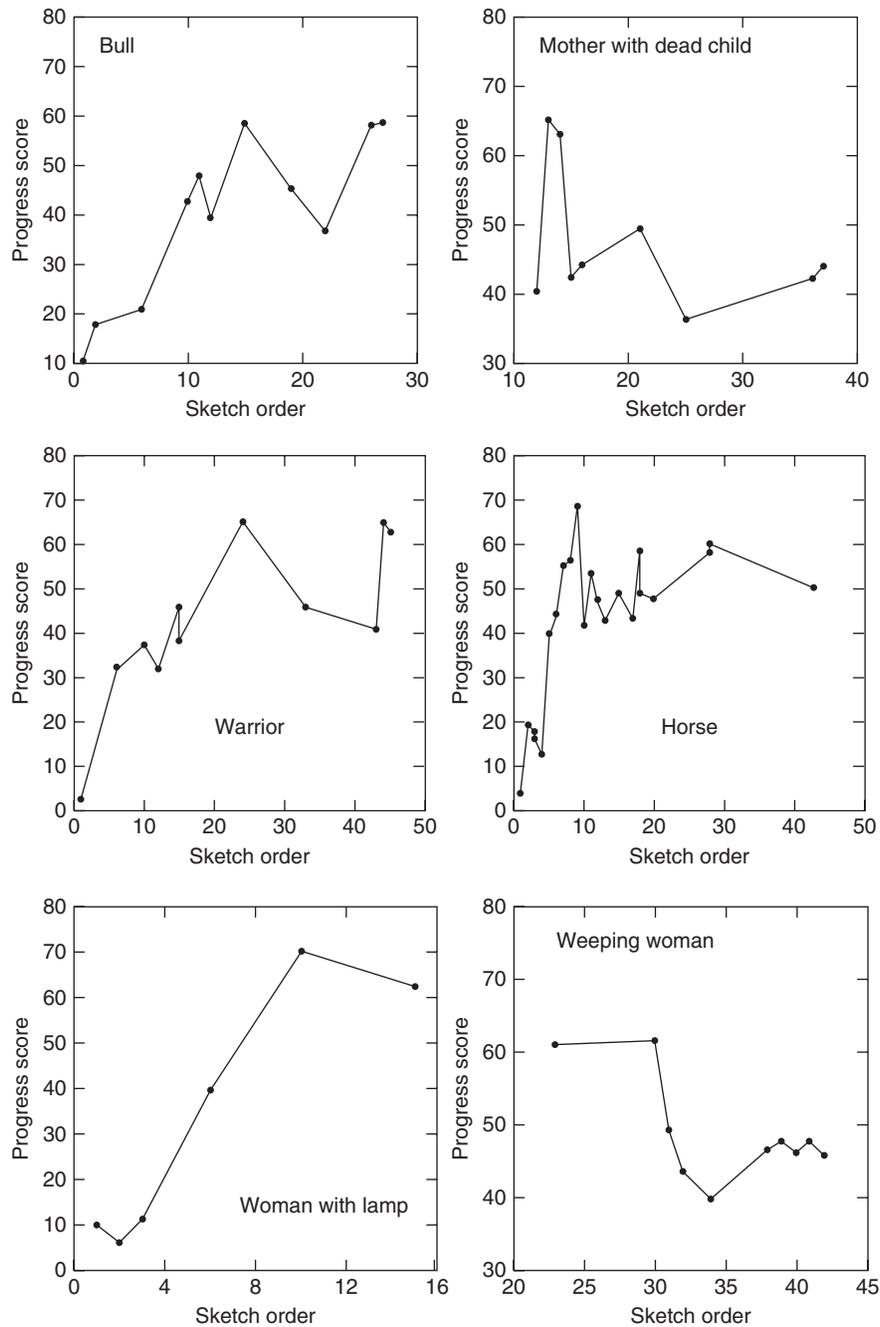

Figure 2 Estimated progress scores plotted as a function of actual sketch order separated by specific figure.

dramatic gesture was transformed until it totally disappeared. Its only remnants are some vestigial elements that now have no connection whatsoever with the fallen warrior. For example, the light in the top center of the finished painting was indirectly derived from the warrior’s fist.

These photographs show another curiosity: Picasso would sometimes attach wallpaper collages directly to the canvas. Not only would these come and go, but they would also appear in different places in the composition. The artist was visibly playing around with the possibility of completing the painting in the manner of Synthetic Cubism, but he changed his mind.

The final painting ended up largely linear and monochromatic, in contrast to many of his earlier sketches. Furthermore, the sketches often exhibited far more intense emotions than those displayed in the completed work. This emotional intensity is especially apparent in the sketches for the weeping woman, some of which images verged on the hysterical. This divergence is apparent in the bottom right-side graph of Figure 2.

All told, the sketches and the canvas photographs illustrate the extremely chaotic nature of Picasso’s creative process. This feature is especially striking given the phenomenal magnitude of the artist’s expertise. He had been painting for at least 4

decades when *Guernica* came into the world. Even so, he still needed to depend heavily on trial and error.

Conclusion

Picasso's stature as a creative artist has if anything increased since his death in 1973. Such contemporaries as Matisse and Braque seem to have lost ground in comparison. Picasso's elevated status was confirmed by a recent quantitative study that measured the amount of space devoted to various artists in standard reference works. Although Michelangelo ranked first, Picasso came in second, followed by Raphael, Leonardo, Titian, Dürer, and Rembrandt. The only other modern artists in the top 20 were Cézanne, Monet, Van Gogh, and Gauguin. Furthermore, Picasso produced a range of work in a diversity of styles and media that is probably unrivalled by any artist in any time or place. At the same time, he lived a fascinating and sometimes turbulent life. Not only is this life well documented, but so is the creativity corresponding to those life events. This wealth of data invites creativity researchers to delve more deeply into someone who can be viewed as the prototypical artistic genius.

This article is reproduced from the previous edition, volume 2, pp. 387–393, © 1999, Elsevier Inc.

SYLVIA PLATH (Victoria Lucas) was a creative American poet who died at the age of 30 in 1963 in England by putting her head in a gas oven. She wrote several volumes of poetry and a novel. Her work was based on her life experiences and had a confessional quality common also to the poets Robert Lowell and Anne Sexton. Plath had a severe depression when she was an undergraduate student, during which she attempted suicide. She was treated with electroconvulsive therapy and psychotherapy. Her life provides an opportunity to explore how creativity and psychiatric disorder interact throughout the course of a life history.

Sylvia Plath seated in front of a bookshelf. (Copyright CORBIS/Bettmann.)

Background

Plath's father, Otto Plath, was born in 1885 in the German town of Grabow. He emigrated to the United States when he was 15 years old and earned a doctorate in 1928, specializing in the study of bees. He began teaching at Boston University where he met a student named Aurelia Schober who was 21 years his junior. After divorcing his first wife, he married Aurelia in 1932. Sylvia Plath was born on October 27, 1932, three weeks ahead of schedule. She was somewhat frail because of a sinus condition that plagued her for the rest of her life. Two and a half years later, her brother Warren was born.

Plath's early years were uneventful. She apparently was quite bright and used her intelligence to please her father, as many firstborns do. She learned the Latin names for insects, and Otto would show off her skill to visitors. From the beginning, she earned straight As in school, impressing teachers with her intelligence and dedication. Aurelia read a lot to the

children as they grew, and Plath's verbal skills were so advanced that she went to school at age 4 and excelled right away. By age 5, she was writing short poems.

Otto fell ill in 1935, and he deteriorated over the next 4 years. He decided that he had lung cancer and chose not to seek treatment so that he would die quickly. He, therefore, initially refused to consult with doctors. In 1940, he noticed weird symptoms and finally sought medical advice. He found out that he had diabetes, which was treatable at that time, but he had waited too long before seeking treatment. In October 1940 his leg was amputated, and he died of an embolism on November 5, 1940, 8 days after Sylvia's birthday. Early loss is common among those who later commit suicide, and it may make them less able to cope with loss later in life.

Aurelia moved to Wellesley where she could raise her children in an educated and middle-class community and give them high-achievement experiences. Plath's first poem appeared in the *Boston Sunday Herald* in August 1941, when she was 8½ years old, and she won a prize for a drawing in another contest. As she progressed through school, her work continued to be outstanding, and she received many awards. She quickly developed an interest in literature and in writing. In junior high school she received straight As and a perfect record of punctuality. Her poems and drawings continued to win prizes. Her IQ was about 160. High school continued in the same vein. Plath took the advanced literature courses and edited the school magazine in her senior year. Her stories and poems appeared in magazines such as *Seventeen* and the *Christian Science Monitor*. She was also active in the local Unitarian church and in the community. She ranked first among the 158 graduates and was admitted to Smith College on a scholarship. Her biographers do not mention psychological problems at this time in Plath's life, though she tended to suffer from depression whenever her sinuses or menstrual cramps bothered her. However, the frequency and severity of the depressions is unclear. Plath's career at Smith was outstanding. From the first, she obtained mainly As, and her literary achievements steadily grew. Throughout her stay at Smith, she worked hard, often ending up fatigued and depressed. She continued to write and submit her work for publication. Despite frequent rejections, she built up an incredible body of published works. Indeed, a \$500 prize from *Mademoiselle* in the summer of 1952 led to an offer by Knopf and Dodd Mead asking her to consider writing a novel. However, not surprisingly, a run of rejection slips led Plath to question her ability and to fall into a depression.

Her junior year led to her most severe depression. She confided to her mother thoughts of suicide, and she saw a

psychiatrist in December of that year. But she continued to study hard and work toward winning a guest editorship at *Mademoiselle* in the summer of 1953, which she indeed won.

The summer of 1953 is the focus of Plath's novel *The Bell Jar*, written mostly during 1961 and 1962. At *Mademoiselle* Plath worked for Cyril Abels, reading and judging manuscripts and participating in all of the social activities planned for the group of guest editors. Abels noticed Plath's distancing manner and tried to break through and relate to the real Sylvia, but she failed to penetrate Plath's social mask. Although the guest editorship was exciting, Plath came home depressed by the experience.

Back in Wellesley, Plath was rejected for a course on creative writing at Harvard summer school, which left her with two months to fill. She could not write, and her depression worsened. After she cut her legs in a suicidal gesture, her mother began locking up the sleeping pills in the bedroom that they shared and took Plath to a local psychiatrist who diagnosed a depressive disorder and recommended electroconvulsive therapy. (In the 1950s, effective antidepressant medications had not yet been developed.) The electroconvulsive shock therapy seemed to make Plath's condition worse, and she developed chronic insomnia.

Plath contemplated using a razor blade to kill herself and she tried to drown herself in the sea. Eventually, on a Monday morning in August 1953, she took 40 sleeping pills from where her mother had locked them up, went into the basement of the house (after leaving a note saying that she was going for a hike and would be back the next day), and crawled behind some wood that was stacked there. (It appears that she threw up some of the pills, which possibly saved her life.) Her mother called the police that evening, and search parties were organized. Plath was not found until Wednesday afternoon when her grandmother went into the basement to do the laundry and heard Plath moaning. After a week in the hospital, Plath was transferred to the locked psychiatric ward at Massachusetts general Hospital where Erich Lindemann examined her. He diagnosed an adolescent nervous illness, whereas another psychiatrist diagnosed an acute schizophrenic episode. Her depression did not lift, and so she was transferred to McLean Hospital where she received insulin shock therapy, then chlorpromazine, and finally electroshock therapy again. This treatment was supplemented by psychotherapy from a female psychiatrist, Ruth Barnhouse. Barnhouse observed that Plath first refused to talk much and was angry at her mother. Barnhouse saw Plath as an intuitive-feeling type in Jung's schema, and Plath said that she felt she had been forced into using thinking to the neglect of feeling. Surprisingly, this time the electroconvulsive therapy helped and during the Christmas holidays Plath's depression disappeared. Plath was released in January 1953. She told a friend that she had tried to kill herself because she feared she had lost her talent to write. She also told him that she had tried to slit her throat when she was 10 years old, and she did have a scar on her throat. Barnhouse had encouraged Plath to no longer suppress her sexual impulses, so Plath had sex for the first time. When she returned to college, Plath confided to another friend that she had both loved and despised her father and probably wished many times that he was dead. When he died, she imagined that she had killed him (a theme that later appeared in one of her poems).

Aurelia heard from one of Otto's sisters that Otto's mother, a sister, and a niece had all suffered from depression, raising the possibility that an inherited predisposition to depression ran in the family. Plath spent another 1½ years at Smith and graduated in June 1955. Although Smith took away the scholarship for her first semester back, the college restored it for her final year. Graduation resulted in many prizes and awards, including Phi Beta Kappa and summa cum laude (one of only four students in her class so honored), and she was awarded a Fulbright scholarship to Cambridge University in England.

Plath had written at least 200 poems, short stories, newspaper articles, and magazine pieces, some of which had been published in national periodicals. Of course, she also received numerous rejection slips, but although the rejections often damaged her self-confidence they did not deter her from writing and submitting her work for publication.

Cambridge University and Ted Hughes

Plath spent 2 years at Newnham College of Cambridge University, where she eventually obtained her second BA. She hated the cold and rainy weather and the poor heating of the rooms. She fell ill frequently with sinusitis, colds, and the flu. She realized how much better prepared the British students were, and she abandoned plans to obtain a doctorate. She kept busy with course work, writing, and dating. Plath determined that she would be, at best, a minor writer and decided to settle down as a wife and mother who would write only in her spare time. Her depression worsened, and she saw a psychiatrist at the university. Then in February 1956, she met Ted Hughes. Hughes, an aspiring poet and writer like Plath, had graduated from Cambridge in 1954 and had worked in various odd jobs. Plath met him at a party in Cambridge and was attracted "at first sight." They married in June 1956.

Plath began to work with dedication on their literary careers, typing up and sending off submissions of both Hughes's work and her own. Their publications grew more and more numerous, and Hughes's first collection of poems was accepted for publication in 1957. They came to the United States, and Plath taught at Smith College for a year.

At this time, Hughes was the more successful poet. He had soon completed a second book of poems and a book of children's stories. His poems appeared in *The New Yorker*. The couple decided to return to England, especially as Hughes was not happy in the United States. But first they spent a year in Boston, and they supported themselves with the money Plath earned working at odd jobs along with their income from writing. Plath audited a course at Boston University from Robert Lowell, during which she met Anne Sexton, and her poems were eventually accepted by *The New Yorker*. Plath went back into therapy with Ruth Barnhouse and dealt with some of the feelings she had toward her mother and, with Barnhouse's encouragement, visited her father's grave.

Hughes was awarded a Guggenheim fellowship, which eased the couple's financial worries, and they were invited for three months to Yaddo, an artists' colony near Saratoga Springs in New York. They spent 3 months touring the United States during the summer of 1959, and during this trip Plath found

out that she was pregnant. They left for England in December 1959. Plath was twenty-seven, pregnant, and headed for permanent residence in a foreign country.

England and Suicide

The couple first rented an apartment in London. Plath gave birth to Frieda in April 1960. Visits to Hughes's family did not go well, as Plath and Hughes's sister Olwyn had severe conflicts. Later that year, Plath and Hughes looked for and found a house in Croton, Devon, with the help of loans from both of their families. Before moving, Plath found out that she was pregnant again. They rented their apartment in London to a Canadian poet, David Wevill, and his German-Russian wife, Assia Gutmann, and moved to Devon. Their literary careers continued to progress, and Plath's first book of poems was published in 1960. They each won prize after prize and by 1961 were successful enough as writers that their finances were thereafter in good shape. In 1961, Plath was awarded a Saxton Foundation grant to work on *The Bell Jar*. Plath gave birth to a son, Nicholas, in January 1962, but Hughes seemed unhappy to have a son and kept distant from the baby. He later admitted that he had not wanted any children. The cold winter made Plath ill and depressed, but life was full and busy with writing, the children, and a new house to fix up. By the summer of 1962, another woman had entered Hughes's life. Hughes and Plath had invited poet David Wevill and his wife Assia Gutman to visit, and soon Hughes and Gutman were in love and having an affair. Hughes left Plath in July, but Plath maintained hope that he would return to her.

Her work did not go well at this time. Plath's *Colossus and Other Poems* had received poor reviews, and the poems written in her new style were being rejected. She was also finding it hard to write. On her 30th birthday in October 1962, she was in Devon with two children, deserted by her husband, and now writing poems furiously every morning. By December Plath had moved to an apartment in London and had rented the house in Devon to others. The last few weeks of Plath's life were difficult. She corrected the galley proofs for *The Bell Jar* and was awaiting publication and comment. She was working feverishly, smoking heavily, hardly sleeping, and eating little. She had lost 20 lb. since the summer and developed influenza, after which the children came down with it. The winter was one of the worst ever, with frozen plumbing, strikes by the electrical workers, and snow and ice everywhere. The weather did not break until the end of January.

The reviews of Plath's book appeared at the end of January, and they were lukewarm. (She had published it under a pseudonym, which meant that reviewers would be less likely to give the work close attention that a work by Sylvia Plath would merit.) Her recent poems were being rejected, and her publishers could not sell *The Bell Jar* to an American publisher. In the last week of her life, from February 4, 1963 to February 11, Plath had a fever and wildly fluctuating moods. She lost her au pair on February 7 after arguing with her, and the weather was still bad. Plath kept in close contact with her physician, John Horder, and after February 4 she saw him daily. He treated her depression on his own, but also tried to refer her to a regular psychiatrist. Horder put Plath on antidepressants

(a monoamine oxidase inhibitor), and then, on February 7, searched for a bed in a suitable hospital so that Plath could be admitted. Two he approached were full, and one he deemed unsuitable. Friends invited Plath and the children to come and stay that day. On the evening of Friday, February 8, she met Hughes briefly and then came back to her friends' home. However, on Sunday she decided to take the children home, despite the protestations of her friends. Horder called her that night. That night she put the kids to sleep, opened their windows, placed milk and bread and butter by their beds, left a note on her downstairs neighbor's door to call Horder, sealed herself in the kitchen, and put her head in the oven and turned the gas on. Horder had arranged for a nurse to come on Monday morning, February 11. The nurse arrived at 9 a.m., but could not get in. She went to a public telephone to check on the address she was supposed to visit, and came back to see two children crying at the bedroom window. She found a workman who helped her break in, and they found Plath. The workman began artificial respiration, and the nurse took over. A police officer rescued the children, but when Horder arrived he pronounced Plath dead at 10:30 a.m. The gas had asphyxiated the downstairs neighbor too, and he did not regain consciousness until the late afternoon.

Discussion

The loss of her father when she was 8 years old looms large in Plath's life, especially because of the way she wrote about him. Plath seemed to be filled with anger over his rejection of her, both while he was alive (neglecting her for his research) and upon his death. Her poem written in the months prior to her suicide casts him as a devil, a concentration camp guard with her as a victim. She viewed Hughes as a father substitute. Yet she loved her father too and casts her suicide attempt years earlier as an effort to be reunited with him. (Interestingly, Plath eventually kept bees, as did her father, and she studied German, the language of her father. Her identification with him was strong.) Plath was depressed throughout her life, and it is likely that she had an affective disorder. Her first major breakdown occurred when she was an undergraduate, and her suicide has partly been attributed to her fear of becoming psychotic again. On top of this, she lost her husband, whom she loved, and who provided her with the environment to flourish as a mother and author. He not only left her, but he rejected her for another. In her novel about her psychiatric breakdown in 1953, Plath shows a distrust of her ability. She had worked hard to get good grades and to publish, but she feared that the success was temporary. However, Plath seemed to be quite persistent in her writing career and sent off poems and stories despite rejections.

Was Plath's Writing Helpful or Harmful?

Is writing therapeutic for creative writers or is it a stressor that can contribute to their psychological disturbance? Martin Silverman and Norman Will have argued that, although Plath tried to control her suicidal impulses by means of her poetry, she failed in this endeavor. Successful poetry, they suggested, must communicate between the inner worlds of the creative

person and the audience. (Presumably they mean *critically* successful, for even poor poetry can serve a useful psychological function for the writer, even if it is merely cathartic.) To be successful, poetry must first achieve a balance between the writer's use of the audience to serve his or her own narcissistic needs (a type of exhibitionism) and the desire to give others a way of structuring the terrors and anxieties that afflict us all. The writer must also achieve a balance between the potentially destructive conscious and unconscious forces motivating the writing and the constructive desires to harness these forces for the purpose of writing creatively. In terms of psychoanalysis, the writer must balance primary and secondary process mechanisms. The writer must also compromise between the fantasy permissible in writing and the acceptance of reality necessary for successful living.

