By rebellion, the individual both affirms uniqueness and establishes a principled connection with all of humanity. It is, for example, an appropriate and normal part of a child's development to rebel. There are at least two important phases of developmental rebellion that all or most people negotiate: (1) the 'terrible twos' and (2) adolescence. Around two years of age, it is normal for the child to say 'no' to a host of demands from its caregivers. This negativism allows the child the opportunity to test the waters of autonomy. Adolescence, in addition, is notorious as a period of rebellion, and quite likely is a crucial epoch for the adolescent to establish an identity separate from the identities of others. Negativism as affirmation is part of the normal development of the self.

Creativity commonly involves two struggles: the struggle to have one's ideas accepted and the intrapsychic struggle for order. Creativity is an inner struggle to rebel against chaos, apathy, and death. All rebellion, ultimately, is a rebellion of the self.

We all have daily instances where deviance not only confirms our identities but also is an antidote for alienation in the face of oppression and impersonal conformity. Some individuals, however, for example, Gandhi and Galileo, go considerably beyond a daily, commonplace nonconformity.

It seems self-evident that there are times when conformity is a good and useful thing. For example, it is important for automobile drivers to conform to the rules of driving, otherwise there would be total chaos on our roads; individualized patterns of driving would be very dangerous, and it would be impossible to predict what any given driver would do. On the other hand, the conformity of blindly sending people to their deaths by execution during Hitler's regime was a bad type of conformity.

Probably the single most prevailing symptom of ineffective rebellion is the individual's unwillingness to understand or pay the price of the rebellion. Effective rebels are fully aware of the consequences of their decisions and actions. Benedict Arnold presents an example of ineffective rebellion. In 1777 Congress

passed over him and appointed five generals for the army. He was upset about this injustice, and General George Washington wrote that he intended to correct the unfair decision. In spite of Washington's support, Arnold was not promoted. Later, in 1778, he was promoted to a command in Philadelphia, but soon became involved in arguments with the local authorities, and was court-martialed. The court-martial decided that he be reprimanded by his commander, who was Washington. Washington reluctantly executed the request, and assured Arnold that he had his support. In 1780, Arnold was given a command at West Point, and apparently his bitterness resulted in his immediate plotting to surrender West Point to the British. The rest is history. The plot was uncovered, the British gave him refuge, and his name became associated forever with backstabbing treachery. He died in obscurity, despised by both Americans and British alike, his name forever linked with heinous deception.

The philosopher Kahlil Gibran has said that 'tolerance is strength'. Societies need not only to recognize their creative individuals but additionally need to afford a supportive climate that allows for a variety of perspectives. A social tapestry that is composed of a narrow, dichotomous range of values – for example, Nazi Germany – is aesthetically, emotionally, and philosophically empty, and lacks the internal integrity and energy for its own survival. Variety is strength, as Darwin well knew. It is not only a need to change that which currently exists but especially a love of life that motivates the creator to seek change. Love and the will to transform that which is loved are interconnected aspects of the creative process. Paul Klee noted that the creative life is one that finds delight in the presence of the seemingly most mundane events. Extraordinary creativity commonly requires extraordinary courage to pursue a vision in

the face of criticism, oppression, and the recoil of the emotional investment society has to continue what is, even though what is may no longer work or is not justifiable for ethical and moral reasons.

Critical Thinking

Glossary

Convergent thinking Whereas divergent thinking allows the individual to find numerous and original ideas, convergent thinking allows the individual to find the one correct or conventional idea.

Divergent thinking This refers to the process of finding different solutions and answers to one problem.

Evaluation Evaluating involves the determination of the adequacy of a solution to a problem. It will play a major

role in determining what is and what is not considered creative.

Stage model of creativity This model maintains that the creative process involves different stages in a sequence. Critical thinking might be more important in later stages of the processes than at the beginning.

Valuation This process is selective, but it is not critical, nor evaluative. It involves mainly the identification of specific criteria.