When they applied their ideas to Sylvia Plath, Silverman and Will asserted that the successful creative process is successful only when the unconscious forces in the writer operate silently and remain hidden from view. This assertion represents a rather traditional view of creative writing. It would seem to express a preference on the part of Silverman and Will for a particular type of literature rather than expressing a universal truth. For example, the unconscious forces motivating Ernest Hemingway may be under control in his writing, but they are certainly not hidden, and the confessional style of poetry developed by W. D. Snodgrass and Robert Lowell and pursued by Anne Sexton and Sylvia Plath is in direct opposition to Silverman and Will's view. In Plath's later poems she revealed her deepest feelings, using her experiences to create the poem rather than to simply transform it. Silverman and Will noted that she described her early poems as "proper in shape and number and every part" but not alive. Her poems moved from being a reordering and reshaping of experience with a poetic purpose to becoming expressions of herself. She identified with her poems, which made their rejection even more painful, and Silverman and Will labeled this change as a "narcissistic regression." The causal sequence that Silverman and Will propose for Plath is simply one reading of Plath's life. Other equally plausible alternative paths can be proposed. For example, it is quite likely that Plath's participation—along with Anne Sexton, with whom she became very close—in a poetry workshop run by Robert Lowell had a major impact on her writing style. Several members of his workshop adopted a more self-revealing content for their poems, and two received Pulitzer prizes for their work (Lowell and Sexton). Furthermore, Plath, as she herself clearly recognized, was prone to recurring depressions. In all probability, Plath had an affective disorder, possibly bipolar, and her depressions were likely to reoccur periodically. It is evident from the severity of her

depression in 1953, which led to a very serious suicide attempt, that she would likely become suicidal again with each new depression (much as Virginia Woolf had).

It is interesting to note that although her writing may not have helped her cope with the stressors, external and intrapsychic, with which she was confronted during the early 1950s, in the later 1950s her switch to a more revealing and personalized style of writing may have helped her survive. Silverman and Will claimed that her writing failed to prevent her suicide. Perhaps it may have postponed her suicide? In the months prior to her suicide, Plath wrote feverishly, sometimes producing several poems in one day. (This feverish activity in the months prior to a suicide was apparent also in Anne Sexton's life.) What would Silverman and Will suggest as a more appropriate strategy for a person confronting intrapsychic turmoil who is not under professional care? It is very likely that the writing helped Plath control her inner turmoil, and some commentators think that the poems she produced were among her finest.

David Lester and Rina Terry have argued that writing poetry can be useful with suicidal clients. They saw the construction and revision of poems as serving a similar function for clients as the journal assignments devised by cognitive therapists by giving the clients intellectual control over their emotions and distance from the traumatic memories. Both Plath and Sexton showed manic trends prior to their suicides, writing poems furiously, poems with more emotional expression and less poetic crafting. Rather than arguing that writing poetry contributed in part to their suicides, it makes much more sense to say that, in their final breakdowns, poetry was no longer able to help them deal with the intrapsychic forces driving them as it had in the past. As their inner turmoil increased, both wrote feverishly, almost like a safety valve letting out the steam under pressure in a boiler, but to no avail because the pressure was building up faster than they could release it.

This final failure of the craft of poetry to keep Sylvia Plath alive may not signify total failure. She was an outstanding poet and functioned quite well given her psychiatric disorder. Perhaps the craft of poetry kept her alive for many years after her self-destructive impulses first manifested themselves.

Glossary

Affect themes in play Emotion-laden content in the play narrative that reflects memories, thoughts, fantasies, and representations of events.

Divergent thinking The ability to generate a variety of associations, ideas, and problem solutions.

Play facilitation Improving the processes that occur in play such as imagination or affect theme expression.

Playfulness Cognitive spontaneity, social spontaneity, joy, and a sense of humor in approach.

Pretend play Play involving make-believe, an 'as if' stance, fantasy, and symbol substitution.

Pretend Play

Play is a universal phenomenon of childhood that comes in many forms. Pretend play which involves the use of fantasy and make-believe and the use of symbolism is the form most relevant to creativity. Pretend play also involves affect and expression of emotions. Greta Fein has conceptualized pretend play as symbolic behavior where one thing is treated as if it were something else. A lego becomes a milk bottle or a block becomes a telephone. Fein also stressed that pretend play is charged with feelings, so that affect is intertwined with pretend play. She viewed pretend play as a natural form of creativity.

Much of what has been written about the development of creativity in children has focused on the development of play. Keith Sawyer conceptualized pretend play in young children as being improvisational in that it is unscripted yet has loose outlines to be followed. Much of creative performance involves improvisation. Lev Vygotsky theorized that imagination developed out of children's play. He stated:

The child's play activity is not simply a recollection of past experience but a creative reworking that combines impressions and constructs from them new realities addressing the needs of the child. (1930/1967, p. 7)

Through play, children develop combinatory imagination—the ability to combine elements of experience into new situations and behaviors. Combinatory imagination is important in both artistic and scientific creativity.

Play follows a developmental process. Before two years of age, children play with objects similarly no matter what their actual functions are. Around two years of age, children discover that objects have specific functions. They recognize that a telephone is used to talk to someone and a plate is used to hold food. Also around the age of two, children begin to discover pretend play. They are able to pretend that a circular block is a wheel. Children continue to develop pretend play abilities throughout their childhood until about ten years of age. There are individual differences in how frequently children engage in pretend play and over what period of time during their childhood. In pretend play, children are able to think symbolically and not be confined to a single use of an object. The child is able to transform the object to represent many things but is also aware of the primary use of the object.

As children develop, their play becomes more complex. Jeffery Dansky (1999) pointed out that in high level play, children display all seven dimensions of original thinking described by Roberta Milgram: associative fluency; imagery; curiosity; fantasy; problem finding; metaphoric production; and selective attention deployment. He concluded that individual differences in play have implications for individual differences in creativity. Dansky also theorized that adopting the 'as if' frame in play may open the door to a mode of problem solving where one can play with ideas and possibilities, which is so important in creativity.

Fein studied the pretend play of 15 preschool children who were master players. From her observations, she concluded that good pretend play consisted of five characteristics:

1. Referential freedom. The 'as if' quality in play where one object is treated as if it were another, one person functions as if they were another, and time and place is as if they were different.
2. Denotative license. Pretend events occur and there is a divergent stance with respect to actual experience.
3. Affective relations. Symbolic units represent affective relationships such as fear of, love of, or anger at. Information about affective events are stored and manipulated in ways that make affective sense for the player.
4. Sequential uncertainty. There is a nonlinear quality to the sequence of events.
5. Self-mirroring. The self is observed through a distance. Children are aware of the pretend quality.

Play and Creativity

In 1983, Nathan Kogan stated that the research on the play and creativity link was the most promising set of findings in the children's creativity literature in the previous decade. The promise of that early research has continued to be realized. Edward Fisher in 1992 conducted a meta-analysis in the play and child development area. He found that the strongest relationships were between play and divergent thinking and play and perspective-taking criteria. He concluded that play does result in improvement in children's development. The strongest relationships were with cognitive abilities important in creative thinking.

It makes theoretical sense that pretend play would relate to creativity because many of the processes involved in the creative act occur in pretend play. In order to study play and creativity, one must be specific about the underlying processes involved. Sandra Russ in 2004 reviewed the literature and developed a model of cognitive and affective processes that occur in both play and creativity. Through pretend play, children practice cognitive processes such as divergent thinking, organizing thoughts into a narrative, flexible thinking, and the use of symbolism and fantasy. Pretend play also is a medium for affective processes to be expressed. Children use play to express emotions and affect-laden fantasy, to regulate emotion, and to experience the joy of the play experience itself. Interpersonal processes can also be observed in pretend play. Characters communicate and interact with one another and role play different perspectives.

Pretend Play and Creative Cognitive Processes

Dorothy and Jerome Singer suggested that areas of cognitive development are facilitated by pretend play abilities. Play helps the child to expand vocabulary and link objects with actions. For example, a child can learn words and actions by labeling objects and their functions through play – “I drink from a cup” or “I go in a car.” Play also helps the child develop object constancy and form event schemas and scripts. Playing peek-a-boo is very exciting for a young child who learns that even though mother is hiding, she will return. Pretending to play house or doctor is another way children learn about their world. Pretend play also helps children learn strategies for problem solving, develop divergent thinking ability, and develop a flexibility in shifting between different types of thought (narrative and logical). Singer and Singer thought that the last two categories were especially important in creative thinking.

Cognitive processes thought to be important in creative thinking are divergent thinking, transformation abilities, and insight. Divergent thinking is the ability to generate a variety of ideas. J. P. Guilford identified divergent thinking as important in and unique to creative problem solving. A typical item on a divergent thinking test would be “How many uses for a newspaper can you think of?” Divergent thinking involves free association, broad scanning ability, and fluidity of thinking.

Guilford also proposed that transformation abilities were involved in creative thinking. Transformation abilities involve a flexibility of thought that enables breaking out of an old problem solving set and seeing a new way to solve a problem.

Insight into the solution of a problem is important in creativity. Early research on play and creative problem solving investigated play and insight ability. Studies found that play in children three to five years of age facilitated insight in a problem solving task. Brian Vandenberg concluded that all the studies had the consistent finding that play facilitated insightful tool use and enhanced motivational activity. Variables of task type and difficulty and age were mediating factors. He discussed the similarity between play and creativity in that both involve creating novelty and disregarding the familiar.

Much of the creativity and play research has focused on divergent thinking. Singer and Singer thought of play as practice with divergent thinking, so there should be a strong

relationship between play and measures of divergent thinking ability. Many researchers found significant relationships between play and divergent thinking, usually independent of intelligence. For example, Russ and her colleagues found consistent relationships between fantasy in play and divergent thinking in preschool children as well as elementary school children. In one longitudinal study, play in first and second grade children was related to divergent thinking ability when they were in the fifth and sixth grades. Children who could use fantasy and imagination on a pretend play puppet task could generate more uses for objects (fluency) on a divergent thinking task. The relationship between pretend play and divergent thinking remained stable over time.

Much of the research in this area has been correlational in nature, but there are some well-carried out experimental studies that found that play facilitates divergent thinking. Dansky completed several studies which indicated that play enhanced divergent thinking in preschool children. In one of his studies, he found that free play facilitated divergent thinking, but only for children who engaged in make-believe. It was the pretend element that was important. Some critics of this research raised the issue of unconscious experimenter bias because the same experimenter gave the play and divergent thinking tasks. Peter Smith and Sue Whitney, in a carefully executed study, failed to confirm the hypothesis that play would enhance divergent thinking in preschool children. However, it is also possible that introducing a new examiner between the play and the divergent thinking task broke the set that was being induced by the play. Thus, there would be no experimental effect of play on problem solving. Another important point is that there have been a number of correlational studies that did use different examiners for the play and divergent thinking tasks and did find significant relationships between the variables.

Although there is much evidence suggesting that similar processes are involved in play and divergent thinking, we must speculate as to the actual cognitive processes that account for the link. Dansky’s theoretical explanation was that the process of free combination of objects and ideas involved in play is similar to the elements involved in creative thinking. He thought that the free symbolic transformations inherent in pretend play created a temporary cognitive set toward a loosening of old associations. Others stressed the role of play in the development of flexibility in problem solving. Play provides the opportunity to explore new combinations of ideas and to develop new associations for old objects. The capacity to see old objects and ideas in new ways should aid in developing transformation abilities; that is, the ability to break out of an old set and see a new solution to a problem. Also, children’s play behavior involves a search for alternate modes of relating to the object, a process similar to searching for alternate uses for objects in divergent thinking tasks. Anthony Pelligrini conceptualized that in play children recombine behaviors and develop flexible strategies. His research with rough and tumble play supports that concept.

In summary, much of the explanations about why play relates to creativity, and especially divergent thinking, have focused on cognitive variables such as cognitive flexibility, loosening of old cognitive sets, practice with associations, recombination of old objects and ideas and symbolic transformations.

Pretend Play and Creative Affective Processes

Pretend play is infused with affect for many children. Children use play to process emotions. J. Singer has discussed how play helps children organize their emotional experience. Affective processes also play a role in creative thinking.

Fein, Russ, and J. and D. Singer are all theorists who have stressed the importance of affect in play in the link to creativity. Fein proposed an affect symbol system that gets activated in pretend play and is important in creativity. An affective symbol stores information about emotional events and is manipulated and worked with in pretend play. Russ, from a psychodynamic framework, stressed the importance of pretend play in helping children access emotional memories and fantasies and associations. Children who are comfortable letting their thoughts roam a broad spectrum of associations and memories that are affect-laden should be more creative. Singer and Singer thought that a cognitive-affective framework was central to exploring imaginative play.

Just as it is important in creativity to play with ideas and images, it is also important to play with affective content. Affect expression in play occurs from a very young age. Interestingly, when we compare affect expression in the play narrative in children from six to ten years of age, we do not find developmental differences in the amount of affect expression over these years. In terms of stability of affect expression, Russ, Robins, and Christiano found significant relations between affect expression in children in play when they were first and second graders, and affect expression in play narratives when they were sixth and seventh graders. This finding suggests some stability in the tendency to express emotion and emotional themes in narratives across time.

Fein viewed affect as being intertwined with pretend play. She suggested that pretend play is symbolic behavior organized around emotional and motivational issues. The proposed affective symbol system manipulated and elaborated in play represents a child's affective relationships. This system could be activated by pretend play or drawing and is important for creative thinking.

Russ, after reviewing the literature, proposed categories of affect that are important to creativity and also occur in play. These include:

1. Access to affect-laden thoughts and ideas. This is the ability to think about emotional content. Affective symbols would be in this category as would primary process thinking, a key psychoanalytic concept.
2. Openness to affect states and feelings. Experiencing the emotion is also important to creativity and children use play to express positive and negative emotions.
3. Affective pleasure in challenge and problem solving. This is the ability to experience pleasure and joy in play and to 'get lost' in the play experience.
4. Cognitive integration, emotion regulation and modulation of affect. This blend of affect and cognition that is important in creative thinking and occurs in play. Emotion is in the context of a narrative.

Russ in 1987 developed the Affect in Play Scale (APS) to meet the need for a standardized measure of affect in pretend play. Until then, measures focused on cognitive aspects of play.

The APS uses puppets and blocks with standardized instructions in individual five minutes play sessions. The play is videotaped and coded for amount of affect expression in the play. Frequency and variety of affect themes is scored with a frequency count. Enjoyment of and comfort in playing is rated on a five point Likert scale, as is imagination and quality of the fantasy narrative. There is also a preschool version of the scale that uses a variety of toys with more structured instructions. Recently, Russ developed a brief rating version that rates the child's play in vivo and does not require videotaping.

Research using the APS with a variety of child populations and researchers found significant relationships between affect in play and creativity. In general, children who express more affect in play are more creative. Affect expression in play has related to fluency and originality in divergent thinking, to teachers' ratings of fantasy ability, and to emotion in memory narratives. In most samples, these relationships were independent of verbal intelligence.

It is important to note that both positive and negative affect in pretend play relates to creativity. Happy themes like having fun and aggressive themes of wrestling or bickering are examples of positive and negative themes in play. Because play is pretend, there may be positive affect accompanying even the negative affect themes. Or the negative affect themes may be modulated in intensity by the child so that they are not too negative.

There is some evidence that the expression of affect in fantasy is cross-situational. Affect in play has related to expression of affect in memory descriptions and expression of affect themes on the Rorschach. The relation to affect themes in memory descriptions could have implications for creative writing. Children who develop the ability to think about emotion-laden memories and express affect in narratives would have an advantage in areas of creative writing where emotions and understanding the emotions of others is important.

Playfulness and Creativity

Playfulness is another general characteristic of play that is important in creativity. It is generally accepted that a playful individual has an internal predisposition to interact within their environment in a playful way regardless of their exposure to tasks, contexts, or materials that may yield behaviors that are related to play. Lynn Barnett defined playful individuals as those who naturally possess the ability to frame or reframe their experiences in a way to provide oneself with "amusement, humor, and/or entertainment."

A pioneer in the research of playfulness, Nina Lieberman attempted to distinguish differences between play behaviors and playfulness as a trait in children. From her research she was able to delineate five components to describe this playfulness quality: physical spontaneity, cognitive spontaneity, social spontaneity, manifest joy, and sense of humor. Physical spontaneity referred to the level of movement and coordination during play. Cognitive spontaneity described the imaginative qualities of play and a child's willingness to assume different character roles and unconventional uses of objects. Social spontaneity emphasized flexibility in interactions with other children and a child's willingness to initiate play and interact with others. Manifest joy described a child's ability to express

enjoyment and enthusiasm while playing. Sense of humor referred to a child's ability to clown around, tease, and joke with other children. Lieberman found that playful kindergarten children did better on divergent thinking tasks than nonplayful children.

Building on Lieberman's work, Barnett developed a more reliable measure of playfulness which also supported that playfulness is a single characteristic that describes an individual's predisposition to play. Barnett and others explored relationships between playfulness and other personality traits. Barnett found that playfulness related to several personality descriptions, such as bright, active, aggressiveness, cheerful, self-confident, imaginative, impulsive, mischievous, and responsible. Other researchers found a strong relationship between playfulness and several adaptive personality traits like creativity, humorousness, emotional expressiveness, curiosity, openness, novelty-seeking, and communicativeness. In addition, children who were considered playful also demonstrate greater levels of positive affect, physical activity, communication, and imaginative and social behaviors in play than less playful children. Other researchers found a relationship between play and personality factors of positive mood, persistence, approachability, and adaptability.

Converging evidence suggests that children who are playful tend to be more flexible in their understanding of the world, more approachable, tend to initiate contact with others, and have an assertive style that may contribute to their ability to act adaptively when distressed. It may be that children who are naturally playful are more effective and efficient at dealing with their problems in their environment. Nonetheless, more research is needed to better understand the relationships between playfulness and positive adaptive behaviors.

Lieberman also discussed the importance of joy in playfulness. Children experience joy in play. Passion and the tendency to become absorbed in the task has been identified as crucial by many creativity researchers. To let passion and joy of learning develop in children is becoming increasingly difficult in our culture. Yet love of the task is necessary to help the individual tolerate all of the negative and frustrating components of the creative process necessary to make a major contribution. In play, children are beginning to experience the joy of getting lost in the task and doing something for the love of it.

Interpersonal Functioning

Developmental theorists, Vygotsky and Jean Piaget, believed that interaction through peers fosters problem solving and play development. Vygotsky identified a zone of proximal development, which includes tasks that are too difficult for the child individually, but are possible with guidance by adults or more skilled peers when the child is playing. Piaget also emphasized the importance of peers in the development of problem solving skills, but suggested the peers need not be more advanced. Through interactions with others at a similar developmental stage, children learn different perspectives, discuss possible resolutions, and decide on the best solution. Children develop problem solving skills, as well as advance their play skills, through this resolution process.

Pretend play is also related to understanding emotions of others, perspective-taking, and empathy with other children.

Paul Harris proposed that imaginative understanding may enable children to understand others' mental states and affective experiences. The research supports this proposition. Understanding the emotions and perspectives of others is important in a variety of domains such as fiction writing, poetry, screenwriting, play-writing, and song writing.

There is also a growing literature on the importance of having imaginary friends in childhood. Marjorie Taylor has done much of the research on the creation of imaginary companions during the preschool years.

Russ in 2004 summarized the play and creativity research and concluded that play is related to many of the cognitive and affective processes important in creativity. Much of the research is correlational but there are some well-designed experimental studies as well. Russ speculated that pretend play helps the child become more creative by:

1. Practice with free flow of associations that is involved in divergent thinking.
2. Practice with symbol substitution, recombining of images, and manipulation of object representations.
3. Expression of positive affect, which is so important in creative work. Playfulness and the love of the experience of getting lost in a task and experiencing joy.
4. Expression of positive and negative affect themes in fantasy. The child develops access to a variety of memories and associations and manipulates affective symbols.
5. Developing narratives that integrates and regulates the emotions.
6. Expanding understanding of the emotions and perspectives of the other.

There is definitely a need for more research that investigates the underlying processes and mechanisms that account for the well-established relationship between play and creativity in children.

Facilitating Pretend Play and Creativity

One way to foster creativity in children is through facilitation of pretend play ability. There have been efforts to improve children's play skills. Many of these play training studies have been in an academic context rather than a therapeutic context. Smilansky's study in 1968 was one of the first to demonstrate that teachers could teach play skills. She worked with kindergarten children from low SES backgrounds in Israel for 90 minutes a day, five days a week, for nine weeks. The children who engaged in sociodramatic play, with help from their teachers, showed significant cognitive improvement when compared with other groups. Teachers helped the children develop their play by commenting, making suggestions, and giving demonstrations. Play training has been found to be effective with mentally retarded populations. Additionally, in Austria, when compared with a control group, low-SES elementary school children who were instructed in play four hours per week had better divergent thinking skills and were happier in school.

One of the methodological problems with many studies in the play facilitation area is the lack of adequate control groups. Smith stressed that adequate research design requires the

inclusion of a control group that involves experimenter-child interaction of a form other than pretend play. He concluded that when this kind of control group is included, usually both the play group and the control group improve. Dansky reached a different conclusion after reviewing the play training literature. He found that many studies did have adequate control groups that controlled for involvement of the experimenter. Dansky concluded that there were consistently positive results in studies with adequate control groups that demonstrated that play tutoring, over a period of time, did result in increased imaginativeness in play and increased creativity.

Russ and colleagues investigated the effects of play intervention techniques on children's play skills and associations with creativity, coping, and life satisfaction. Participants were 50 first and second grade children in an inner city school (99% African-American). Children were randomly assigned to either the imagination play group, the affect play group, or the puzzles/coloring control group. Each participant met five times with a play trainer in individual sessions. A standardized play intervention was used for each play group.

The major result of this study was that the play interventions were effective in improving play skills. The affect play condition was most effective in that, after baseline play was controlled for, the affect play group had significantly higher play scores on all play and cognitive processes. These children had more affect in their play (both positive affect and negative affect), a greater variety of affect content, and better imagination and organization of the story than did the control group. The imagination play group also had significantly more positive affect and variety of affect than the control group. Another major finding was that, on outcome measure of divergent thinking, there were significant effects for group. When we did a follow-up study of these children four to eight months later, only the imagination group had improved play skills over time. Results for the affect group did not hold over this period. Also, the increase in divergent thinking did not hold. The longer lasting effect of the imagination intervention on play skills is interesting and warrants more research. In general, the results are promising that a brief standardized play intervention can improve children's play skills, which may, in turn, enhance creativity, coping, and feelings of life-satisfaction.

Kasari and colleagues in a randomized controlled study with autistic children, found that a play intervention resulted in increased symbolic play. This was a very rigorous study that began the intervention at the child's current developmental level of play. The training involved modeling and prompting. Children in the play group, compared with the joint attention and control groups, showed increased symbolic play that generalized to play with the mothers. This study is relevant to creativity because children with autism have deficient pretend play skills. Techniques that facilitate play in these children should be effective with other groups as well.

Erin Barton and Mark Wolery, in a review of the literature on play with children with disabilities, concluded that there is a consistent relation between pretend behaviors in the child and adult prompting and modeling. However, there were many methodological problems with the studies. The authors did think that teachers could prompt pretend play in the classroom, but for generalization to occur, multiple exemplars of materials and multiple trainers should be used.

There is some research that guides parents in helping children to develop their play skills. Singer and Singer, in 1999, developed a video-based program for parents and other caregivers of preschool children that uses make-believe play to enhance literacy. This is a comprehensive program called 'My Magic Story Car.' Children watch pretend play games on the video and then play the games. In a nationally tested study, they found that key literacy skills improved after the program was utilized. In addition, the majority of children continued to play the make-believe games on their own without adult intervention and teach the games to other children.

The building of empirical research on specific play interventions is encouraging and needs to continue. Future research should continue to identify the specific prompts and techniques that facilitate play. More randomized controlled studies with rigorous methodology are needed. Hopefully, these prompts and techniques could be adapted to a variety of settings and child populations. Dissemination of the scripts to parents and teachers for everyday use is an important next step.

Changes in the Culture of Play

Over the past few decades, time for free-play has decreased. Children are heavily scheduled for structured activities and the computer and videogames have taken over much of childrens' free time. Children throughout the world do not have enough opportunities to be involved in unstructured activities. However, even considering the shift in focus, David Elkind suggests that children maintain the same desire to play. Although there are fewer spaces and less designated areas of play, children continue to play games and create learning experiences. They reinvent outdoor areas for make-believe games and change routine activities into games of finishing first or lasting the longest. Although it is difficult to generalize, it seems that many children continue to foster their creativity and problem solving through play.

Recent findings by Russ and Dillon are consistent with Elkind's view. They reviewed play studies from 1986 to 2008 with different school-based populations that used the same standardized play task, instructions, and scoring system (Affect in Play Scale). They found that the organization of the play narrative and amount of affect expression has remained stable over this 20-year period. Imagination in the play narrative has significantly increased in recent years. These findings suggest that children are finding ways to develop abilities to express imagination and affective expression even though there is less unstructured time available to them.

Conclusion

Research continues to support the relationship between pretend play and creativity. Both cognitive and affective processes that are important in creativity occur in play and, we think, are developed in play. The studies that are developing play interventions that facilitate play skills and creativity are crucial in expanding our understanding of how play helps child development. Increasing sophistication of research design, measurement tools, and play facilitation techniques are necessary to

move the field ahead. The study of the individual child is also important to include in our research repertoire. Fein's study of master players continues to be a rich source of information and research ideas. If we can continue to build research evidence that play facilitates creativity and child development in general, then we will have strong arguments about the importance of play in order to influence social policy. In the meantime, children will continue to find ways to develop their imagination and find time to play.

Glossary

Canon A body of literary works said to define the tradition.

Foot A group of syllables serving as a unit of meter, in verse: for example, *spondee* (two accented syllables); *iamb* (one unaccented syllable preceding one accented syllable); *trochee* (one accented syllable preceding one unaccented syllable); *anapest* (two unaccented syllables preceding one accented syllable); *dactyl* (one accented syllable preceding two unaccented syllables).

Free verse Rhymed or unrhymed poetry composed without attention to conventional rules of meter.

Image and imagery A figure of speech, especially metaphor or simile; a representation of a thing.

Line Phrase or words that make up a theoretical pattern of verse: for example, *dimeter* (two feet), *trimeter* (three feet), *tetrameter* (four feet), *pentameter* (five feet), *hexameter* (six feet).

Meter Measured, patterned arrangement of syllables in lines of poetry according to stress and length.

Mimesis Imitation or representation.

Muse One of the nine goddesses who presided in Greek mythology, over art, literature, and the sciences. The spirit that inspires a poet.

Poem An arrangement of words in verse, always rhythmical, sometimes rhymed, expressing facts, ideas, or emotions in a style more concentrated, imaginative, and powerful than that of ordinary speech, sometimes in meter, sometimes in free verse.

Poesis Making or invention.

Rhyme Correspondence of end sounds in lines of verse or in words.

Rhythm Regular recurrence of grouped strong and weak, stressed and unstressed, long and short, high-pitched and low-pitched syllables arranged in feet or cadences, in alternation.

Stanza A group of lines of verse forming one of the units of a poem.

Symbol A sign that refers to or stands for another thing, usually abstract.

Verse A sequence of words arranged metrically in accordance with some rule or design.

Definition

A poem is an arrangement of words in verse, always rhythmical, sometimes rhymed, expressing facts, ideas, or emotions in a style more concentrated, imaginative, and powerful. Poetry is of poems.

Introduction

Poetry is the oldest form of literature. It is characterized by meter, rhythm, rhyme, and/or verse. Called by many the highest of the linguistic arts, it is written by poets. (The obsolete term 'poetess' is no longer in use, as both male and female practitioners prefer to be called poets.) Both poetry and the other form of literature, prose, are distinguished in that they are written from the imagination. Poetry, however, is metrical or at least cadenced. Poetry is an art form in which every word, punctuation mark, capital letter, line break, rhyme, rhythm, and stanza have meaning. Poetry is an art form in which things always mean more.

Kinds of Poetry

Lyric Poetry

Lyric poetry has a strong emotional component, using imagery, especially of nature. The emotion is compressed with attention to sensuality. Lyric poetry has its origins in musical singing,

chanting, and reciting to accompaniment. By the Renaissance, however, the bard (singing and strumming poet) gave way to the lyric poet who wrote to be read and not for a musical presentation.

The lyric poem came to have its own rules:

1. Edgar Allan Poe (1809–49) said it must be brief;
2. Samuel Taylor Coleridge (1772–1834) said it must be unified and metrical;
3. William Wordsworth (1770–1850) said it must be "the spontaneous overflow of powerful feelings";
4. Friedrich Hegel (1770–1831) said it should be subjective, personal, and intense;
5. Arthur Schopenhauer (1788–1860) said it should be "an inverted action of mind upon will";
6. John Stuart Mill (1806–73) said it should be concrete, like a brief overheard conversation;
7. Northrup Frye (1912–91) said it is "an internal mimesis of sound and imagery";
8. Herbert Read (1893–1968) said it is "the imaginative prehension of emotional states";
9. James Joyce (1882–1941) said it is where the poet "presents his image in immediate relation to himself."

The relation of the form to music is apparent in that the words of songs are still called 'lyrics.'

Lyric poetry includes not only popular and folk songs, drinking songs, hymns, lullabies, and love songs, but

philosophical poetry, dream visions, satire, odes, epigrams, sonnets, and elegies. Lyric poetry has its traditions in all cultures and geographical regions. In recent years, it has taken digital form, using hyperlinks to visual and kinetic elements and even texts generated by machine.

Narrative Poetry

Narrative poetry includes the epic poem, the romance, the ballad, the verse tale. The narrative usually tells a story of historical import. Narrative poems are difficult to categorize metrically, as sometimes they look like prose, and sometimes they use strict meter and verse. An example of the former is John Clare's *The Badger*; an example of the latter is Byron's *Don Juan*.

Dramatic Poetry

Dramatic poetry imitates speech, and is exemplified by the Greek tragedies, Shakespeare's plays, Molière's work, Goethe's *Faustus*, Pushkin's *Boris Gudonov*, Ibsen's *Peer Gynt*, Eliot's *Murder in the Cathedral*, and Shange's *For colored girls who have considered suicide/when the rainbow is enuf*.

History of Western Poetry

Each national and ethnic group has its own revered and special poetic heritage. Because this encyclopedia is written in English and published in the United States, within the sphere of the roots of that language, this brief history will concentrate on the history of western poetry.

The first poet of the Western canon was Homer, who wrote the *Odyssey* and the *Iliad* circa 2000 BCE, yet poetry is much older than Homer, who wrote from oral traditions dating from as far back as the eighth century BCE. Poetry is older than writing. In the Judeo-Christian canon, much oral poetry was captured in the Old Testament, especially in such books as the Psalms. One of the most common forms of poetry was the hymn, an ancient Greek liturgical genre. Hymns have been found in all cultures, including aboriginal, Oriental, and African. Hymns were religious verses which praised the gods, heroes, or patriotic or religious abstractions.

Poetry was the spoken form of hymns and songs. By the fifth century BCE, Socrates (470?–399? BCE), Plato (c. 428–347 BCE), and Aristotle (384–322 BCE) were functioning as critics of poetry, and their works formed the first literary criticism. Poetry was described as being about heroes, gods, and common people; poetry was of concern to the public; poetry was itself a form of entertainment and delight to the people; poetry was touched with the divine, inspired by gods or Muses; poetry was both an art and a craft; the poet was secular, not a priest, prophet, or god. In Socrates' dialogue with Ion, Plato defined poetry's themes:

Is not war his [Homer's] great argument? And does he not speak of human society and of intercourse of men, good and bad, skilled and unskilled, and of the gods conversing with one another and with mankind, and about what happens in heaven and in the world below, and the generations of gods and heroes?

In his dialogues, Plato viewed poetry as both inspiration and imitation. Poetry was a gift possessed by poets, and Socrates said it was not an art but "an inspiration; there is a divinity moving you." The divinity was like a stone magnet that attracted iron which in turn attracted other iron. The Muse inspires the poet who inspires others.

All good poets, epic as well as lyric, compose their beautiful poems not by art, but because they are inspired and possessed. (*Ion*)

Poets fall under the spell of music and meter.

For the poet is a light and winged and holy thing, and there is no invention in him until he has been inspired and is out of his senses, and the mind is no longer in him; when he has not attained this state, he is powerless and is unable to utter his oracles. (*Ion*)

Yet Plato also thought that the poet was an imitator. That is, the poet committed these inspirations to written language which is imitative, a *mimesis*. The language is referential, that is, representative of the emotion and captures the emotion through certain linguistic conventions such as metaphor, simile, and other figures of speech – as well as through imagery, rhyme, rhythm, and sound. Poetry as *mimesis* was inferior, as it was but an imitation, a copy, of the real form which existed in the ideal, nonmaterial world. Thus poetry was not truly creative, as it was written or oral representation and not original. This idea lasted until the time of the romantics in the eighteenth century, when poetry became *poesis*, or making. In Plato's *Republic*, the poet was to be relegated to a lesser height than the politician because of this imitative representation.

To Aristotle, however, poetry was more true than history because the poet could fabricate truth from the elements of history rather than exhaustively tell the facts. The poet is able to tell the truth on a deep level, being able to see the patterns, and the overarching themes. Aristotle said:

The distinction between historian and poet . . . consists really in this, that the one describes the thing that has been, and the other a kind of thing that might be. Hence poetry is something more philosophic and of graver import than history, since its statements are of the nature rather of universals, whereas those of history are singulars. (*Poetics*)

Though Aristotle spoke of the forms of poetry called drama (tragedy and comedy) and the epic poem, subsequent critics and thinkers have credited Aristotle with denoting the true nature of poetry. Poetry can capture the inner essence of a situation whereas history cannot. This idea about poetry was not to resurface in any major way until the late seventeenth century. Until then, poetry was often viewed as a branch of logic.

Hence poetry is something more philosophic and of graver import than history, since its statements are of the nature rather of universals, whereas those of history are singulars. (*Poetics*)

The fact that poetry spoke of universal truth was the aspect of poetry that attracted the romantics in the eighteenth century and up to the present. Unlike the classicists of the Middle Ages and the neoclassicists of the seventeenth century, who produced poems in strict Platonic imitation, *mimesis*,

the romantics and later poets did not focus so much on the prescribed forms with their prescriptive line lengths in certain kinds of syllabic meter (i.e., iambic, trochaic, anapestic, and the like), but instead focused on the Aristotelian idea that the poem speaks more truly of a situation than a historical text could. The poem defined the inner reality. It was constituted of inner truth and not outer conformity to verse standards.

The poet thus was thought of as a seer, someone who could probe to the inner depths. However, the poem was not mere psychological essay, but a form of art evoking the Aristotelian fear and pity, a sense of beauty and of awe in both the poet and in the audience with its wedding of words and the elements of rhythm, rhyme, and stanza. The purpose of the poem was not to persuade, for that is the purpose of rhetoric and not poetry. The very form of the poem combined with the elements of poetic syntax, and put together with the denotative 'meaning' created something beyond meaning, inseparable from the form. The words of the poem form sound, a pure, nonintellectual substance heard by the ear and resounding within the throat or the breast. Mimesis was thus combined with poesis.

Nineteenth century romantic philosophers debated the meaning of the sense of beauty (fear and pity) evoked by the poem (imagination), the form of the poem (sense), and the moral influence of the poem (intellect). In Germany, Kant (1724–1804), Schlegel (1772–1829), von Schiller (1759–1805), Hegel (1770–1831), Schopenhauer (1788–1860), and Nietzsche (1844–1900) thought about and debated the aesthetics of poetics.

In England William Wordsworth wrote a preface that became classic, to the second edition of his *Lyrical Ballads*. The poems were written in common language and not in neoclassical diction. Meter alone distinguished poetry. Although meter is also present in prose, poetic meter has regularity detectable in the line. Followed by poetic reflections by Samuel Coleridge (*Biographia Literaria*), John Keats (1795–1821), Percy Bysshe Shelley (1792–1822), and George Gordon Lord Byron (1788–1824) these English romantic poets asserted their own philosophy. They revered the noble poet standing alone against the vagaries of the world and sentimentalized the peasant and the savage. The solipsism of self-reference in some romantic poetry led to a backlash by postromantics such as Victorian critic John Ruskin (1819–1900) and poet Matthew Arnold (1822–88).

In France, romanticism was personified in Jean-Jacques Rousseau (1712–78), a prose writer who had great influence on poetic thought with his visions of oneness with nature. Lamartine (1790–1869), Vigny (1797–1863), and Hugo (1802–85), among others such as Baudelaire (1821–67) continued with pantheistic and magical realistic views of nature as the source of feeling and a guide to spiritual wholeness. They also advocated a return to common language and disavowed classical form. By the end of the century, the poet was regarded as having a special magical relationship with the unknown and poetry were regarded as prophecy. The works of Arthur Rimbaud (1854–91) and Stéphane Mallarmé (1842–98) expressed this.

At the end of the nineteenth century the French symbolists such as Jules Laforgue (1860–1887) along with Mallarmé, Rimbaud, Paul Valéry (1871–1945) and Verlaine (1844–1896) asserted that poetry was overwhelmingly music and should capture from music the elements that belong to poetry.

Poetic symbol shows a relationship between the thing and the readers. Prosody, or the ancient forms of verse, should be utilized in this attempt. Symbols expressed truth through suggestion rather than narration. Symbolist poetry also uses experimental grammar, many allusions that may make the poetry rather obscure. Paul Claudel (1868–1955) asserted that the symbol is metaphoric, that is, a relationship between two subjects. Each object is named and compared with another object, perhaps a divine object. For Claudel, the syllogistic nature of the old poetry should be replaced by the logic of the metaphoric and the symbolic.

In the dialectic of poetic history, Apollinaire (1880–1918) asserted a return to the lyric sensibility. His work and thought paralleled the rise of cubism, Fauvism, and the modern in the visual arts. Apollinaire coined the word 'surrealism' which signaled that the world of poetry was on the threshold, just outside the world of realism. The surreal deals with the ordinary and with the everyday and does not try to comprehend the divine or the spiritual. The poetry of the surrealists, especially Bréton (1896–1966) and Eluard (1895–1952) dealt with love of the woman, seeing her as equal to man.

French poetry of midcentury was called *engagée* by Jean Paul Sartre. Dealing with the Second World War, the Resistance, and the meaning of devastation, it tried to make sense of existence (*existentialism*). Poets separated from poetic movements, isolated themselves from current chic thought, and wrote as receptors of events around them.

T. S. Eliot (1888–1965) brought French symbolism to England. The romantic metaphysical way of looking at poetic subject matter and the symbolist way were similar, he thought. The comparison of poetry to music was essential. The subject matter was difficult, evoking religious symbols and obscure texts. American imagist Ezra Pound (1885–1972) was another influence on symbolist poetry, and on Eliot, who dedicated his poem *The Wasteland* to Pound. Pound defined the image as "an intellectual and emotional complex in an instant of time." The pentameter was to be broken and straightforward line similar to the sequence of the musical phrase was to ensue.

Irish poet William Butler Yeats (1865–1939) spanned the romantic and modernist era. His *A Vision* (1925) is a prose explanation of how he used symbolism, mythology, and symbolism in dealing with opposites: objectivity and subjectivity, art and life, soul and body. Postwar poets with competing theories – the Georgians – Walter de la Mare (1873–1956), Robert Graves – who advocated a return to nature and myth; the soldiers who died (Rupert Brooke (1887–1915), Wilfred Owen (1893–1918) who argued a pacifist or patriotic vision of their experiences in the First World War; the colonialists – Rudyard Kipling (1865–1936) – who wrote of England's glory overseas; dominated the poetry of the early twentieth century. By the 1930s, English poetry had become concerned with leftist causes such as the Spanish Civil War – Stephen Spender, W. H. Auden (1907–73). In the postwar Dylan Thomas (1914–53) wrote on personal themes in formal and experimental verses. The Movement of the 1950s was short-lived, and no theoretical schools of poetry have dominated British poetry since.

US poetry was derivative or simultaneous with the movements in British and French poetry until the liveliness of post-Second World War signaled an ascendancy. For example, Walt

Whitman (1819–92) acclaimed a romantic vision of poetry derived from Ralph Waldo Emerson (1803–1882) (who called for a transcendental vision whereby there is an association between the word, the thing, and absolute truth) and Edgar Allan Poe (1809–49) (who argued for the importance of the imagination). Whitman's *Leaves of Grass* (1855) proclaimed the importance of the body as much as the soul. While Whitman was representative of Emerson's call for a poetry of the democratic person in nature, Emily Dickinson (1830–56) represented Emerson's call for a poetry hermetic and private. She became the most well known woman among romantic poets on all continents. Other American romantic poets such as Henry Wadsworth Longfellow (1807–82) and James Russell Lowell (1819–91) were very popular but their works have not stood the test of time. Dialect poets such as James Whitcomb Riley (1849–1916) and son of former slaves Paul Laurence Dunbar (1872–1906) and the late romantic poetry of southern Sidney Lanier (1842–81) signaled a regionalism and ethnic emphasis that was to continue in American poetry.

Premodernist poets such as Robert Frost (1874–1963) continued to write pastorals with the subject matter of nature. Frost began to use the speaking voice within poetic form, responding to the call of the romantics. He eschewed free verse, which was advocated by the symbolists and which contains lines of irregular length that evoke the cadence of music.

Modernism advocated that there is a connection between art and life. The construction of the verse was irretrievably linked to the meaning of the words. Verse did not serve to convey words, but was itself an irrevocable structure intrinsic to the meaning. Symbolism and imagism were two different ways to achieve this unity. Symbolism (Poe, Baudelaire, Rimbaud, Mallarmé, Valéry) advocated a turning in to the subjective with impressions of the external world expressed in implied emotions and sensations. Imagism (Pound) called for a visual flash which stood for both the emotion and the thing. William Carlos Williams (1883–1963) sought to use the American idiom (a romantic precept) in a variable foot (the line as a musical bar) in an imagistic way (the word as thing). Hilda Doolittle, known as H. D. (1886–1961) incorporated psychoanalytic concepts into her images. Eliot declared himself a British citizen, but his deep influences were from his childhood in St. Louis, Missouri. Wallace Stevens (1879–1955) wrote with affinity to the symbolism of Mallarmé and Valéry. If poetry is connected to nature, it is connected through figures of speech and relationship to music. Hart Crane (1899–1932) tried to take in modern industrialization with the symbol of the Brooklyn Bridge and a hearkening back to Whitman's romantic optimism.