Introduction

For some time, creative thinking was seen almost as synonymous with divergent thinking. Divergent thinking tests provided a sound alternative to the, by that time popular, IQ tests. Their validity and predictive power for creativity made them a widely used tool in creativity research, to the point that divergent thinking tests were seen as criteria for creativity. However, nowadays it is generally accepted that creative thinking also entails convergent and critical thinking. While divergent thinking involves the generation of ideas, convergent thinking refers to the capacity to provide a single (or few) adequate idea(s). Creativity is usually associated with the capacity to produce something new and adequate. Divergent thinking would be needed to generate ideas, and convergent thinking would be used for choosing adequate ideas. Critical thinking can be considered as a part of convergent thinking. It involves the evaluation, analysis, synthesis, and interpretation of something to provide a judgment. Critical thinking, thus provides the 'why' and 'how' of choosing one idea. In this sense, as creativity, it is always seen as a higher-order skill.

Aspects of Critical Thinking

As in the case of creativity, there is a lack of an agreed upon operational definition of critical thinking. However, there are certain aspects that are commonly addressed within research on critical thinking. Research in critical thinking is usually associated with two main traditions, one more psychologically oriented and focused on teaching meta-cognition skills – thinking how to think – and one more philosophically oriented, more interested in the ontological nature of the phenomena of thought and judgment.

In general terms, critical thinking is seen as a purposeful skill. This means that critical thinking is related to dispositions. As in the case of creativity, to be a critical thinker involves not only specific cognitive abilities, but also willingness to assess and evaluate information in a critical manner. In other words, the intention of a person to be critical is crucial to developing

critical thinking skills. In this sense, critical thinking has been seen as self-regulatory judgment.

Second, critical thinking generally involves the analysis and identification of central issues and assumptions. That is to say, critical thinking requires analyzing how arguments and thoughts are constructed and if they are robust in their formulation. Linda Elder and Richard Paul from the critical thinking community divide the elements of thought into point of view, purpose, questions at issue, information, interpretation and inference, concepts, assumptions and implications, and consequences.

Third, these elements of thought are evaluated in order to provide a judgment. This judgment, a single 'correct' answer, is generally based on the application of logical thinking. Because of this, certain advocates of critical thinking have maintained that critical thinking is about providing standards of thought. Judgments should be evaluated in terms of clarity, credibility, accuracy, precision, relevance, depth, breadth, and significance.

Finally, critical thinking is always associated with the identification of bias in ideas or statements.

From the above aspects, it can be seen that critical thinking can be considered a specific form of convergent thinking.

Critical Thinking in Relation to Creativity

Critical Thinking and the Stage Model of Creativity

Critical thinking and creative thinking have different conceptualizations. For this reason there are diverse perspectives on the relationship between critical thinking and creativity. A sequence or stage model of creativity would involve the idea that critical thinking is used in specific stages of the creative process, while it would, in fact, inhibit creativity in other stages. It is generally agreed that the first phases of the creative process involve divergent thinking and should not involve critical thinking. This is the case, for example in brainstorming techniques. In the first stage, brainstorming session participants are only asked to generate ideas, irrespective of their quality and without being critical about them. This idea relies on the assumption that the human mind adopts 'modes'

of thought for action, and that if one is set to use divergent thinking, without use of a regulatory mechanism that blocks inadequate ideas, these will flow more freely and easily. This is also the basis of some other creativity techniques developed by Edward de Bono, such as 'six thinking hats.' The technique consists of making people in a group work with imaginary hats on. Each of the hats determines what type of mental process the person is allowed to carry on at that specific time. A white hat, for example, involves the collection of facts and information, a red hat deals with the feelings and emotions associated with the problem, a black hat represents critical judgment, a yellow hat represent positive judgment, a green hat stands for new ideas, and a blue hat represents the mode of seeing the big picture. There is however no conclusive evidence on the claim that this is the way the mind works, and it is not clear if in a creative process a clear separation between divergent and convergent modes of thinking is strictly necessary.

First, providing a creative solution might involve critical thinking from an early stage. If critical thinking is understood as the capacity to produce self-regulatory judgment that results in interpretation of a phenomenon, then critical thinking is crucial for problem identification. As Mark Runco indicates in the conclusion to the book *Problem Finding, Problem Solving and Creativity*, problem finding skills constitute an important aspect of creativity. Problem identification derives from critical thinking, and thus creativity would be enhanced by it from the beginning. Even further, it may also be the case that critical thinking fosters the creative process during phases of generating ideas. Creativity involves the combination of complex, sometimes opposed cognitive, personality, and social characteristics, and it seems that the creative process is nurtured by movement between these opposite extremes. If this were the case, critical and convergent thinking might play a role in each of the phases of the creative process, and not just the final stages.