Regional and ethnic Black writers also hearkened back to romantic visions in structuring their poems around spirituals – Langston Hughes (1902–67) and Countee Cullen (1903–46); and images of small towns and large cities in the Midwest – Carl Sandburg (1878–1967) and Edgar Lee Masters (1868–1950). Women also followed romantic principles – Edna St. Vincent Millay (1892–1950) and Elinor Wylie (1885–1928) – in their lyrics and formal sonnets.

The influence of imagism, surrealism, and symbolism continued with poets such as Robert Bly (b. 1927), who talked of the 'deep image' which would psychologically take the reader into a formerly unconscious place; with Allen Ginsberg (1926–96), who with the Beats looked to Whitman as well as

to Pound in advocating a counter-cultural lifestyle with a poetic line that resembled jazz. The so-called 'Black Mountain' poets – Robert Creeley (1926–2005) and Denise Levertov (1923–97) were allied with the abstract expressionists of the mid-century art world and they called for open form poetry with stresses more gestural than formal. The 'confessional' poets – Anne Sexton (1928–75) and Sylvia Plath (1932–63) – took after Robert Lowell (1917–77) in their frank autobiographical work. The New Critics called for an 'objective' look at the work, apart from autobiography, as the work stood by itself, apart from personal history, geography, or culture. Among other poetry movements have been Acmeism, Beat, Concrete, Cowboy, Futurism, Feminist, Harlem Renaissance, Jazz, Language, Metaphysical, New Formalism, New York School, Objectivism, Slam, Fugitive, Post postmodern, and the like. Each of these has propounded a series of principles and has been a reaction to or response to another movement of poetry (see American Academy of Poets.)

Formal verse gave way to the ironic lyric. Modernism gave way to postmodernism. Constructivism gave way to deconstruction. By the end of the twentieth century poetry was looked at as sign, for it had a dualism. Poetry was physical words on a page; the medium was ink on pulp. However, while prose was also physical words on the page, the medium was in the background. In poetry, the physical words are the foreground as well. This led poetic philosophers to contemplate the difference between signification and content. The experimenting of early and mid-twentieth century poets who aligned their work with movements in music and art shook the very Platonic and Aristotelian foundations of what poetry is. At the millennium we were left with these questions. Can poetry stand up to the creative imperatives of the other arts or is it merely a fundamentally poor imitation? Can poetry show truths through art that philosophy and religion cannot show? Can poetry continue to be a political force with a critique of bourgeois values? Can poetry align itself not with an obscure elite but with the common people? These questions continue to plague poets. Post postmodern poets have wrestled with morphing recent scientific discoveries with the language and lines of poems.

Creativity and Poetry

Poetry is inherently creative in that the creative process whereby poetry is made utilizes the Seven I's of inspiration, imagination, imagery, intuition, insight, incubation, and improvisation.

All creators talk about inspiration. Literally, inspiration is a taking in of breath. In terms of creativity, inspiration provides the motivation to write. When one takes in breath, one fills the lungs with air, with environment, with the stuff of life, and after the intake comes the necessary release. For poets this release is in the writing of the poem. Various kinds of inspiration have been recorded: the visitation of the muse, or the inspiration of love and desire; the inspiration of nature; inspiration through substances; inspiration by others' works of art and music; inspiration from dreams; inspiration from social injustice; inspiration of novel surroundings. The topics of poems range throughout these, and many other situations of inspiration.

In order to be inspired, the poet must experience insight. Insight in the creative process is the ability to see and

understand clearly the inner nature of things, especially by intuition. Insight involves restructuring the problem so that it can be seen in a different way. The creator experiences a feeling of delight in what is called an 'Aha.' It could be argued that poetry is one of the most regular providers of ahas for its readers, who are moved to fear and pity by the writing of the poet, whose insight provides insight to the apprehender, the reader or hearer of the poem.

All creators experience, during the creative process, a period of incubation, of fallowness where the inspirations that provide the insights are resting. Poetry is a solitary art, for the most part, as the poet meditates, walks, reads, and thinks about the meanings, images, and puts things together into the whole that is the finished poem.

Imagination is a faculty much discussed in creativity literature. Imagination in the creative process refers to a mental faculty whereby one can create concepts or representations of objects not immediately present or seen. The Romantic era of the eighteenth and nineteenth century began to view imagination as the primary criterion for the writing of poetry. Coleridge said imagination was the main power used in writing poetry: a "synthetic and magical power." Any writer can string images together but the poet infuses the images with imaginative power and with passion and makes not an account of imagery but of emotional truth. The poet must have an innate sense of music:

But the sense of musical delight, with the power of producing it, is a gift of imagination; and this, together with the power of reducing multitude into unity of effect, and modifying a series of thoughts by some one predominant thought or feeling, may be cultivated and improved, but can never be learned. (*Biographia Literaria*)

Even the intellectual deconstructionists and postmodernists say that imagination is necessary in uniting poetry with philosophy. In their discussions, imagination remains the creative force behind poetry.

Imagery is also part of the creative process. The term *imagery* is psychological, the ability to mentally represent imagined or previously perceived objects accurately and vividly. Imagery is an attribute of imagination. Imagery is not only visual, but also auditory, tactile, olfactory, and gustatory. While imagery is to be infused with the poet's imagination and sense of music in order to produce the truly creative poem (as opposed to the nonpoem, the 'fancy'), the *image* is the organic heart of the poem to twentieth-century modernists. The image is the concrete metaphor for inner reality. The poem itself becomes the image, an energy field made corporeal. Pound said, "The image is not an idea. It is a radiant node or cluster; it is a . . . VORTEX, from which ideas are constantly rushing." The image is then both a description and a metaphor for the creative energy of a field surrounding the image. The image is a reference to a visual, aural, or kinesthetic semblance named to subdue or elaborate the unnamable.

To postmodernist deconstructionist Jacques Derrida, the image fills out the words. The reader, with imagination, completes the poem's empty spaces with the image. Thus figurative images – onomatopoeia, irony, metaphor, simile, and the like – the rhythmic conventions of poetry – function as rivers to complete the effervescent meaning of the poem. The poet as creator is at the mercy of the image created, for the references

evoked by the images are uncontrollable. The reader in the physical act of reading, the eyes moving across the page, taking in the letters in type upon paper combined into words and an evocative language, enters into a dark room which is only illumined by images evoked by the words put into patterns created by the poet.

Images become symbols, icons, imagery. These also are creative, both in the spiritual sense of having been infused with import and meaning by centuries of thought, but in the individual sense of resonance with an interior truth to which the reader (or hearer) gains access through the associations evoked by the aesthetic creation of the poet. Consider the imagery in this line from Whitman's 'Song of Myself.'

I hear the bravura of birds, bustle of growing wheat, gossip of flames, clack of sticks cooking my meals.

The reader is thrown to the auditory by the first two words, and the image of swaggering, bragging birds, chests puffed up, sitting in trees loudly chirping comes upon the ear. To hear growing wheat 'bustle' evokes the humming sounds of fussing, moving females, scuffling and scurrying, who more often 'bustle' than men. With 'bustle' comes a transition to 'rustle,' which is a sound evoked by the word, and perhaps to the taffeta dresses women wore at that time, which had appendages called 'bustles.' All these and many more images associate to the ear from the juxtaposition of 'bustle' with wheat growing.

Whitman adds the 'gossip of flames' to his auditory images. Gossip has a sound that is quiet, as it is usually passed from one person to a trusted other in a hallway, a doorway, before a meeting. Gossip is hearsay, rumor, not truth. To associate 'gossip' with fire makes the flame seem friendly, for gossip is usually exchanged between friends about other friends or acquaintances, and the person who gossips usually trusts the person to whom she is gossiping. Thus the auditory image is homey, friendly, but a little cruel and dangerous as well.

The 'clack of sticks' also creates astonishing auditory imagery, as 'clack' seems too loud for what sticks do when they hit each other. 'Clack' is a sound word, but in the increment of sounds, sticks would not 'clack' but would perhaps 'click' or make a dull 'thwack.' That they 'clack' enhances their flame-readiness, for they must be quite brittle and quite large. Yet they are 'sticks' and not 'logs' and so the imagery presented by the juxtaposition of the two words 'clack' and 'sticks' tells the reader in her dark recess that creates imagery, exactly how big the sticks are. Big enough to cook a meal, quite dry, but not logs. Thus the reader must be creative also, in trying to understand the imagery created by the poet.

Another aspect of the creative process that poets use is in the connection to intuition. Poetry has recently (in the twentieth century) been called a form of intuition. Though ideas can be deduced from a poem, the poem itself is the idea, and that is intuition. Phenomenological theories of poetry assert that the reader grasps the poem through a kind of 'inseeing' – according to Henri Bergson (1859–1914) – who advocated the importance of intuition over intellect, expounding the idea that there are two opposing forces: he promoted the idea of two opposing currents: lifeless matter in conflict with organic life as the vital urge (*élan vital*) strives toward the freedom inherent in the poet's and poem's intuitive creative action.

Finally, while poetry is formally structured, metrical, and musical, many poets have used the regular practice of improvisation by which to write. The accidents that come from regular practice, from trying out new words, new ideas, new syllabic formations, often come through improvisation. Although improvisation is a key skill in the domains of music, poets also use it, especially poets who write free verse, but formalist poets also improvise. The poet James Merrill, who wrote much free verse, used automatic writing as an improvisational technique: William Butler Yeats, who wrote much formal verse, also used automatic writing as inspiration for work.

Conclusion

Poetry is one of the oldest domains of creativity, practiced instinctually by humans throughout evolutionary time. Because of this, the future for poetry is assured; whether new forms will evolve through technology is immaterial, for the human creative instinct to produce poetry has always existed and will continue to exist.

Problem Finding

R Reiter-Palmon, University of Nebraska at Omaha, Omaha, NE, USA

Glossary

Ill-Defined problem Problems that have multiple possible goals and no consensus on what the best solution may be.

Problem construction The process by which individuals structure ill-defined problems and identify the goals and other elements needed to plan the problem solving effort.

Problem definition Altering a previously identified problem, before solutions are attempted, to make it workable.

Problem finding The umbrella term for activity that occurs before problem solving. Includes problem identification, problem definition, problem construction, and so on.

Problem identification Recognizing that a problem exists before defining or solving the problem.

Problem representation Schemas that capture the central features of prior problem solving and guides future problem solving efforts such as goals, restrictions, procedures, and information.

What is Problem Finding?

One major approach to the study of creativity is the examination of cognitive processes involved in creative problem solving and creative thinking. Most of the cognitive process models include problem finding or an associated construct as the first step. J. P. Guilford was the first to recognize the importance of problem finding, coining the term 'sensitivity to problems.' Other models used terms such as problem definition, problem identification, problem formulation, problem generation, problem discovery, and problem construction. While specific definitions of each term vary somewhat, all have a common thread and to prevent confusion, the term problem finding will be used throughout this article. Problem finding is an umbrella term that includes the multiple aspects delineated in the literature. Two major aspects of problem finding have been identified. One includes problem anticipation and identifying problems or opportunities in the environment when they are not presented to the problem solver. The second aspect includes structuring and defining the problem in a way that provides a starting point to formulate a solution.

Other work has differentiated problem finding tasks by the degree to which the problem is given to the problem solver. This ranges from problems that are well structured and given to the problem solver (presented problems), to ill-defined problems where the problem solver identifies the problem (discovered problem), to problems that are found or generated by the problem solver where none existed before (created or generated problem). The role of problem finding is particularly important when problems are ill defined for two reasons. One aspect of problem finding calls for identifying possible problems in the environment, many times when problems are not clearly identified, or even known. These types of problems are ill-defined by definition, as no problem is presented to the problem solver. The second aspect requires the structuring and defining of the problem. If the problem is well-defined or structured, there is no need for problem finding.

It is important to note that while problem finding is seen as the first step in creative problem solving, followed by other processes such as information search, idea generation, and idea

evaluation, the creative problem solving process is not as fixed. Many process models assume a more cyclical nature where individuals may cycle back to earlier processes. This likely will happen as a result of difficulties encountered in later processes. For example, finding new information that requires the individual to think about the situation or problem in a new way may result in reformulation of the problem. Similarly, if during idea evaluation, the individual identifies that no good ideas were developed, he or she may cycle back to earlier stages – either to the idea generation phase or the problem finding phase.

The Process of Problem Finding

While most creative problem solving models include problem finding as the first process, there are only a limited number of models of the problem finding process itself. Early models such as those by John Dewey and Guilford provided a separation between problem recognition followed by problem definition. Min Basadur suggested that both ideation and evaluation play a role in problem finding.

A more detailed process model of problem finding was suggested by Michael Mumford and his colleagues. This model starts with attention and perception. Individuals need to attend to and perceive a gap or a problem in the environment. It seems that when problems are well-defined, there is no such perception, and the process of problem finding either is bypassed or occurs quickly and automatically. This first step corresponds to what appears in theoretical models as one aspect of problem finding – problem anticipation or identifying opportunities in the environment. Attention and perception of environmental cues trigger problem representations. Problem representations are knowledge structures based on past problem solving efforts and include four types of information (a) the goals and outcomes associated with the problem solving effort, (b) information required to define and solve the problem, (c) procedures and operations performed on the information in order to solve the problem, and (d) constraints and restrictions on the problem solving effort.

Problem representations are activated through environmental cues. If the problem representation has been associated with a specific cue in the past, it will be activated. More ill-defined problems and situations are likely to have more diverse and complex set of cues. In addition, ill-defined problems will likely have cues that are associated with multiple problem representations resulting in more problem representations being activated. As the problem or situation is more well-defined, structured and less complex, it is more likely that a small number, or even one, problem representation will be activated. If the problem is identical or very similar to a problem solved in the past, the problem representation associated with that problem solving effort will be activated. When only one problem representation is activated, it is likely that the problem solver quickly and automatically completes the problem finding process moving immediately to problem solving. When multiple problem representations are activated, and a single problem representation cannot be used, the problem solver must find a way to create a new problem representation which includes a mix of the elements from the activated problem representations to guide problem solving. This will likely result in a more creative way to define the problem, and therefore more creative solution.

The process described above has several important implications. First, in most situations, problem finding will occur automatically. These situations include routine problems, problems that have been encountered before and solved successfully, or problems that are similar to previously encountered problems. Active engagement in problem finding will occur only when the problem is different enough from past experiences or includes diverse information that elicits multiple problem representations. A second implication is that the problem finding process, like the creative problem solving process as a whole, includes both divergent and convergent elements. The activation of multiple problem representations, multiple ways of perceiving the problem, is a divergent process. However, the integration of the various problem representations into a new single coherent (and original) representation is a convergent process. Finally, an important implication of this model is the role that knowledge plays in the problem finding process. Activation of problem representations occurs based on the similarity of cues perceived in the environment and existing problem representations. Therefore, some knowledge is necessary for effective problem finding to take place. Further, the availability of a pool of potentially useful problem representations would be beneficial.

Importance of Problem Finding

Problem finding has been linked to creativity in a wide range of domains. The seminal study by J. W. Getzels and Mihaly Csikszentmihalyi linked problem finding behaviors with originality and aesthetic value of paintings created by art students. More importantly, problem finding measures were also predictive of artist's success measured 7 and 18 years later.

Problem finding ability and effort (a) predicts creative accomplishments and creative problem solving in everyday problems and (b) predicts creativity above and beyond known predictors such as divergent thinking and intelligence.

Factors Affecting Problem Finding

Research found that active engagement in problem finding increases the creativity of the process itself and of the resulting solution. In some studies, participants were given instructions to think about the problem prior to solving it, to identify goals, or to rephrase the problem in different ways. Other research induced active engagement by training the problem finding process (alone or in combination with other creativity relevant processes). A recent meta-analysis on the effect of creativity training found that training in problem finding was one of the best interventions for improving creativity.

The effect of expertise on problem finding is not fully understood. Experts spend more time defining the problem relative to novices, and are likely to have more problem representations that can be used in defining the problem. Conversely, experts are more likely to evaluate new problems as similar to those that they have encountered in the past, resulting in the use of a dominant problem representation.

Recent work suggested that dialectical thinking, especially acceptance of contradictions, is related to problem finding. Other personality variables linked to effective problem finding traditionally have been related to creativity in general including openness, tolerance for ambiguity, and flexibility. It is not surprising that the variables related to effective problem finding are related to cognitive style or individual difference in processing information.

Other variables related to problem finding are related to motivation. Individuals who see themselves as creative, have creative self efficacy, and self esteem, are more likely to engage in effective problem finding. Active engagement in problem finding is an effortful and time consuming activity. It is therefore likely that only those individuals who are motivated to engage in the process will do so. While some research exists on the role of personality and motivational variables in problem finding, the literature is limited, and more work is needed.

Situational variables also influence problem finding. Ill-defined problems posed by the problem solver generates more solutions than a presented problem (even when it is ill-defined). This finding may also speak to the motivational aspects of problem finding and creativity. When problems are generated, they may reflect the interests and concerns of the problem solver and therefore are more likely to be more involving and interesting.

Other task characteristics include the degree of consistency of information presented in the problem. More ill-defined problems tend to include more diverse cues, some of which may be inconsistent or in conflict with one another. Diverse cues or contradictory information in the problem has been linked to increased originality and creativity of the solutions, presumably based on the effect these cues and contradictions have on the diversity of the problem representations activated and the need to integrate diverse problem representations. This finding mirrors findings regarding individual differences, where dialectical thinking, or the ability to work with and accept contradictions has been linked to increased problem finding and creativity.

Problems and situations also may vary in the degree to which they elicit affect and the type of affect they elicit. Affect is an important variable that has not been studied in the

context of problem finding. Affect has been found to influence creativity, specifically, positive affect seems to improve creative performance, whereas the effects of negative affect are mixed, and depend on the task and more specifically on the type of negative affect (e.g., anger or sadness). It is expected that problem finding would be influenced by affect, however; how it will be influenced is not yet clear. Further, it is possible that affect resulting from the problem itself may have a stronger effect on problem finding, as it is more closely tied to this process.

Finally, available time and time pressure affect the problem finding process. Problem finding takes time and effort, and past research consistently found that individuals who spend more time on this process, develop more alternatives for how the problem is viewed, and also develop more creative ideas that are more effective. Because the process tends to be automatic most of the time, it is likely that time pressure will result in an automatic application of the process instead of active engagement.

Measurement of Problem Finding

Problem finding is typically automatic and does not have an outcome that can be evaluated therefore probing is necessary to observe the outcome. A typical approach of evaluating problem finding involves asking participants to define the problem in multiple different ways. However, this probing is a direct manipulation of problem finding, one that is also used to induce active engagement in problem finding. It is therefore difficult; if not impossible, to study problem finding directly without also manipulating it. In order to further our understanding of the problem finding process, it would be helpful to identify a way to measure problem finding without manipulating it or creating active engagement.

The fact that measuring problem finding requires the manipulation of problem finding also raises another important issue. How we manipulate problem finding may affect the results of the process. One popular method uses a variation of John Baer's approach, in which an ill-defined problem is presented, and participants are asked to restate the problem in as many different ways as possible. This sort of manipulation induces active engagement and forces participants to think in an effortful manner about how to define the problem. In addition, this specific approach seems to be geared toward a focus on goals, which are only one element of the problem representation. It is possible that different approaches for inducing active problem finding, with a focus on other elements, such as constraints or information needed, may result in somewhat different outcomes.

Finally, the approach discussed above for eliciting information about the problem finding process presents the problem solver with an ill-defined problem. Providing the problem to be solved allows for control in the study of problem finding, as all problem solvers react to the same stimulus. However, by providing a problem, the focus is on one aspect of the problem finding process, that of structuring the problem. However, as previously stated, problem finding includes both the process of identifying opportunities and problems as well as defining the problem. When the same ill-defined problem is presented to all participants, by definition, we are focusing on presented

problems and the process of defining the problem. We are not able to investigate generated problems and the process of identifying problems and opportunities. Only a handful of studies have evaluated the latter, finding increased creativity for generated problems compared to presented problems.

Teams and Problem Finding

Teams are faced with many opportunities to engage in creative problem solving. Organizations use teams to address the need for having multiple stakeholders (such as members of different departments) involved in decision making, or when problems are too complex for one individual to solve. Research on cognitive processes at the team level, whether they relate to creativity or more routine problem solving efforts, is sparse. The only area that has received much attention is that of brainstorming. Earlier processes to idea generation such as problem finding, and later processes such as idea evaluation have received minimal attention.

When individuals work in a team to solve problems, problem finding must be evaluated from two perspectives. Each individual within the team will engage in problem finding and the problem may be defined differently by each individual. Problem finding and defining of the problem is a result of the problem representations elicited by cues in the environment. Both attention to these cues as well as the problem representations available to the individual will be based on past experiences which differ from one person to another. Therefore when problems are ill-defined, individuals within a team will view the problems in different ways. Past research on team problem solving and decision making suggests that teams that are heterogeneous (based on gender, expertise, and the like) are more likely to experience difficulty reaching a consensus on a solution and difficulty communicating effectively.

The availability of multiple problem representations at the team level, just like at the individual level, may lead to integration of these problem representations in new and creative ways, leading to a new problem representation and more creative solutions. However, as individuals typically engage in the problem finding process automatically, they may not be aware that other members of the team may define the problem in a different way. This can lead to misunderstanding and difficulty in communication in heterogeneous teams. Further, it is less likely that individuals will discuss the problem finding process or how each one defines the problem. Teams typically focus on the solution that is needed, and team members assume that other team members view the problem in a similar fashion. Disagreements about solutions may often be traced back to lack of agreement on how the problem is defined or the elements of the problem, such as differences in goals, restrictions, or information available or needed.

Conclusions

Problem finding has been identified in theory and in research as the first step in the creative process, and therefore influences later processes and has a significant role in creative production. While the last decade has seen an increase in empirical work on

this topic and more is known today about problem finding, there are still many unknowns. Empirical research is needed in areas of the different types of problems and problem finding (such as problem identification vs. problem definition), measurement of problem finding, individual differences and situational variables that influence problem finding, and the process of problem finding in teams.

Problem Solving

T B Ward, University of Alabama, Tuscaloosa, AL, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Algorithm An operator that is a precise rule, which if followed, will guarantee a solution.

Goal state The desired end in a problem.

Heuristic A rule of thumb that may narrow the set of possible moves and increase the likelihood of success but which does not guarantee a solution.

Operator Means of transforming or moving from one state to another in a problem.

Problem A discrepancy between one's start state and goal state in which there are generally obstacles

that prevent movement to the goal state in a single step.

Problem solving General term applied to the process whereby the person overcomes obstacles and moves from a start state to a goal state.

Problem space A person's internal representation of a problem, including knowledge states and operators.

Start state The beginning point in a problem.

State General term referring to the representation of knowledge at a particular point in a problem.

Introduction

Problem solving is a topic that is difficult to delimit. Much of what people do on a day-to-day basis could be called problem solving, but without making some distinctions among types of problem solving, it is difficult for researchers to make progress in differentiating the processes involved and how they operate. To help narrow the focus, different ways of defining problem solving can be considered, but to begin to understand problem solving it is necessary to step back and consider a definition of the term *problem*. Without a clear sense of what constitutes a problem it is not possible to specify exactly what might be involved in solving it.

A traditional way to describe a problem, based on early work by Allen Newell, Herbert Simon, and colleagues, is in terms of *start states* and *goal states*. Using this terminology, a problem is a discrepancy between a start state and a goal state. Put differently, if there is a gap between where a person is now and where that person wants to be, then a problem exists. Describing problems this way leads to the definition of problem solving as the process whereby people eliminate the discrepancy or move from the start state to the goal state. As noted below, the process has traditionally been characterized as a search through problem states.

Notice that this definition puts the emphasis squarely on the processes involved. In some ways, the particulars of the problem are not vital; all problems and all problem solving has something in common. It does not matter exactly what specific starting situation a person wants to move from or what specific goal state is desired. What matters is the processes used in generating the steps that move the person from the beginning to the end, and those steps are usually mental operations that work on the person's existing knowledge or seek new knowledge.

To use a simple example from everyday life, if your car has run out of gas and you are on the side of the road about to be late for a meeting, you have a problem. The start state is that you are out of gas and have a meeting to get to, and the goal state is being filled up so you can drive to the meeting.

(There are also other ways to think about the goal state, which we will consider later in this article.) Problem solving in this case would be whatever steps you take to acquire the gas so that you can continue progress to your destination. Even though there are physical steps involved in this example (e.g., acquiring a container to bring gas to your vehicle), the emphasis in the study of problem solving, of course, is on the mental steps, the thought process you use as you try to figure out a solution; that is, how you reason about getting from the start to the goal.

A difficulty in thinking about problem solving as the process of eliminating the discrepancy between a start and goal state, however, is that this characterization is exceedingly broad, potentially encompassing virtually everything humans do. It can and does include everyday situations such as running out of gas, but also more life-threatening situations, such as that confronted by the Apollo 13 astronauts and NASA ground crew in 1970 when an oxygen tank ruptured causing significant damage and disruption to systems on the spacecraft while it was nearly 200 000 miles from Earth. It can also encompass short-term situation such as those already noted, or longer-term issues, such as a company not having as much profit in a quarter as it would like or having poorly rated customer relations. Start and goal state discrepancies can be on a local scale, such as a string of unsolved burglaries in a particular town, or on a global scale, such as disease, poverty, famine and other human conditions.

Beyond the variations in significance, scope and time-scale, we are almost always in some state and about to transition to another (unless unconscious or asleep or otherwise not using our minds or bodies). To continue with the out-of-gas example, if your car stopped right next to a gas pump and you only have to put the nozzle in and fill up, it would not make sense to call that a problem in the same sense as if you were in the desert, miles from any gas station with no container to transport gas even after you walked or got a ride to one of those distant stations. To continue with the Apollo 13 example, if the crew had back-up oxygen canisters, and could have easily changed one out for another, the incident would probably not be well remembered and would not have been a problem

in the same sense. To differentiate these situations, we can narrow the definition of a problem somewhat by including the idea that there ought to be some obstacles or impediments that prevent immediate movement from the start to the goal state in a single move.

A Common Language

Even with some attendant difficulties, characterizing problem solving as the processes involved in removing a discrepancy or making your way from a start state to a goal state is helpful because it can reveal the commonalities across otherwise very different situations. It also provides a language for describing the important elements of those situations. Again returning to the Newell and Simon characterization, which still has a dominant influence on our understanding of problem solving, the problem solver's internal representation of the problem can be referred to as the *problem space*. It contains states of knowledge, referred to as *problem states*, as well as the means of moving from one state to another, called *operators*. The states included in the problem space are the start state, along with any of its givens, the goal state and any of its specific requirements, and all possible states in between. In this way, problem solving is thought of as a search through the problem space, finding the path from the start state to the goal state. To return to the out-of-gas example, for instance, the internal representation of the start state might include the knowledge of the fact that you are out of gas, the current location and time, the meeting location and time, and any other factors known to you as the problem solver. The goal state might include you being physically at the meeting along with any materials you need for your role in the meeting.

The construct of a *subgoal* is also useful in describing problem solving in that progress toward the goal state can be understood in terms of accomplishing subgoals along the way. Determining whether or not you own a gas can and have it with you might be a subgoal along the way toward your overall goal of getting to the meeting, for example.

Operators are legitimate and helpful procedures for transforming one state into another. They are the cognitive processes of most interest in psychological approaches to understanding problem solving. They generally fall into two classes, called algorithms and heuristics. The distinction is that algorithms are rule-like procedures that, if followed correctly, will bring you to the correct solution, either the overall goal or a sub-goal, whereas heuristics are rules of thumb that may guide us in the direction of a solution, or narrow the number of possibilities we consider, but do not guarantee we will find a correct solution.

Algorithms play a vital role in achieving problem solutions, but a rich literature in creative problem solving also documents how slavish adherence to them can block people from seeing even very simple solutions. An example is the classic water jar problems used by Abraham Luchins and Edith Luchins. Consider that you have three containers A, B and C. A can hold 21 cups of water, B 127 cups and C 3 cups, and your task is to measure out 100 cups of water. The solution is to fill B completely, empty 21 cups into A, and then 6 more cups using the 3 cup capacity of C twice. After getting a series of such problems, all of which can be solved with the same

B-A-2C approach (e.g., A=5, B=20, C=2, Goal=11), people develop and apply that algorithm to such an extent that they do not readily see simpler solutions to subsequent problems for which the algorithm will not work (e.g., A=28, B=76, C=3, Goal=25). This inhibition due to adherence to an old established approach is typically viewed as analogous to the blocked thinking that prevents people from seeing new creative solutions to a situation. As discussed in the section on 'Problem Types,' heuristics can sometimes help where algorithms would either fail or be impractical.

Although real world problems, such as poverty, are vast in scope and critically in need of solutions, research observing the mental operations at work when people attempt to solve them is not typical. Instead, researchers who study problem solving tend to use much simpler tasks that can be handled, most often by individuals, in a relatively short time-frame, such as the water jar problem just described. Another example of such a task is a cryptarithmic problem, such as the classic DONALD + GERALD = ROBERT problem. It is easier to see when written as a standard addition problem:

$$\begin{array}{r} \text{DONALD} \\ + \text{GERALD} \\ \hline \text{ROBERT} \end{array}$$

In this problem, each letter corresponds to one and only one digit, and the task is to find the correct mapping between letters and digits so that the sum is correct. In addition to the knowledge of the overall goal, the start state given to problem solvers includes the additional piece of information that D=5. The rules of addition certainly qualify as algorithms and are relevant to this task. Adding 5 and 5 (D and D) and getting the sum of 10 leads to the conclusion, with certainty, that T=0. Thus, a subgoal of determining the mapping for one of the letter-digit pairs is accomplished by applying that algorithm. Using that operator transformed the starting knowledge state to a new one that includes not only D=5, but also T=0 (and possibly that 1 is carried to the next column, if the solver realizes that). We can also see the role of heuristics, such as "start with what you know" or "begin with the rightmost column (because you may need to know about carry bits)." The heuristics alone will not guarantee solutions, but they may help to narrow the steps to be considered.

Algorithms can also be thought of as brute force procedures for ensuring a solution. When thought about this way, it is clear that they may have a special role in simpler problems with few possible states, but need to be supplemented with heuristics in more complex problems. Chess is the prototypic example of a complex problem. The limits on working memory preclude one from considering all possible next moves and their ramifications for all possible responses by one's opponent and so on. To help narrow the possibilities, heuristics are needed. Certain principles, such as "control the center of the board" and "attempt moves that threaten an opponent's pieces with more than one of yours" might increase the probability of a win and narrow the set of moves you will consider. They alone however, cannot guarantee achieving the goal state of checkmating your opponent's king.

The emphasis on using legitimate operators, whether algorithms or heuristics, is because you actually have to reach the goal. One cannot just decide that $5+5=7$ or that a 'white

diagonal' bishop can move to black squares. For the gas example, a teleportation booth might be nice and, if it worked properly, might get you where you are going, but as far as we know, teleportation is not currently feasible. This is not to say that wildly impossible ideas are useless. In some circumstances they help to suggest a new way to represent the problem, and might be especially valuable when we are stuck.

In considering the movement from start states to goal states, we can also think about procedures for determining the next move. One such procedure is *hill climbing*. A way to think about hill climbing is that the goal is the highest point in the problem space. One wants to get to the top of the hill, the highest possible point in a landscape. In using this procedure, the next move would always be one that gets you to a higher point, never to a lower point. This would work fine in a simple situation where there is just a single hill and one has started at its base. However, if the landscape is really one with several hills and a single one that is higher than the others, and one has started at the base of one of the lesser hills, there is a difficulty. Using the hill climbing heuristic will get you to the top of that hill, but all possible next moves will lead you lower and you will stop. Since moving lower violates the hill climbing principle, it fails, and succumbs to the problem of a local maximum. You reach a local high point, not the global high point that is your goal.

The problem with hill climbing can be seen concretely in another classic situation used to study problem solving, namely the Hobbits and Orcs problem. In that problem, the start state is that there are three Hobbits and three Orcs on one side of a river that must be transported to the other side of the river, subject to some constraints. There is a boat that can carry two individuals at a time across the river. It is important however that the Hobbits never be outnumbered on either side of the river; if they are, they will be eaten by the Orcs. If you have not already tried to solve this problem, you may wish to do so now, but if you want to solve it on your own, temporarily skip the next paragraph and just consider the take-home message in the one that follows it.

To begin one can send a Hobbit and an Orc to the goal side, with the Hobbit returning in the boat so that others can be transported. Note that if the Orc brings the boat back, the two Hobbits still on the starting side will be outnumbered, so it has to be the Hobbit who brings it back. Next, two Orcs can be sent over to the goal side, with one returning the boat to pick up more individuals. At this point, there are three Hobbits and an Orc on the starting side and two Orcs on the goal side. Now, two Hobbits must go over in the boat, because if a Hobbit and an Orc go over, that one Hobbit will be outnumbered three to one on the goal side. Likewise, once to the goal side, neither of the Hobbits can bring the boat back to the starting side alone because the one that remains on the goal side would be outnumbered. At this point, there seems to be an impasse until you realize that two individuals can bring the boat back to the start side instead of just one, and that one should be an Orc and one a Hobbit. That way, when the boat gets back to the start side, there are two Hobbits and two Orcs there as well as one Hobbit and one Orc on the goal side. The idea of two rather than one going back in the boat seems to go against the goal of getting them all to the other side, yet is necessary for a solution. Once this impasse is resolved, the remaining steps are

straightforward. Two Hobbits go to the goal side, sending an Orc back with the boat. With all three Hobbits now on the goal side, the Orcs can be transported and never outnumber them.

The solution to the Hobbits and Orcs problem illustrates an important aspect of creative problem solving, namely that people sometimes operate according to implicit assumptions or constraints and those constraints can prevent them from achieving problem solutions. To solve the Hobbits and Orcs problem the implicit assumption that only one individual brings the boat back must be dropped to achieve the goal state. That specific problem is a well-defined one with a clearly identified goal state, but relaxing constraints is also applicable to less clearly defined problems. Consider for example a problem of limited parking on campus, a situation that plagues many universities. One can think in terms of building more parking decks or implementing shuttle service from remote sites, but a potentially creative alternative might occur by dropping the assumption that classes need to be taught during a limited set of ordinary daytime hours. Perhaps there are enough spots for all who need them if not everyone is coming to campus in the day time as opposed to some coming for classes at 3:00 AM. Whether that is a viable solution or not is debatable, but it would not occur as a possibility without relaxing the class time constraint.

An alternative procedure for determining the next step in a problem is *means-ends analysis*. Means-ends analysis compares the current state to the goal and chooses operators that remove the greatest difference between them, but it can allow for moving toward a subgoal that might actually be away from the overall goal. To return to the out-of-gas example, after determining that you do not have a suitable container, you might choose to walk to a hardware store in a direction opposite the nearest filling station to acquire one before moving in the direction of that station, because doing so satisfies a necessary subgoal.

Problem Types

Although there may be some utility to having a common way to characterize otherwise different situations, it is also vital to a rich understanding of problem solving to recognize that there are distinct types of problems, each with its own special features. One common distinction is between problems that are classified as well-defined versus those that are classified as ill-defined. This distinction is especially relevant to the field of creativity research. Well-defined problems are those that have a clearly specified start and goal state. An example might be the type of arithmetic problem noted previously. There is clear information about what is currently known, the values of two numbers that are to be added together, and the relevant procedures, such as the rules of addition, are readily determined. Likewise, the goal state, the sum of the two numbers, is unambiguous. Another example, though a bit more complex, is the cryptarithmic problem discussed in the previous section. The start state is well specified in terms of what is known, what is to be determined and what the relevant procedures are for getting there.

At the other extreme are problems with little in the way of definition for start and goal states, such as, do something meaningful with your life, start a successful business, or

produce a work of art that will be lasting in its effect on culture. It is difficult to identify the start state, other than perhaps noting that one has not yet done something meaningful, successful or lasting in that regard. Likewise the ways in which a life can be meaningful, a business successful or a work of art lasting are endless and completely open. Nor does one need to consider such complex tasks to capture the notion of ill-defined problems. Simply painting a painting, writing a poem or short story, or designing an experiment can be thought of as ill-defined problems. These ill-defined problems are the ones that sometimes are held up as the stuff of which creativity is made, though there is no question that creativity can be applied to much better defined problems than these. They are the types of problems that lead to the view that perseverance, tolerance for ambiguity, a willingness to risk failure, and other such traits are critical to being creative.

Because well-defined problems have clearly defined start and goal states, and because they have a single correct answer, creativity is sometimes considered to not be applicable to them. Sometimes divergent thought, or the seeking of many possible answers rather than the single correct one is considered integral to creativity. Ill-defined problems, with their many potential avenues for solution, fit better with the notion of requiring or even encouraging divergent thought. However, this perceived limitation on the link between creativity and well-defined problems is partly a matter of description. Sometimes the creative work on a problem is rethinking it or defining it clearly, as discussed in the article on 'Problem Finding.' That is, creative effort may help a person change an ill-defined problem into a well-defined one.

Well-defined problems, whether well-defined as originally presented to the solver or as constructed through problem finding, fit readily into the search framework described in the previous section. Problem solving is a matter of finding the right path in the problem space between the start and goal states. Other than noting that their start and goal states are not clear, however, ill-defined problems may need different constructs such as finding a different way to represent the problem.

There are some classic problems that are used to illustrate the importance of problem representation. How we represent a problem often determines our likelihood of solving it. For instance, consider the monk who begins a journey up a narrow mountain path at dawn, stopping along the way to eat and rest, reaching the temple at the top by nightfall, where he stays overnight to fast and meditate. At dawn the next day he begins his descent along the same path, again stopping along the way, reaching his original starting point sometime that afternoon. Not surprisingly, his journey down takes less time than his journey up. Your problem is to this: is there some point along that path that he occupies at exactly the same time on each of the two days, and can you prove it? Your initial thoughts might lead you to the idea that the answer has to be 'no.' Since the journeys take different amounts of time, you might first think it unlikely because there could be many specific times when he is on the path on the way up but not on the way down, on toward evening, for instance. And anyway you might reason, when he is on the way down he will be near the upper part of the mountain early in the morning, but on the way up, he will be near those points in the evening.

Not possible you might reason, but without any way to prove your conclusion. However, the correct answer is that there is such a point, and showing it reveals the importance of problem representation. As long as we represent the problem in terms of a single monk going up and down, it is extremely difficult to think out how there could be such a spot and time. But if instead we change our way of thinking, and represent it as two monks, one starting at the bottom and one starting at the top, then the solution becomes clear. If they walk along the same mountain path, at some point they have to pass one another, so they are then at the same point at the same time of day. Note that this is true even if they make their journeys at different rates. Even after hearing this solution, some problem solvers balk, in part because this type of rerepresentation is difficult to construct, and there is a suspicion that it may be flawed. "What if the one is eating or resting when the other passes by," might be an objection, but note that the objection contains the phrase "passes by." Of course at that exact moment, they are at the same place on the path.

Let's return to our out-of-gas scenario. We initially said that the goal state was to fill the car to be able to drive to the meeting, but we could characterize the goal state quite differently, that is, we could rerepresent the problem. If the goal state is simply being at the meeting, then a variety of other possibilities come into play, including hitchhiking, calling a friend for a ride, renting a car, taking a bus or other form of mass transit, borrowing a pair of roller skates or any of a huge number of potentially relevant steps. Which of those might be feasible, of course, depends on the particulars of the situation, but none would come to mind if we narrowly focus on the goal state as acquiring gas. We might even radically alter the goal as being one of having some sort of presence at the meeting, even if it is only virtual. So, a web application on a cell phone might get us there, including all of our electronic data and slides relevant to the meeting. Again, problem representation is the key to the types of solutions considered, and consequently to successful problem solving. Importantly, something like a web application would not be part of the problem space if the way of representing the goal state was limited to a physical presence at the meeting.

An approach to problem solving that directly embraces the notion of determining the best way to represent problems before actually attempting to generate solutions, has come to be known as Creative Problem Solving (CPS). CPS was developed initially by Alex Osborn and Sidney Parnes, and subsequently refined by others. It includes an initial stage, comprised of three substages, during which people are supposed to identify, clarify and otherwise clearly define the problem to be confronted. The substages are variously called (a) objective finding, mess finding, or constructing opportunities, during which people identify a broad goal, (b) fact finding or exploring data, during which they determine what is known and what still needs to be known, and (c) problem finding or framing during which the exact nature of the problem is defined and specified. It is during the first stage that an ill-defined problem may become better defined. The next stage is idea finding or idea generation during which people generate ideas for possible solutions to the problem as defined. In the last stage, preparing for action, which is comprised of two substages, people choose and refine a solution from the

many possibilities (solution finding or developing solutions), and implement the solution including finding ways to increase acceptance of the chosen solution (acceptance finding or building acceptance).

Beyond the well-defined versus ill-defined distinction, an alternative way of characterizing problems, proposed by psychologist Jim Greeno, is to classify them into one of three types: *arrangement problems*, *inducing structure problems*, and *transformation problems*. Let us consider each of these types in turn.

In arrangement problems, the solver must arrange objects or elements in a way that satisfies some criterion. One simple example of such a problem is an anagram. In an anagram one starts with a string of letters that do not form a word and must arrange them to form a word. For example, given the letters grutohoh one can arrange them to form the legitimate word 'thorough.' Unless there is more than one word that can be formed, as in the case of eanoc, there is a single correct answer to each such problem.