Critical Thinking and Intelligence

Another possible interpretation of the relationship between creative and critical thinking relates to intelligence. In most cases tests of intelligence involve convergent thinking skills. Items on tests of intelligence frequently have only one correct answer. It is thus necessary to critically evaluate the options provided. There seems to be evidence that the relationship between creativity and intelligence involves some sort of threshold, below which no creative performance is possible. Individuals above the threshold might or might not be creative. Below the threshold individuals lack basic information processing skills and are relatively uncreative. In this view, critical thinking will relate to creativity, but only above a certain threshold. That is to say, individuals without some threshold level of critical thinking will not be able to be creative.

Critical Thinking and Persuasion

There is another possible interpretation of the relationship between critical thinking and creativity. More and more, creativity research is acknowledging persuasion as an important component of the creative process. Creative individuals are

those who are not only capable of producing new adequate ideas, but who also have the capacity to 'sell' their ideas, so that the idea is taken further. This type of interpretation of creativity is more prominent in research related to innovation and economic perspectives on creativity. According to this approach, critical thinking is crucial in order to provide adequate arguments that make the idea attractive. This relates very much to the critical thinking movement, which calls for certain standards of thinking involving clarity, credibility, accuracy, precision, relevance, depth, breadth, and significance. It is likely that creative individuals with good persuasive abilities employ some of these elements when making an idea appealing to others.

Critical Thinking and the System Theory of Creativity

Yet another possible relationship between creativity and critical thinking can be taken from the system theory perspective. In this theory, Mihaly Csikszentmihalyi proposes that creativity can only be understood in terms of the interrelationship among three elements: the individual, the domain and the field. The domain refers to specific areas in the 'culture' where the creative product has been constructed: mathematics, poetry, music, etc. Thousand of domains compound the culture. The field refers to all the individuals who act as gatekeepers to the domain. They evaluate whether a product is or is not creative. The actor refers to the individuals who pursue the creative action. In this theory, critical thinking will also play a role not only in the individual who carries out the creative action, but in the validation of what constitutes creativity and what not. If creativity is, as understood by Csikszentmihalyi, "a post-hoc social attribution to new ideas and objects that find favor in the marketplace of ideas or of commodities" then critical thinking is important for creativity. In fields where the gatekeepers have limited critical thinking capacity, the acceptance of innovative ideas might be easier than in those where critical thinking is prominent. These aspects relate to the distinction between evaluation and valuation. Evaluation will mainly look at what is wrong with the options, while valuation will focus on the positive sides of the idea. These two (evaluation and valuation) are important in assessing whether a product can be regarded as creative or not. It is likely that valuation plays a major role in the determination of the originality of a product, while evaluation will be more important in determining its adequacy.

Critical Thinking in Education

Creativity and critical thinking are usually seen as cross-curricular competencies included explicitly in the syllabus or in the national curriculum. The promotion of both creativity and critical thinking has been made a political priority in many countries. However, it is less clear if creativity and critical thinking are actually being encouraged in education.

It seems reasonable to think that convergent thinking has an advantage over divergent thinking in educational settings. Group work might require conformity and convergence among individuals. The form of education still most prominent

usually involves a teacher giving a talk in front of the students and asking questions that have only one adequate answer. Traditional teaching has usually been done in a transmission manner, where teachers 'pass' knowledge to their students. In addition, convergent skill tasks are also easier to grade in a traditional manner, since they involve one correct answer. Within this traditional pedagogy, however, critical thinking has had a certain amount of support, probably more than creativity. From a philosophical tradition, the so-called Socratic system involves a series of questions and answers between the teacher and the student. Through the creation of a dialectic process between the teacher and the student, the latter can discover new knowledge as he or she is guided critically through his or her assumptions and structures of thought. In this way, students can learn to be critical thinkers.