Anagram problems are also helpful in illustrating the differences between a brute force algorithmic approach and the use of heuristics as discussed previously. One could apply an algorithm of beginning with each of the letters in the given string and constructing all possible variations on arrangements for the other letters until one happens upon a word. This type of non-creative algorithmic approach would be easy enough with short strings, such as dre (dre, der, red, rde, edr, erd). However, for longer strings, such as grutohoh, the procedure is more tedious. Ultimately one would achieve a solution, but it might be extremely time consuming to get there. In such a case, heuristics, such as using typical orthographic patterns might help. One would not need to consider arrangements with long strings of vowels or consonants, such as uoo, grth, and hrgt.

Inducing structure problems require the problem solver to induce or discover the structure present in a set of elements they are given. A classic example would be series extrapolation. Consider the sequence 2, 4, 6, 8. What is the next element in the sequence? The correct answer is 10. The structure in the set of elements is that they are increasing by 2. A slightly more complex series might be 9, 2, 7, 4, 5, 6. What is the next element? The correct answer is 3, with the structure being an interleaving of odd numbers decreasing by 2 and even numbers increasing by 2.

A potentially more interesting version of inducing structure is an analogy problem. Consider the type of problem that might be seen on an abilities test, such as cat:lion::dog:?. The key to solving such a problem is discovering the relation between the first two items and producing something that is related to the third item in the same way. One characterization of the relation between cat and lion is that they are felines, with the one being a domesticated pet and the other more generally found in the wild. Possible answers, therefore, might be wolf or fox, that share a similar relation with dog, being canines, and differ from it in the same way along the dimension of domesticity. Note that either fox or wolf would be better answers than elephant, for example, that also differs in domesticity but does not share the canine relation. Put differently, the quality of a solution to an analogy problem depends on the match between the relations involved. Analogy plays a major role in creative endeavors, and more detail about analogical thought is available in the article on Analogies.

Transformation problems involve executing a set of operations to transform one state or situation into another. The Hobbits and Orcs problem described earlier is a good example of such a problem. One must transform the situation of three Hobbits and three Orcs on one side of the river into all six on the other side of the river according to a set of constraints. Another classic example of a transformation problem is the Tower of Hanoi. In a simple form there are three pegs, a, b, and c. At the start there are three disks of decreasing size on one of the pegs, say a, with the largest on the bottom and the smallest on the top. The goal is to recreate the stack of disks on one of the other pegs, say c. The rules specify that only one disk may be moved at a time and that a larger disk cannot be put on top of a smaller disk. As in the Hobbits and Orcs problem, the Tower of Hanoi also requires temporary movement away from the goal. After moving the smallest disk to c, the peg where we want it to be, and moving the medium disk to b, one has to move the smallest to b to make room for the largest on c. You have to be willing to move away from the goal temporarily in service of achieving it eventually.

Still another way of characterizing problems is to distinguish between *insight problems* and *noninsight* or analytic problems (see articles on 'Insight' and 'Incubation' for more detailed information). Generally, insight problems are those that seem to involve a restructuring of information or a key realization to achieve their solution. Consider the woman in a particular town who married 20 men from that town, without divorcing any of them or any of them dying, yet broke no laws even though bigamy is illegal in that town. How can this be? As long as one conceptualizes the information as specifying that she is married to 20 men, the answer seems to elude us. If one realizes, however, that she is of the clergy or a justice of the peace and that she performed the marriage ceremonies for the men, there is no problem with her marrying 20 or more. In this way, insight problems do require a rerepresentation.

Consider also the coin dealer who immediately called authorities when offered a supposedly ancient coin that appeared to be old, with an emperor's head on one side and the date 544 BC on the other. How did the dealer know it was a fake? Of course, BC would not have been used as a designation on coins or anything else at that point. Again, a realization seems to be required.

Insight problems need not be merely verbal. A classic, more perceptual example is the task of using six matchsticks to create four equilateral triangles all with a side length equivalent to the length of a match. Readers can struggle with this problem on their own, but a stumbling block is representing the problem in two dimensions. While the solution appears easier if one realizes the triangles can be put together in three dimensions, those type of clues do not always help problem solvers.

Insight problems are seen as different in some respects from noninsight problems, such as algebra or logic problems, where steady plodding progress to a solution is required. They do seem to differ in that ratings of warmth, how close one is to a solution go up suddenly at the point of solution for insight problems and more gradually for noninsight problems. One interpretation of that difference is that insight problem solving does not involve a search through a problem space as in the Newell and Simon view, but an alternative

view is that people could be making incremental progress on both types of problems but not be consciously aware of it in insight problems. However, the phenomenon itself does seem to differentiate the types of problems. It also appears that asking people to think out loud as they solve problems (see next section) can interfere with solving insight problems, but tends not to interfere with solving noninsight problems. So, the insight–noninsight distinction does appear to be a useful one.

Insight problems are also closely related to another topic that has been of interest in the field of creativity, namely functional fixedness. One of the most noted examples of functional fixedness is the two-string problem in which the solver is confronted with the situation of two strings hanging down, some distance apart. The person must tie the two strings together, but they are far enough apart that he or she cannot simply hold one and walk over and grab the other. There also happens to be a pair of pliers on the floor. People often do not think to use the pliers in the problem, because their ordinary function, tightening or loosening bolts, does not seem to apply. Yet, one solution to the problem is to use the pliers as a weight, tie them to one of the strings and set it in motion like a pendulum. Then the swinging string can be grabbed while holding the other. To achieve that solution, one must overcome functional fixedness and realize an alternate use for the pliers.

The insight problems used in laboratory studies of problem solving are highly simplistic and often seem to involve a trick. In addition, they tend to have one right answer, leading some to question their usefulness for understanding creativity, since creativity often involves more open-ended situations. The fact that these problems have a single well defined answer or goal state yet require a kind of reconceptualization, makes them similar to both well-defined and ill-defined problems at the same time.

Many of the often-cited real world cases of insight are much more complex than simple tasks used in research. For example, Archimedes' realization of how to measure the volume of Heiro's crown, or August Kekulé's insight that the structure of benzene must involve a ring of carbon atoms seem to capture much richer knowledge than alternate interpretations of the word 'marry.' Yet they also share with these more simplistic problems a key feature; there is one correct answer and the new idea is compelling largely because it came with the conviction that the problem solver found the answer.

So far, this article has focused on problem solving by individuals, but much problem solving in real world settings takes place in groups. Special issues come up when considering group problem solving, such as the dynamics of group behavior and the advantages or disadvantages of working on a problem individually versus in a group. A particular topic that comes into play is brainstorming, in which problem solvers are requested to hold off judgment on ideas, produce a large quantity of ideas, especially unusual ones, and to piggyback on the ideas of others. Brainstorming and other aspects of group problem solving are discussed in the article on 'Group Dynamics.'

Methods of Inquiry

Because the focus on understanding problem solving has been on the processes involved, procedures that reveal those

processes are of most interest. Although it matters whether or not people achieve the correct answer, it is more important to understand how they got there, or why they did not get there if they failed to solve the problem. In laboratory studies of problem solving there are two standard ways of obtaining such information: preserving or in some way capturing intermediate products that people develop along the way, and collecting verbal, think-aloud protocols.

Intermediate products could be formulas or calculations used in math problems, sketches in preparation for a more complete drawing or design, tentative guesses or hypotheses written down or any of a wide range of thoughts embodied in the materials created by the problem solver on the way to a solution. They can provide a window into the person's thought processes.

Verbal protocols are collected when an investigator asks a participant in a study of problem solving to talk out loud while solving the problem. Protocols can contain evidence of knowledge states and the application of operators in transforming those states. To return to the DONALD + GERALD = ROBERT problem, an initial statement might, for example, look like, "Let's see, I know D is 5, so if I add the two Ds I get 10, so T must be 0, and I'll be carrying 1 to the next column. I better make a note of that." Collecting verbal protocols as the person is solving the problem can have drawbacks. It is possible, for example that solvers may not always know how they moved from one point to another in a problem. But, collecting protocols during the problem is needed for getting a look at the process and it yields better information than retrospective accounts. In addition, the evidence seems to show that it does not interfere with the basic nature of the process, with the possible exception of disrupting insight problem solving.

An alternative means of coming to understand problem solving is developing computational models designed to simulate it. Verbal protocols can be used to identify key changes in states of knowledge and the operators that bring them about. They can capture the use of algorithms and heuristics. That information can then be used to develop computer programs with the goal of matching what humans do on the same and other related problems.

Summary

Problem solving is best thought of as eliminating the discrepancy between the current, less desirable situation and some more desirable goal state. This definition leaves room for many types of problems, from those that are well defined and easy to confront to those that are ill defined and more difficult to approach. Some problems can be solved readily as stated, and others require reconceptualization, a different way of representing them in order to make progress. Some are difficult because of unnecessary limiting assumptions or fixation, and some require an insight if they are to be solved. Although creativity is applicable to most situations, it is typically thought of as being more relevant to ill-defined problems or those that require restructuring, overcoming fixation, or achieving insights.

Glossary

Child prodigy A child who performs at an accomplished professional level in a highly demanding domain.

Collaborative creativity Recognition that most transformative efforts take place as a result of more than one person.

Common creativity The form of creativity that enlivens and enriches daily life, is clever and refreshing, but only known to those close to its creation.

Domain specific creativity Recognition that creativity varies in relation to the domain in which it takes place.

Extreme creativity Of the several forms of creativity, extreme creativity represents the pinnacle of achievement; Mozart, Madame Curie, Judith Jamieson, and Einstein are examples.

Moderate creativity Innovative or original work that transforms a domain but does not achieve the highest level of impact.

Introduction: Prodigy Research and Creativity Research

In this article we will discuss the relationship between creativity and child prodigies, particularly in light of recent research and theory in both areas. In the past few decades the study of child prodigies has been revived after nearly half a century of neglect, while the domain of creativity studies has taken some important turns that bear directly on how to understand the prodigy's astonishing achievements.

We will begin with a discussion of the prodigy, defining the phenomenon and summarizing what is currently known about it. Next, we will discuss recent work in creativity studies that may be relevant to the study of prodigies. Finally, we will turn to the ways that creativity studies may inform efforts to better understand the prodigy and how the prodigy may help sharpen our understanding of the variety of ways that creativity can be expressed.

Child Prodigies

The child prodigy is an ancient phenomenon, described in venerable texts like the Old Testament (David and Goliath) and the New Testament (Jesus in the Temple). There have been famous prodigies in history (Joan of Arc), in sports (Tiger Woods), and in entertainment (Shirley Temple). What distinguishes each of these cases and all other child prodigies is that they have achieved seemingly impossible heights in their areas of endeavor while still mere children.

Although child prodigies have been known through history, systematic research is a relatively recent phenomenon. Essentially, studies began in the early part of the last century, languished between about 1930 and 1980, and then re-emerged in the mid-1980s through a small set of studies that continues to grow. Traditionally, the child prodigy was seen as a sign or portent, something out of the usual course of nature

that often meant that major changes were in the air. Prodigies for most of history were not just children, but could be any anomalous event or occurrence (a hurricane or unusually long drought) that gave rise to concern about the future.

The earliest research on prodigies tended to focus on single or small numbers of cases in the domains of music, chess, mathematics, and a few other areas of achievement. The studies were mostly descriptive, although a few also provided some data on IQ and other early psychometric and personality tests. The most detailed study was of a Hungarian piano prodigy of nine named Ervin Nyiregyhazi, a boy who disappeared from public view for nearly 50 years, was 'rediscovered' in 1973 and died about 14 years later in 1987. Other than occasionally in the popular literature (Ruth Szeminska, Yehudi Menuhin), little was written about prodigies by scholars.

In 1986 a study of six boy prodigies launched contemporary research; there were two chess players, a science/mathematics prodigy, a musician/composer, a writer, and a child whose gifts seemed to be protean and who was given the label 'omnibus prodigy.' There was a brief discussion of creativity in this group of children, but creativity was not the main focus of the research.

For the purposes of this and future research, a prodigy was defined as a child younger than 10 years of age who has reached the level of a highly trained professional in a demanding area of endeavor. Each of the participants in the study probably reached this criterion, even the 'omnibus prodigy' who had composed several orchestral works before his tenth birthday. The writing prodigy may not have quite reached the criterion because of the childish themes of his writing. On technical grounds, his writing was sophisticated and well constructed.

This research helped organize subsequent work in several ways: it provided a relatively clear definition of the child prodigy; it offered a broad framework within which to interpret the extreme behavior of a prodigy as compared with other children; and, it helped differentiate the specific nature of

the child prodigy from general high intelligence, the previously most common explanation for the prodigy's great accomplishments.

Subsequent research and theory has tended to confirm earlier findings, although not without controversy. Some scholars have disputed the definition of a prodigy as always needing to be younger than 10 years old, others have questioned the use of the term prodigy at all, preferring 'precocious' to prodigious, and still others have questioned whether the prodigy must possess uncanny natural gifts and talents to achieve the highest levels of performance in his or her domain. Systematic study of the relationship between the child prodigy phenomenon and creativity has not occurred to date, although examples of great creators like Mozart have tended to link the prodigy with creativity.

Mozart is of course a near mythic figure who produced compositions that have not only withstood the test of time, but that have become ever more revered within the Western canon. And Mozart was without doubt a prodigy. The problems with interpreting Mozart's case as emblematic of child prodigies in general, however, are twofold: first, very little solid evidence concerning Mozart's earliest years is available, leaving us with mostly anecdotal, unreliable information; and, Mozart was very unusual, even among child prodigies.

Most prodigies are masters of existing forms and are not noted for their record of major changes in the domains from which they derive their notoriety. In other words, unlike Mozart, most child prodigies in most areas in which prodigies have been found, have excelled in how well they are able to perform known and recognized marks of great achievement in their domains. For a musician it might be to perform a challenging piece of music (a Rachmaninoff piano concerto, for example), for a chess player it might be to win against world-class competition, for a mathematician to solve a major set of problems that only master mathematicians can solve.

This does not mean that child prodigies cannot be creative in other ways in their chosen domain, but the usual benchmarks for great creative contribution tend to be outside the areas of expertise for all but a select few prodigies. Even a famous performer like Yehudi Menuhin, the remarkable child prodigy violinist, produced no new works for the violin in his venerable lifetime. Yo Yo Ma, one of the greatest cellists of all time, has produced no compositions of note. Advances in the domain of creativity studies have given us tools by which to interpret qualities of child prodigies' performance that may be appropriately labeled creative, although not in the usual sense of contributing major new works for the domain that others may perform.

A possible exception to what has just been proposed may occur in the domain of visual art. Prior to the appearance in the West of a book about the amazing Chinese painting prodigy Wang Yani, it was believed by most scholars that visual art was a domain in which prodigies do not occur. Since there are only a relatively few domains in which prodigies do occur, this was not in and of itself a surprising situation (e.g., there have been no child prodigies in physics, philosophy, engineering, genetics). Once Wang Yani's work was available, however, the domain of prodigy study began to discover more cases, including some in the West.

Given that visual art requires originality as well as technical mastery, at least in Western contexts, the increasing number of child prodigy visual artists (including more girls, also unusual prior to 1986), implies that the link between child prodigy and creativity may be stronger than previously believed, at least for the domain of visual art. Or it may be that most child prodigy artists to date have actually mostly produced variations on canonical works using existing techniques and themes as some critics have maintained. It is a reasonable prediction that in future studies, child prodigies and creativity will be studied together, certainly among child prodigy artists and perhaps in other domains as well. In any case, it is a major shift to have prodigies in the visual arts to study.

Creativity Research Relevant to Prodigies

Several shifts and advances in creativity studies have made that area better equipped to shed light on the nature of prodigies. Among the more relevant areas of creativity research for prodigy studies are the following:

1. creativity is increasingly seen as specific to the domain in area it is expressed;
2. creativity is considered to be a developmental process at least as much as it is seen as a set of distinctive traits or personal qualities, occurring as a confluence of a number of forces sustained over a period of time;
3. creativity is understood to be a matter of judgment (subject to change) by those given authority to make these judgments;
4. creativity is increasingly understood to include a number of different forms, ranging from humble and relatively common innovations, to unusual but not truly exceptional contributions, to fundamental and transformational revolutionary changes; finally,
5. creativity is now seen as typically collaborative, social and cultural as much as it is the unique expression of an individual's potential, especially in those forms of creativity that emphasize innovation, improvisation, and performance.

For each of these qualities, there are implications for how child prodigies are defined and understood.

Creativity as Domain Specific

For much of its history, creativity has been conceptualized as a set of traits and qualities existing independently of the specific domain in which they are expressed. Although there may be some traits of this sort, it is increasingly clear that there must also be domain specific talents and proclivities that are distinctive to each area of creative activity. The qualities that make a creative architect are not altogether the same as those that make a creative dancer, mathematician, or novelist. For the study of prodigies, the more that is known about the qualities that mark creative efforts in various domains in which prodigies are found, the more likely we will be able to understand the prodigy's abilities, including possible limitations in those abilities. By recognizing that each domain has its own set of distinctive qualities, in addition to whatever general ones may be applied, we may better comprehend the nature of the

prodigy's accomplishments, at the same time as we may be able to better distinguish between astonishing technical mastery and innovative, adventurous, or transformational efforts.

Creativity as a Developmental Process

The qualities that contribute to a creative process, both the general as well as the specific ones, are seen as subject to change over time; creativity traits may in some instances increase or decrease in strength, while domain specific talents and abilities are seen to become organized, disorganized, reorganized, and occasionally transformed during an individual's lifetime. In addition to the individual developmental process, domains in which creative contributions are made also develop and change. Knowing the developmental history of a domain may be helpful in understanding why one contribution is seen as creative at a particular point in time, another less so.

For the study of prodigies, both areas of developmental change are relevant. Prodigies are better understood as examples of extremely rapid development through a challenging domain that, typically, requires much longer to master. By knowing the developmental markers that distinguish levels of mastery from novice through master performer, we can locate and compare the prodigy's accomplishments with those of others who seek to master the domain.

Also, if it is understood that a domain is currently focused on a particular set of challenges (e.g., mapping the genome, integrating electronic music with more traditional forms), the work done by individuals or groups of individuals can be seen in the context of an evolving domain. Some historians of science who study the domain of physics have remarked that were Albert Einstein a young physicist today, the likelihood of his revolutionizing the domain would be small. The unique talents, preoccupations, and sensibilities that equipped Einstein admirably to attack the problem of relativity would not serve him as well in conceptualizing string theory or alternative universes.

For the study of prodigies, an understanding of the history of a domain provides a context for what the prodigy does. It appears to be the case that prodigies appear in domains that have certain features in common; for example, where the knowledge structures of the domain are either transparent or readily accessible such as in music or chess. It also appears to be the case that prodigies tend to master existing forms rapidly more often than they create new forms (even Mozart may be so described), so by having a sense of how a domain has evolved, what its current and past demands have been, and knowing what distinctive technologies and techniques have been available for practicing that domain over time, we can place the prodigy's accomplishments within a meaningful cultural, historical and evolutionary context. That context may include information on the qualities that would mark a creative contribution to a domain as compared with a contribution that is marked more by remarkable technical proficiency, the hallmark of the prodigy.

Creativity as Changing Judgment

When they were both active composers, the works of Antonio Salieri were generally judged to be superior to those of his younger rival Wolfgang Mozart. Two centuries later, Mozart's

works are precious and revered icons of Western music, Salieri's relegated to oddities only known to the public by virtue of their place in Peter Shaffer's play about Mozart life and death. Galileo Galilei was condemned for heresy by the Catholic Church for supporting Copernicus' theory that the earth rotates around the sun; 350 years later the Church admitted that errors had been made, but did not apologize for its condemnation of Galileo. What may be recognized as a prodigy's achievement may also change with time; some gymnastics and figure skating moves that were amazing 30 years ago are routine today. Doing these things would have meant world-wide recognition only a few decades ago, while they are considered journeyman accomplishments in contemporary competitions.

Forms of Creativity

Perhaps the most significant shift in the domain of creativity studies for the work on prodigies has been growing recognition that creativity is many things, not a single thing. For most of its history, the study of creativity revolved around efforts to assess a single trait of creative potential using one or another form of test. Alternatively, research on the 'creative personality' attempted to define a profile of the kind of person who would most likely be a creative thinker. Only recently have scholars begun to conceptualize a variety of ways to be creative, ranging from relatively modest changes involving everyday events, such as a fresh approach to flower arrangement to a revolutionary and fundamental shift in the very principles upon which a body of knowledge rests (e.g., a theory of evolution by random variation and natural selection).

Several schemes for representing variation in creative activities and processes have been proposed; although they vary in several ways, they have in common recognition that the qualities that are necessary and sufficient for one form of creativity may or may not be those that give rise to another form. It may be a different set of circumstances and processes that account for an innovative marketing campaign as compared with a new approach to music composition or a solution to a centuries-old mathematics problem as was achieved in the 1990s by Andrew Wiles for Fermat's Last Theorem.