However, some people maintain that increasing critical skills will be associated with a constraint in providing original ideas. As has been explained above, however, this is not necessarily the case. It is likely that critical and creative thinking are not independent, but it also seems likely that there is some interaction between the two, since the creative process most probably involves some aspects of critical thinking.

Conclusions

Critical thinking can be seen as part of the more general convergent thinking skills that involve the production of one correct answer. The relationship between creativity and critical thinking will depend on the different conceptualizations of the constructs and what aspects of each of the processes are taken into account. The stage model approach to creativity helps to resolve the apparent paradox between creativity involving both, critical thinking and divergent thinking. In different moments, the creative process involves different cognitive tools. Critical thinking might play a role, not only at the end but also during the creative process. Furthermore, critical thinking involves valuation and evaluation, which are necessary for problem identification and persuasion, as well as for determining the originality and usefulness of ideas.

Cross-Cultural Differences in Creativity

M Fryer and C Fryer-Bolingbroke, Creativity Centre Ltd, Paignton, Devon, UK

© 2011 Elsevier Inc. All rights reserved.

Glossary

Cross-cultural Comparing, or dealing with, two or more different cultures.

Culture A group of people, usually living within one country or region, who have shared motives, values, beliefs, identities, and interpretations or meanings of significant events that result from common experiences of members of collectives and are transmitted across age generations.

Individualism – collectivism The strength and cohesion of bonds between people; in individualist societies people are

independent and take care of themselves, whereas in collectivist societies they are part of a larger group to which they are responsible.

Power distance The amount of independence individuals have in their society and the extent to which government or authority exerts a controlling influence.

Uncertainty avoidance The extent to which people feel uncomfortable in new or unknown situations.

Introduction

This article examines how creativity is defined by culture, in what ways different cultures encourage or discourage creativity, how some countries are working to develop creativity, and briefly considers the assessment of creativity cross-culturally. It includes a summary of the results of a number of research investigations into creativity and cross-cultural differences. For the purposes of the article, a small piece of research was also carried out in which a number of highly-respected creativity researchers were asked for their views about creativity in their own countries. Combined with existing research on creativity within and across various cultures, this article aims to present some of the key thinking about this issue in an accessible way. There are some common themes, findings, and experiences which transcend cultural boundaries, but also important differences as well.

The picture is complex and its interpretation is made more difficult both by gaps in the research data and sometimes by the use of research instruments designed for one culture and used in quite a different one. Indeed, Raina criticized the narrow *ethnocentric* boundaries of most creativity research and argued instead for a *garland making perspective on creativity and cultural diversity* - one which allows a diversity of approaches to flourish and which recognizes the complexity involved:

Be like a garland maker, O king: not like a charcoal burner.
(Mahabharata in Raina, 2004: 27)

As Raina explained, this famous metaphorical statement contrasts the creation of a garland of many flowers and colors against a charcoal burner burning all kinds of diverse wood into a homogeneous dead matter. He stressed the importance of building on the insights of both East and West:

... [considering] creativity as an infinite and endlessly diverse phenomenon which provides meaning and purpose to many in life and a sense of human purpose in relation to [the] cosmos ... [rather than] universalising a particular culture and inferiorising or ridiculing others' discoveries in various domains as only myths.
(Raina, 2004: 27)

In 2002, The Creativity Centre ran the international conference *Creativity and Cultural Diversity* in the United Kingdom, because a great deal of creativity research had been focusing primarily on a white Western approach, largely ignoring contributions from other cultures. Indeed, much cross-cultural research which had been carried out before this date tended either to use US testing methods or focus on a Western definition of creativity. This was something the conference organizers sought to address, and the publication following the conference, also entitled *Creativity and Cultural Diversity*, aimed to go some way toward addressing this imbalance in perspectives.

Since then however, it appears there has been a small increase in research published internationally which has been carried out from different cultural perspectives, and it does seem that many of those working in the field are now recognising that there is more than one approach to defining and assessing creativity.

Making Cross-Cultural Comparisons of Creativity

One of the difficulties to be faced when making cross-cultural comparisons of creativity is that it is often defined in different ways. This can happen both between cultures and even within cultures, for example, within subcultural groups or different classes in a society.