Along with the increasing consensus that creativity is best conceptualized as domain specific, the ideas that creativity varies (within domains) in its strength, its range, its reverberations through that domain, the degree to which it transcends existing constraints have also gained credibility. It becomes a more complex but more proximal task to describe and explain the particulars of a certain kind of creative accomplishment and the specific qualities and circumstances that may have given rise to its appearance. It seems likely that in future studies we will more likely see more modest claims for the key features and key elements that are involved in a particular form of creativity of a given strength during a particular period of that domain's history. Claims that are intended to apply to all forms of creativity of all degrees of power and at all times in all places will most likely be abandoned.

Creativity and Collaboration

Several major studies have appeared in the creativity literature in recent years attempting to document the pervasive influence

of collaborative processes as critical to virtually all creative achievements. Some well known cases of the 'lone creator' such as Einstein or writer J. D. Salinger did their work in much greater a social context than we tend to believe. In some of the more extreme cases of creative contribution, the person known for making the contribution spent several years in intense collaboration before going on to construct and communicate a work that becomes recognized around the world. Such was the case with Einstein, Freud, Watson and Crick, and Andrew Wiles. Many others who hold esteemed places in various domains benefited from collaboration throughout their most productive periods; Mozart, Picasso, Martha Graham, and Darwin are cited as examples.

For more modest forms of creativity such as creation of a new software platform or a better weapons system, collaboration is essential. In most natural sciences, particularly physics, research is almost always done in large collaborative collectives of several hundred members. This is because the equipment needed to carry out experiments is scarce and astonishingly expensive, and the amount of data needed to add significantly to knowledge is huge.

For the prodigy, the relevance of the importance of collaboration for creative contribution may help differentiate the prodigy from others who demonstrate extreme talents and who perform at a very high level. Because prodigies in most of the domains in which they occur are young children, the term collaboration may not be an appropriate one. The process of preparing a prodigy to reach the highest levels of his or her domain is without a doubt one that involves sustained efforts by a number of people (parents, teachers, mentors, patrons, technicians, for example), at least during the child's early years the roles of others would likely be better described as preparation, support and enabling than true collaboration. Collaboration, after all, implies shared if not equal participation in a creative process.

Prodigies and Creativity

Having reviewed some of the contributions to knowledge about prodigies and about creativity in recent decades, it now remains to bring the two areas of study together to see what can be said about child prodigies and creativity. There are four ways to describe the relationship between the child prodigy's phenomenal achievements and what is known about creativity.

First, it is fair to say that child prodigies are creative in certain respects. The fact that a child is able to amaze a sophisticated audience with an astonishing display of technical virtuosity suggests that such a performance is both unusual and distinctively appropriate enough to be labeled 'creative.' The question is in just what sense is the child prodigy's performance creative.

Second, although it is reasonable to describe a child prodigy as creative, it is likely that this creativity is limited to the specific domain in which the prodigy is performing. That is, if the prodigy plays chess, it is unlikely that the creative aspect of that playing would extend to other domains. There are no recorded cases in which a child's achievements extended beyond the boundaries of a single domain. Even the 'omnibus prodigies' that rarely appear begin to focus their efforts and are known for their exceptional ability in a single area; the child so described in one study had focused his efforts in music composition by ten.

Third, there are few prodigies who transform the domain within which their prodigious achievements take place. A prodigy is defined by performance at the level of a highly trained adult professional in the same domain; as remarkable as that level of performance is, it does not necessarily mean that the child would be rated as among the very best performers in that domain. It means that the child's performance would meet whatever criteria are currently established to qualify as a professional in the domain. Among professionals, only a small number during any period will be recognized as one of the leading performers. The members of every symphony orchestra in every city in the country are professional performers; the soloist who travels around the world to perform with the leading orchestras has exceeded the criteria for being labeled a prodigy by a considerable margin.

Finally, knowing that the prodigy tends to master existing forms, where creativity is the transformation of forms, helps put the prodigy's achievement in perspective. What marks the prodigy's achievement as remarkable is not its tendency to bring a new form into a domain. The prodigy masters an existing domain to a level of proficiency so as to be considered good enough to do that activity as a professional. Among those who have reached the professional level, a very small number bring sufficient new meaning to a performance and/or transform existing techniques or technologies to a sufficient degree to be considered creative in the more exalted sense.

Making a distinction between prodigious and creative achievements in no way diminishes the feats of the remarkable children who amaze us with their seemingly uncanny ability to perform at the highest levels in domains that are very demanding and difficult, and do so in a relatively short period of time.

The prodigy's achievement affirms that culture has found a way to make a complex area of human achievement sufficiently accessible to children to allow the most talented of them to mount its heights in a very short time. Having done so leaves the domain essentially unchanged. Unless the very fact of this feat is to be labeled as 'creative,' the domain presents the same challenges to those who aspire to master it as it had before the prodigy did so.

There are cases where the distinction between prodigious and creative are less clear, and the recent efforts in creativity studies to differentiate among various forms of creativity may be helpful in modulating what may be too much of an either/or distinction. For example, although a great performance of a piece in the classical repertoire changes none of its notes, that performance may have qualities of interpretation, expression of emotion, and depth of meaning that have not been captured before. This form of creative interpretation may have a long term effect on other performers, on decisions to include the piece in concerts, in the buying public's purchase of recordings of that piece, and the like. Given that creativity represents a significant transformation of a challenging domain, interpretive efforts may be appropriately called creative. But few would confuse them with a singular contribution that leaves the domain changed in fundamental ways. Prodigies often do the former, rarely the latter.

Conclusion

To conclude this discussion of prodigies and creativity, we have seen that recent efforts in scholarship in both areas of study

have helped clarify and explain both topics. Advances in the study of creativity have taught us that prodigies are creative in certain respects: they are amazing in being able to perform at a very high level, thereby astounding us with their achievements. This in itself may be seen as creative. They also occasionally bring a new and fresh interpretation to an existing piece of music, chess opening, artistic style, or dance form, earning a claim to a form of creativity achieved by a small number of professional performers. Only the rarest of the rare among prodigies could lay claim to the most powerful creative achievements, those that transform a domain in an irreversible and enduring way. Of the many thousands of musical performers and composers, there are a tiny number – Mozart, Beethoven, and a few others – whose works have become established foundations of the domains to which these composers devoted their lives.

It should be emphasized in closing that this discussion is in no way intended to diminish the truly astonishing things that prodigies sometimes do. A prodigy represents one of the most rare and precious manifestations of harmony between cultural and biological evolution. To have found a way to give full expression to the natural human potential of its young is one of culture's highest aspirations. In the prodigy we see that effort in one of its most successful forms, a tribute to our civilization, and a gift from all previous generations to all future ones.

Programs and Courses in Creativity

M Murdock[†] and S Keller-Mathers, Buffalo State College, Buffalo, NY, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Course A formal structure for offering instruction; in teaching environments, a course is the smallest single unit of coherent concepts and goals for learning that fit into a larger curricular program, usually with some kind of accumulating credit toward a degree or certificate in training environments, a course also contains a coherent set of goals and instructional activities, and is usually self-contained, as in a one day course in creative thinking, it may or may not lead to some kind of local certification.

Curriculum All the experiences that go into a coherent plan of learning that focus and guide the choice of activities and instruction. Curriculum relates to what should be in the complete learning plan and why it is present.

Discipline A coherent body of knowledge that is instructive; offers potential for teaching and learning.

Instruction Those elements that relate to the goals, activities, and selection of content designed to directly instruct learners in the concepts they need to know within the larger curricular framework. Instruction focuses on what specifics are needed and how material will be delivered.

Interdisciplinary programs or courses Starts with a discipline and uses activities or approaches which are

connected beyond mere series of integrated events or actions; focuses mainly on integrating the tools and approaches from several disciplines to discover the relationships among them.

Multidisciplinary programs and courses Those that can be added on to another discipline that already exists. Often short term; neither the initial system nor its structure has to change to accommodate unless teacher or learners make the connections. Content is domain specific.

Multifaceted Having more than one part or made up of multiple constructs.

Programs (a) Formal delivery structures used to deliver creativity; (b) content materials and activities used within the delivery structure.

Technique How a person chooses to apply a tool or combination of tools, processes, or approaches.

Transdisciplinary Beyond the parameters of traditional disciplinary views; transdisciplinary approaches connect, are present, and are at the core of other disciplines. Highest level of steady integration. Starts with issue or problem and uses problem solving to bring disciplinary knowledge together.

What is Contained in a Program or a Course: Some Guiding Definitions and Issues to Consider

Programs and courses are part of the foundation of any topic as it gains internal coherence and external credibility and grows toward the parameters of a discipline. Programs and courses are two of a number of elements that include such structures as the creation and on-going growth of research and applied journals, the development of professional organizations with guidelines for ethical behavior, and on-going national and international conferences. Each of these structures adds some formal pathway to encourage growth, thinking, research, and communication that will increase the body of knowledge of a topic and our understanding of the instructiveness of it. In creativity, courses and programs fit into this category because they are the bottom line formal structures for the teaching and training of its content.

[†]This article is dedicated to Dr. Mary C. Murdock (1947–2010), a leader in the design of creativity education curriculum. Mary spent her career teaching creativity at the university level, challenging over two decades of graduate students to find their creative passion. This, her final article, gives voice to her wisdom and perspective on creativity programs. Mary embodied the creative spirit, and is a continuing source of inspiration to her colleagues and students.

Certainly attempts to identify, categorize or classify programs and courses are a worthwhile venture, if for no other reason than to put a temporary bookmark in our progress in making creativity accessible. Numbers are one benchmark of health. These efforts, however, are not without challenges.

Challenges in Understanding the Meaning and Impact of Programs and Courses

In the creativity literature and practice, the term program or programs is used in several different ways, which has caused no small amount of confusion. Reviews of programs often contained a mixture of the longer, more formal curricular work and the shorter, more instructionally oriented activities, or even packaged materials of activities and skills, such as the Purdue Productive Thinking Program, that can be used by a variety of people in many contents to add creativity to their courses or workshops. By curriculum, we mean all experiences that go into a coherent plan of learning to focus and guide the choice of activities and instruction. Curriculum relates to what should be in the complete learning plan and why it is present.

Another option contains a variety of instructional approaches and philosophies that may be mixed. By instructional approaches, we mean those elements that relate to the goals, activities, and selection of content designed to specifically

instruct learners in the concepts they need to know in the larger curricular framework. Instruction focuses on what specifics are needed and how the material will be delivered.

It can be difficult for a reader or a reviewer to make sense of what to include and why to include it or to determine the status or development of programs and courses and their commensurate impact on the development of the field. Traditionally, surveys, questionnaires, and on-line investigation and personal inquiry have provided these kinds of data.

A second challenge in identifying creativity programs or courses lies in the difficulty in establishing longevity and in embedding them in the context of either teaching or training. This is necessary so that they can survive on their own merits. Otherwise, they may just have a champion who may sponsor them initially. Then this champion may lose interest or not be able to sustain the onslaught of possible criticism in order to gain acceptance for something new. By the time research is completed and an article written and published, the data are out of date, both in the creation of new programs and courses, and in the demise of them. The shelf life of a creativity course or program is short in comparison to more traditional content. English 101, Introduction to English, or Basics of English are going to be around, recognized, and accepted in programs of study in many colleges and universities consistently over time. No one will ask "What is this?" Creativity 101, however, will get no such pass.

A third challenge concerns where creativity programs come from. Although the variety of choices is dynamic, the range, expertise and peer review may be somewhat lacking. There are four traditional pathways for the development and presentation of creativity programs and courses:

1. academic institutions with formal degree granting curriculum such as the Master of Science Degree in Creativity at State University College at Buffalo, New York;
2. centers associated with academic institutions, such as the Center for Applied Learning at McMaster University in Hamilton, Ontario, and the Torrance Creativity Center at the University of Georgia, Athens;
3. centers either privately funded and run, such as the Center for Creative Leadership in Greensboro, North Carolina or those tied to an established institution either by location or some course access; and
4. internal creativity units or teams within organizations.

Well-established programs or courses are often located in academe where they have been through an extensive peer review process.

Programs can refer to either formal delivery structures, such as courses or training sessions, and the learning processes used to deliver them or to the content of materials and activities that are used within them. Thus, a program (as it appears in the creativity literature) could mean a formal program of study with curricular coherence and scope and sequence in courses that lead to an academic degree. A program might have a more instructional focus with more emphasis on a set of activities of some days or hours' duration sponsored by a Center, or by an independent contractor, often for some kind of local credit or local credential. As used here, programs may refer to either, though the prevailing literature tends to focus more on materials than on formal delivery structures.

A course is a formal structure for offering instruction. In teaching environments, a course is the smallest single unit of coherent concepts and goals for learning that fit into a larger curricular program where one may accumulate credit toward a degree or certificate. In training environments, a course may contain a coherent set of goals and instructional activities and is usually self-contained, as in a one day course in creative thinking or a week long course to introduce the Creative Problem Solving process.

Again, the term course has been loosely used, though it generally offers some kind of topic related to the broader phenomenon of creativity, such as a course in creative product or a course in habits and blocks to creativity. Academe courses in creativity are often easier to establish than longer-term curricular initiatives: (1) they can be more easily focused on some interdisciplinary aspect such as creativity in business or creativity in the arts; (2) they often only need a single sponsor or champion. Their time frame from initiation to implementation is reasonably short. In consulting, center, or other development outside of academe, courses are often simple and quick ways to make a point, particularly as it relates to the originator's goals, and to get information out.

These critical factors continue to influence both how others view creativity programs and courses and how they are crafted. One should be cautious to develop them with purpose, in accessing what they are intended to do, and in presenting them to others as accurate exemplars of what we know about the discipline.

Historical Context for Programs and Courses in Creativity

The development of programs and courses in creativity is historically embedded in three major questions that have consistently been asked: (1) What is creativity? (2) Is creativity teachable and how do we know? and (3) How is creativity teachable?

What Is Creativity?

In any domain or discipline the parameters of its content depend upon having coherent concepts that are clear and connected to each other in a logical, understandable way. In simple terms, domain or disciplinary content must make sense both to those who have expertise in the area and to those from other fields who look at it with outside eyes.

The parameters of the domain of creativity are connected by one over-arching characteristic that is often misinterpreted and misunderstood. There is general agreement by theorists and practitioners in the field that creativity is a multifaceted phenomenon. Mel Rhodes' work in the late 1950s and early 1960s to find the similarities and differences in definitions of creativity and imagination illustrated the early variety of views people were using, even from this limited perspective. His definitional work supported a framework to organize creativity for study into four categories that had distinct but overlapping elements: the creative person, creative process, creative product, and creative press (now generally referred to as climate or environment).

This broad definition has served as a standard framework in deliberate creativity for both organizing concepts and developing programs and courses as multifaceted. For example, in the early development of programs and courses, there was a strong research emphasis on obtaining information about creative people – who were the highly creative; what were their traits and qualities; were there particular qualities that were more general or some specific to creativity only? Thus, courses and programs (where they existed in early times) often had content related to personal creativity and how people might or might not enhance what they had. The Institute of Personality and Research (IPAR) work of McKinnon and colleagues at Berkeley added data to the person component of creativity. Much has been done to refine the person approach since those early days but the concept of the creative person was a starting point and programs and courses followed suit.

In the 1950s and 1960s, more attention began to be directed toward creative process. What steps, stages, or repeating aspects of how people could get more creative results to problems and challenges, either personally or professionally, were the focus. This led to an expansion not only of courses and programs in process such as Synectics, Creative Problem Solving (CPS), and Lateral Thinking, but also a stronger overlap in activities that involved person and process. The process approach was very popular because it moved the focus of programs and courses away from a more personal view of creativity and into the realm of results and outcomes of problem solving that involved people. In other words, it focused on what you get when you deliberately apply tools and techniques to a situation with no obvious answer. Although tools and techniques had been popular with person approaches as well (brainstorming, e.g., was well-known as early as the late 1940s and early 1950s) they came into their own during this time as well. Process required tools to deliver specific results and many tools became associated with divergent thinking and idea generation.

In the late 1970s and throughout the 1980s there was increased research interest and follow up in practice about creative press or environment. Researchers such as Teresa Amabile in the United States and Goran Ekvall in Sweden, began looking at a more social, interactive approach to creativity. Identification of basic creative climate concepts which could be explained and identified, instrumentation and applied work to support those concepts, and activities that could help people understand and practice them were developed.

Ironically, the concept of creative product as an element to be explored more specifically did not begin to receive attention until the 1990s and beyond. Much of the more direct line to product came earlier, through the demand in the workplace for innovation. Innovation is, in some ways, a similar concept for creative product. It is the new outcome that comes from market demand and push. Programs and courses in innovation have been widespread in the organizational workplace. They are also popular in the consulting business because people recognize the term and associate success and competitive edge with having new ideas that are ahead of the pack. In the programs arena, business curricula often have courses in innovation, as do MBA programs, and a variety of entrepreneurial studies have courses. In creativity, Susan Besemer has developed instrumentation and a theoretical framework to support basic concepts that identify the characteristics of creative products

in general and has applied this work in education and organizations. The innovation/creative product development is another example of how practice sometimes leads theory and then theory catches up.

Rather than any one particular definition or approach being the sole determinant of our views about what creativity is, we have, instead, all of the implications that go with the word multi. No matter what words are used to define creativity: multi, multiples, many, options, choices, the use of the term implies that to expect or, indeed, seek a unified theory of creativity with one definition, one angle, or one approach, is not authentic to the true nature of the phenomenon in question. That it is in the very nature of creativity to be multifaceted is not a problem but, rather, an opportunity. It is neither a simple nor simplistic construct. It is instead a constellation of skills, techniques, and processes that describe how people bring about something new.

This newness or novelty is the generally accepted hallmark theoretical characteristic of creativity and is most frequently accompanied by its partner in practice, usefulness. These two elements, the theoretical element of novelty and the practical element of usefulness, constitute a well-accepted definition of creativity that works in many different situations. In addition to this basic definition, Rhodes' analytic framework has served as the standard and useful organizer for both organizing concepts and developing programs and courses.

Is Creativity Teachable?

Once the multiple concepts and constructs of creativity began to be moved into the public eye by theorists and practitioners, they needed to pass the test of verity. (Who says this information is accurate or correct? What research exists to support the ideas that people are putting forth?) If theorists and practitioners were maintaining that teachers, trainers, consultants, and everyday people could deliberately learn, improve, or enhance the natural creativity they already have, how would the average person know that this was information on which he/she could rely? This teachability issue sparked a controversy that, for some outside the domain, is still not yet resolved. Within the discipline itself, however, the teachability issue has reasonably been put to rest. Here we find that, not only did research catch up with practice with both quantitative and qualitative support, but practice continued to develop with ongoing feedback and program evaluation, cases, examples, and behavioral indicators that people's creative thinking could be impacted and changed in more deliberate ways.

Early work in cognitive theory by such researchers as J. P. Guilford and E. P. Torrance, and the personality work of Frank Barron and Don MacKinnon at Berkeley, set the stage for further exploration into the nature of deliberate creativity. In more recent times the work of Robert Sternberg and his colleagues as well as the work of Howard Gardner and David Perkins have clarified and elaborated upon the cognitive concepts of deliberate creativity and how they operate.

On the applied side, in the late 1960s and early 1970s, a major research project was conducted (within this series of creativity courses developed by Osborn, Parnes, and Noller) to examine the efficacy of the undergraduate courses established at Buffalo State College. The Creative Studies Project

was one of the earliest pieces of applied research designed to explore the efficacy of creativity and creative problem-solving (CPS). Its results did indeed support the teachability of creativity and CPS. Evidence continued to accumulate for the teachability of deliberate creativity (as evidenced in reviews such as those of E. Paul Torrance, Laura Hall, John Feldhusen, and Ban Eng Goh). Inquiry supporting teachability has continued, on the applied side, in the organizational context as well, most notably with the ongoing work of Min Basadur.

How Is Creativity Teachable?

As theorists and practitioners refined their understanding and articulation of what deliberate creativity was and built support for how it was teachable, they came face to face with the question that is most pertinent to those in the field – how is creativity teachable? How can we best help others to learn about it? What are best practices? What have other people tried? How can we improve our practice to create better programs and courses? Without the constant burden of proving, justifying and explaining what creativity was and if it could be learned and taught (although the questions are still not resolved nor agreed upon universally), there is now more time for those who are serious about the discipline to concentrate on refined and improved practical approaches for instructiveness beyond the dependence on tools that has been prevalent. As one would expect in any other discipline, practice and application are the keys to learning about creativity deliberately – support, by the way, for the teachability of creativity that even early practitioners maintained.

In recent times there has been more work on the cognitive and affective elements of creativity, particularly in regard to higher-order thinking skills. Work from Project Zero at Harvard has begun to accumulate examples and research based support for how to identify and practice skills and dispositions that are a part of the larger picture of how people think creatively are being studied. How to look at more subtle and specific ways to explain what is happening in the field and to develop instructional materials and curricular frameworks that will deliver deliberate creativity to others in more effective ways are being identified as well.

How to Teach Creativity: Some General Issues to Consider

In addition to previously mentioned process pathways into teaching and training, courses and programs need a content home, a location or home base in terms of philosophy or approach to the material. This philosophy serves as a guide for how to design instruction and just where to put creativity in the mix. This content location comes from three traditional disciplinary approaches: interdisciplinary, multidisciplinary, or transdisciplinary.

If a program or course takes an interdisciplinary approach, the instructional approach starts in a discipline and focuses on integrating tools and techniques from several other disciplines, looking for relationships among them. Its activities and instruction should be more than a series of connected events strung together.

If a program or course has a multidisciplinary philosophy, the intent is to add on to an existing discipline. Often the

approach is short term and the initial discipline itself does not have to change unless the participants want to. It is content specific.

The final approach, transdisciplinary, takes the view that creativity is beyond the disciplines. This approach views creativity and its concepts as being at the core of what needs to be taught. Connections can then be made into other content areas but they come back to creativity as the core. This philosophy pushes back on the domain specific argument that one must be creative in something. The more productive approach would be to understand that the domain specific argument is rooted in practice and the transdisciplinary counterpart relates to the theoretical soundness and accurate identification of what creativity is. In order to be used effectively in a practice in a domain, one must have a knowledge base in the content of creativity, regardless of domains it might connect to. Therein lies the transdisciplinary connection, because concepts of creativity can be found in almost any discipline and form a powerful core beyond what the other disciplines have to offer. Take, for example, flexibility, one of Guilford's original elements of divergent thinking. In order to adapt, rethink, adjust or cope with complex thinking, one will need this skill. It is core and beyond the skill bases of most disciplines, yet without it, one is limited in how to approach or find anything new, different, or surprising. It may happen naturally on occasion, but the deliberate awareness that sets up understanding, practice, and decisions about when to apply and why will remain tacit.

Each of these approaches has unique strengths and drawbacks and each, in its own way, has had an influence on the development of creativity courses and programs. When deciding how to teach creativity, determining its philosophical position determines what you choose to instruct and why.

The Future of Programs and Courses in Creativity

Throughout its development, creativity has never lacked for dynamism or change – multifaceted concepts, infusion of new theory, new practice, and new approaches. Theory and practice are more balanced in programs and courses today than they have ever been. New ones emerge and either grow or die. Older ones survive, thrive, or fall by the wayside. Periodically there are attempts to locate, count, or otherwise determine the current status of programs and courses. There are also program reviews so that some degree of development can be determined, but a seriously accurate assessment would be nearly impossible to reach. By the time information gets back to the researcher and an article gets to print, some programs are on a downward spiral and new ones are being created. In spite of clear parameters, the exact nature of the program or course may have been misunderstood or changed to appeal to a different audience. Still, it is a worthwhile effort and we can say with confidence that the number of courses and programs continues to increase.

Currently there are several trends at work that impact programs and courses: (1) more creativity courses; (2) increased use of technology; (3) more transdisciplinary impact; and (4) continued effort to balance theory and practice.

Interest in creativity is sometimes strong and sometimes weak, often depending on external circumstances and the perceived need for change and new thinking. Economic pressures,

a host of complex social situations, fear of change and ambiguous situations tend to get people interested in learning about ways to overcome their problems or to find new challenges. Current times support these factors as influential. The market for creativity programs and courses seems to be expanding.

The impact and development of technology has increased throughout education and organizations. The tendency toward maximizing technology in the delivery of content, with on-line courses and multiple site delivery are increasing, making virtual options much more available. Creativity content has always been a potential money maker in a curriculum, particularly in a single course or series of core courses. As a stand-alone degree, the work is harder due to the basic premise that creativity must be applied in something. However, courses continue to flourish and so do programs, many with on-line options. Questions that remain are such ones as: Is one course enough? Is a full degree more credible? How much formal work is enough to establish credibility and expertise? Interdisciplinary and multidisciplinary offerings, such as degrees in other subjects with a concentration in creativity, are appearing.

Historically, creativity has had strong roots in practice and, indeed, its practice has often outstripped its theoretical development. Creativity programs and courses generally were not only often first situated in practice and then followed by conceptual support, their practice often led the way to further research. The relationship between theory and practice is not a race. Sometimes one moves ahead of the other but, eventually, the two have to find a pace that is productive and collaborative. Much of the early research (and some of the contemporary work as well) was rooted in the practical needs of consultants and other practitioners who saw, in their authentic practice, the power of finding options and having choices about how we might solve problems. The need for novelty, newness, differentness, or multiple perspectives or options is strong in almost all areas of endeavor – in our workplace, in organizations, in education, in the arts and in the sciences. It is also important in our everyday lives and in our individual problem-solving. In practice, when we see that something works, we explore how and why that may be without waiting for someone to conduct a study and tell us what we should think and do. In theory, when we look at practice, our task is to explain, to describe, and then support or refute practices and beliefs that might be spurious. Balancing theory and practice will always depend on funding, interest, creative

thought, and motivation, but, as more programs and courses develop, so does the field and domain. With more and more people interested in working over the long-term focusing on the domain of creativity itself, as well as more people taking creativity courses and programs within other domains, the confluence of information and support will continue.

Glossary

Cognitive module A cognitive module is a hypothesized cognitive structure which is specialized to solve specific cognitive tasks. Various characteristics have been attributed to these structures, such as being informationally encapsulated (i.e., does its work without recourse or access to other cognitive processes). Some have argued that language in general has the properties of such a module, and within language, processing of syntax, for instance, proceeds initially independent of pragmatic or semantic factors.

Communication Accommodation Theory (CAT) This theory was developed to provide social and cognitive reasons for code-switching in language (the concurrent use of more than one language form in speech). For instance, it has been proposed that when speakers seek approval in a social situation they are likely to converge their speech to that of their interlocutor (such as by adopting the same accent or dialect); in contrast when one wishes to emphasize the social distance from the interlocutor one might engage in the use of divergent speech by emphasizing the use of the linguistic features of their own in-group.

Conceptual metaphor Sometimes referred to as 'root metaphors,' a conceptual metaphor is the understanding of one idea or conceptual domain (target domain) in terms of another (source domain). As such it provides linkages between sentences that differ semantically. As a basic concept in cognitive linguistics, this notion challenges some basic concepts in language and thought, such as by situating metaphor in conceptual and not merely linguistic terms and by eliminating a traditional basis for the distinction between literal and nonliteral language.

Descriptive grammar As contrasted with prescriptive grammar (cultural expectations of proper linguistic etiquette), a descriptive grammar provides the rules with which acceptable grammatical structures are produced and understood. A good descriptive grammar must describe the cognitive operations for all the basic forms used in a specific language group, such as the ability to embed one structure within another or the ability to recognize that two sentences mean the same thing despite syntactic differences.

Design features of language The features represent a list of 16 characteristics that are claimed to distinguish true language from communication devices employed by nonhuman animals. Among these characteristics are the following: Interchangeability (the ability by speaker-listeners to receive and also send the same message), semanticity (speech sounds can be linked to specific meanings), arbitrariness (there is no direct connection between the signal and its meaning), displacement

(the ability to talk about things that are not physically present), productivity or creativity (the ability to create new messages by combining already-existing signs), and prevarication (the ability to make false statements or to lie).

Linguistic creativity The open-endedness in natural language wherein new meanings can be given to existing words or phrases, that new words can be created as needed, and that novel word combinations can be generated (and understood by a naïve listener). It has been argued by Chomsky and others that humans can produce an infinite number of syntactically appropriate sentences, and must do so from a finite set of cognitive rules.

Nonliteral language A traditional approach assumes that there is plain and conventional mode of speaking, typically called literal language. Contrasted with this is nonliteral language, or embellishments that deviate from this norm. Despite the long history and acceptance of the distinction, there is no consensus on the definition or what constitutes literal language or where the boundary exists between the literal and nonliteral. Even if one were to consider it deviant, nonliteral language is not rare and encompasses a wide array of figures of speech, such as metaphor and simile, and rhetorical devices such as hyperbole and irony commonly found in creative text. Since the mid-1980s there have been movements both in cognitive psychology and in linguistics that have undercut the importance for this distinction, arguing that literal and nonliteral language alike are based on the same cognitive structures and found in both everyday and artistic language usage.

Protolanguage As used more traditionally, a protolanguage is a hypothesized root language for modern languages that one reconstructs based on the comparison of vocabularies and grammars. In this way, one can identify a language family that evolved from a common language. As used in a larger evolutionary perspective, a claim has been made that in the evolution of our species there was at least one of our hominid ancestors that exhibited a nonsyntactic form of language that limited how the world could be represented and in which communication of intent was highly dependent on perceptual and pragmatic factors. The argument is that evidence for this earlier form of language is still present in modern humans.

Universal grammar This linguistic theory is based on the notion that all human languages have a substantial commonality, and hence that one can describe these commonalities in a generalized descriptive grammar. This basic notion can be traced in one form or another back to the thirteenth century. In the twentieth century, this idea has been associated with various linguists, most notably Noam Chomsky who has advanced a 'principles and parameters'

approach predicated on the proposition that syntactic knowledge can be modeled on two mechanisms: first, a finite set of principles common to all languages (e.g., all sentences must have a subject) and, second, a finite set of

parameters that determines syntactic variability from language to language and which is set by experience with a given language (e.g., a parameter that determines whether the subject must be overtly expressed).

Psycholinguistics is the study of how linguistic knowledge is acquired, represented and used by the human mind. As such, it brings insights from both linguistics and psychology to bear on the cognitive aspects of language comprehension and language production. Because humans can create an infinite number of sentences that others can understand, the basic mechanisms involved are central to the understanding of everyday creativity. To some, the core issues should be limited to language production and comprehension in adult native speakers whereas others see a more expanded set of appropriate topics, such as children's acquisition of language, second language learning, language disabilities, neuro-linguistics, computational models or simulations of human language and artificial intelligence. Since the first edition of the *Encyclopedia of Creativity*, there have been notable changes in the field, though a central motif continues to be attempts at explaining linguistic creativity, the open-endedness found in all natural language which permits for the creation of new words, the creation of new meaning for existing words and the ability to understand and produce, in principle, an infinite number of utterances, many of which will be novel. In this review, the emphasis is on adult native language usage, with computational and neurological evidence brought in only in a secondary fashion. The structure of this review is to first describe what makes language unique, and speculations about the role(s) played by language in the evolution of human creativity, followed by a discussion of the seminal work of Noam Chomsky with an emphasis on the impact that he has had on molding how the debates on everyday linguistic creativity should be structured. Finally there will be a lengthier discussion of some of the more notable changes that have occurred in psycholinguistic research over the last decade and a more brief discussion of how creativity is created as a form of social linguistic interaction. In all instances the emphasis will be on psycholinguistic implications for our understanding of human linguistic creativity.

Introduction

The study of language is important to creativity because, arguably, language is the quintessential everyday human creative activity. Adult native speakers cannot only produce sentences they have never heard previously but other native speakers, for whom this also is novel, can understand them. It has been argued that all humans, regardless of culture and language community have the innate ability, in principle, to generate and comprehend an infinite number of utterances from their native language, even in the absence of explicit prior experience. Thus, it has been argued, the mechanism(s) responsible for linguistic creativity can provide insights into characteristics of the human mind necessary for creativity in general.

What Is Language and How Did It (and Creativity) Evolve?

The traditional approach holds that language is one of the unique defining characteristics of being human. As such, attempts have been made to identify characteristics of language that make it different from communication devices used by other animals, such as mating or alarm calls. Albert Katz (1999) listed the 'design features' of human language identified by Charles Hockett and the parallel of these features to aspects of both everyday and domain-specific expert levels of creativity. Notable characteristics include interchangeability (people both generate and comprehend language; people are capable of both generating and appreciating creative output), displacement and prevarication (linguistic messages and creative output alike can refer to objects and events that employ symbols that can be manipulated in ways that are not constrained by the here-and-now or other constraints of environmental 'reality'), and reflexivity (humans communicate about communication; critiquing or commenting on what has been said or written is not only a basic characteristic of language per se, but is also the basis for literary and critical analysis, and other aspects of scientific and artistic creativity). Katz noted that the parallels between the characteristics of language and creativity might indicate that (a) language is the underpinnings and basis for the increased creativity seen with humans relative to closely related primate species or (b) creative thought arises from a conceptual system that is reflected both in language and creative output.

In recent years, evolutionary psychology has attempted to disentangle the locus of the language and creativity parallels. Genetic mapping demonstrates that the divergence in the evolutionary lineage that led to the modern day chimpanzee (our closest living relative) and to the modern human took place somewhere about 5.5 million years ago and, despite that time span, the genomes of humans and chimps differ by only about 2%. There is evidence of nonlinguistic expert-level creative activity with some of our hominid ancestors: stone tool usage by *Homo habilis* and with the more sophisticated tool kit and evidence of long distance hunting by *Homo erectus*. Although the fossil evidence cannot definitively prove whether these creative jumps were associated with the evolution of language, some suggestive evidence is the presence of Broca's area (an important language brain center in modern humans) from the cast of a brain cavity of *Homo habilis*, and with changes to the vocal tract more compatible with speech in *Homo erectus*. Our species, *Homo sapiens*, first appeared in an archaic form about 500000 years ago, with more modern forms found in the fossil record about 200000 years ago. Starting about 45000 years ago, and especially from about 30000 years onward, there is an explosion in expert-level creative output, including many examples of symbolic expression (e.g., decorated tools, beads, ivory carvings and, of course, spectacular cave drawings).

The linguist, Derek Bickerton, and some anthropologists have taken this historical record as indicating that the evolution of language had two important phases, both with implications for creativity: an initial stage of protolanguage (evidenced in *Homo erectus*), namely the type of language seen in pidgin languages and in early stages of language development in children. This language is nonsyntactic, of the form ‘animal see, me run,’ in which context and direct perceptual experience would be needed to disambiguate what had been said (and would not be considered a ‘true’ language because it fails to meet several of the criteria described by Hockett, such as the criterion of displacement). The second stage, associated with *Homo sapiens*, would consist of true language, with a fully developed grammar. With grammar one can escape the here-and-now and exhibit all the design features of language. To Bickerton, language evolved primarily to serve a representational and not a communicative function. Thus with protolanguage one can only represent the world in a limited manner whereas with a true grammar one can represent the world in a rich varied way – one can talk, and think, counterfactually, about events not present (as in the past or future) or even about the fantastic and nonexistent. From this perspective the range of expert level creativity seen today in the arts, sciences, and other human activities would only be found in modern humans.

In contrast, some others, while not dismissing the importance of syntactic-based language to creativity, have argued that the evolution of creativity encompasses many cognitive and representational systems, such as mimicry, analogical thinking, and mental imagery each of which can be separable from language. Arguably animal homologues to these processes can be the basis for observed creative activity in animals, such as the productive thinking by chimpanzees described by Wolfgang Kohler in the early decades of the twentieth century. Moreover, more recent comparative studies have shown that many cognitive abilities initially attributed to language can also be found in some form in chimpanzees, including prevarication and behavioral evidence suggesting that these primates have the ability to recognize the mental states of other chimps, a prerequisite for many forms of expert-level creativity.

Psycholinguistics: Some Traditional Approaches

If indeed language is the prototypical form on everyday creativity then a central question turns to understanding the mechanisms whereby humans comprehend and produce language. The first half of the twentieth century was dominated by behaviorist theoretical approaches to language, exemplified by the linguist Leonard Bloomfield in the 1930s and the psychologist B. F. Skinner in the 1950s. This approach eschewed mental concepts and argued that language can be understood as stimulus-response patterns. Skinner, for instance, argued that syntax could be understood as a form of stimulus-response chains similar conceptually to the behavior chains one could train an animal to perform. The dominance of behaviorist approach led to almost half a century in which the representational and mental processes of concern to modern psycholinguistic inquiry were virtually nonexistent. One notable exception to the behaviorist trend during this time

span is found in the mentalist work of Edward Sapir and Benjamin Lee Whorf (the so-called Sapir-Whorf, or linguistic relativity, theory). The basic claim is that a person’s native language sets up a series of ‘lenses’ through which reality is understood and interpreted. A corollary of this approach is that the language used by a person (in a given cultural context) provides insights into the minds of a given linguistic community or culture. Initial psychological tests of the hypothesis did not support a strong version of the hypothesis, which claims that the structure of a language determines the contents of thought. However there is support that has emerged in recent years from the laboratory of the psychologist Lera Boroditsky and others for a weaker version, namely that different languages shape or predisposes one to think of space and time in different ways. The emphasis on the representational aspects of language, both as seen in the recent work on linguistic relativity and with Bickerton’s approach to the evolution of language, have direct implications for our understanding of creativity. For instance, a classic block to creativity is functional fixedness, that is, the difficulty or inability to conceptualize events or objects in other than canonical ways. Psycholinguistic experiments have demonstrated that how one labels the objects presented for use in a productive problem-solving situation influences whether or not the problem is solved. Labeling objects as ‘box and tacks’ permits invites thinking of these as two objects, each of which can be used to solve the problem whereas labeling the same objects as ‘box of tacks’ invites participants to represent the objects as unified (and hence that the box cannot be used as an aid to creative problem solving). The theory on the one hand makes contact with the geneplore model of creativity and empirically-based computational models of problem solving in which the representation of a problem determines the likelihood that a solution will be found (and that creative leaps involve restructuring how one represents a problem) and the theoretical extension, not proven, that because different languages (of which there are about 5000 in use world-wide today) represent reality differently, some languages are better equipped to perform certain type of creative activities.

By the 1950s there was a paradigm shift away from behaviorism toward mentalist approaches in psychology and language alike. Prominent in this movement was the work of the linguist Noam Chomsky, who, in the late 1950s, influenced psychologists initially with a critique of Skinner’s approach to language, especially with regard to Skinner’s attempt at explaining syntax as a chaining mechanism. Although Chomsky’s specific theoretical arguments have undergone many changes since the publication in 1957 of his book *Syntactic Structures*, he has maintained an emphasis on grammar and on everyday linguistic creativity. Any model of language he argued must be capable of predicting which combination of words is felt to be acceptable and which unacceptable to an adult native speaker (labeled a ‘descriptive grammar’). Language is a paradigmatic case of human creativity given our ability to produce and understand novelty on a daily basis. Because natural languages are infinitely large, Chomsky argued that any acceptable descriptive grammar must be generative in the sense that from a finite set of rules one can describe the structure of the infinite set of sentences that are grammatically acceptable. In essence the goodness of a descriptive grammar is its ability to generate

the sentences of a language and to associate each sentence with an appropriate grammatical description, a fatal flaw with the chaining mechanism proposed by Skinner (which Chomsky argued was a variant of a finite state grammar). An important evolution in his theorizing was the development of transformational-generative grammar, based on the insight that one cannot understand linguistic creativity or language competence by merely describing the structure of the utterances we produce or sentences we read (the surface or s-level); rather we have to consider also the thematic relations being described (a more abstract deep or d-structure). Given these two levels of representation we would then need some transformational process between these structures (thus, for instance, conserving the intuition that the same meaning can be expressed in multiple ways).

Although many aspects of Chomsky's approach has been modified or rejected by others over the years, the influence that he has had on the field has been monumental and many of his approaches to the nature of the human mind have direct relevance for discussions about human creativity. One such claim is for the biological basis for language in humans. Because humans become proficient in the comprehension and use of their native language surprisingly rapidly, Chomsky (and others) argue that linguistic competence is biologically based, and as such there must be universal grammar – the innate schema of initial assumptions which all humans bring to language learning, and on the basis of which they construct the grammar of their linguistic community (from among all the possible grammars that one could have learned). One possibility for this that Chomsky proposed in some of his later writings is that humans are born with a common set of principles each of which can be set to one or another parameters. The specific parameter settings are based on exposure to a given language, even the impoverished experiences that one faces in early development. To the extent that creativity is dependent on the presence of grammar, then creativity too is biologically based.

A second important claim made by Chomsky is for the modularity of the mind, in the sense that it consists of a set of autonomous processing units, each one with its own set of rules specialized for domain-specific information. Processing within a module is informationally encapsulated such that the workings of the module precede independent of activity in other units; the output of a module is usually available to general intellectual capacities. With respect to language, the argument would be that the processing of language occur independent of other intellectual activities and, within language itself, the processing of syntax proceeds independent of pragmatics or semantics. Employing the standard Chomskyan methodology of logically considering the intuitions about the acceptability of sentences, often those artificially constructed to make a point salient, one can easily show that a sentence such as "colorless green ideas sleep furiously" is intuitively understood as syntactically acceptable yet meaningless. Thus, one can conclude that the processes that lead to acceptable syntax is not based on whether or not the sentence is semantically interpretable, and, by extension, that syntax and semantics are separable.

An implication of a modular approach for our understanding of creativity is that, if correct, much of creative processing