The Influence of Language on Creativity Definitions

In many languages there is more than one word to denote creativity. For example, in English there is often great confusion between *creativity* and *innovation* which have many overlapping features and tend to be used interchangeably. In Polish it seems there is a similar overlap between the words *twórczość* and *kreatywność*. According to Kwasniewska, *twórczość* is used in an artistic context, to describe the sum of one's creative work rather than one's potential. It is most often used to describe the fact that a person creates something. *In this meaning it is more important that something comes to life than the fact that this thing is*

unique or novel. For scientists however, *twórczość* always needs to be both novel and valuable.

Kreatywność is used in business contexts, to describe one's intellectual potential rather than one's work, as a feature of character. So in Polish you would say that a person, but not a picture, is *kreatywny*. The term *kreatywny* often means that someone is innovative and produces novel ideas (although these are not necessarily valuable).

According to Lubart, this was described a little differently by Necka, Groham, and Slabosz, who used *twórczość* to refer to eminent creativity works, whereas *kreatywność* refers more to everyday creativity, or a personal trait.

With regard to India, as India is a multilingual country, each language has its own word for creativity which may not exactly translate into an English meaning. As well as this, in India creativity tends to be viewed as a faculty which is distinct from intellect. In this context it is known as *pratibha* or intuitive creative power. In Hindi, the terms *srijanatmakata* and *sirksa* are used for creativity. The root *sri* means – to produce, to create, procreate, let go, let loose, and release. *Sirksa* means intending to eject, wishing to create and produce.

Even when the definitions are the same, there is often variation in how different elements are valued or prioritized over one another.

The Focus of Interest: Product Versus Process

Some cultures place most value on creative products, whereas others see creativity more as a process. In Western cultures much of the focus is on producing a novel or original product. Lubart contrasts this with an Eastern perspective “in which the key to creativity is the process more than the result. The creative process is cyclic, non-linear, and enlightenment-oriented.” This was reinforced by Fryer–Bolingbroke’s survey. For example according to Sharma-Sen, in India creativity is seen as self-actualization, self-fulfilment, and self-realization. In Indian creation mythology, “the creator lets flow out of himself a part of his substance which progressively evolves into the world and then enters his world as himself (atman).”

Jackson and Messick’s Creativity Criteria and Their Cross-Cultural Relevance

Although it has been widely accepted that it is useful to adopt some common criteria for defining creativity, even these pose challenges for a cross-cultural approach. For example, the four creativity criteria (*novelty*, *transformation*, *condensation*, and *appropriateness*) identified by Jackson and Messick have proved invaluable for creativity researchers, but these do not always translate well across cultures.

Novelty

In the West, novelty in some form is normally regarded as a necessary, if not sufficient, condition of creativity and it is the impact a novel product or process has which determines whether or not it is seen as creative.

To assess whether a creative product could be regarded as novel in a global sense would require a high level of specialist

knowledge. On the other hand it can be argued that a creative product is novel for the person who made it (for example a child doing something for the first time, with no knowledge of what has gone before).

Societies also vary in terms of the amount of novelty they will tolerate. To illustrate this Cropley gave the example of the sentencing of Galileo in 1633 for supporting the Copernican position that the earth orbits the sun.

According to Sharma, in India, among the traditional rural semi-urban people, creativity is perceived as the skill to create artefacts, which they believe need not be original every time. However, whether such artefacts can legitimately be called creative is a matter for debate and depends on who is qualified to judge. Sharma went on to say that “among the urban educated, the Western notion of creativity (implying novelty, originality) is accepted.”

Transformation

In Western cultures there is an assumption that a highly creative new product demonstrates a radical shift in approach. However this may not be the case in some Eastern cultures. Lubart described how Li compared Chinese ink-brush painting and modern Western painting:

Chinese ink brush painting was viewed as a “vertical” domain in which some elements are essential in each work, and certain aspects can be modified ... In contrast, modern Western painting is a horizontal domain with novelty allowed, supposedly, on all aspects. Thus, novelty can occur “in all directions” in modern Western painting, but only in certain directions in Chinese ink brush paintings. (Lubart, in press)

According to Lee, when Malaysian creativity researcher, Leonard Yong, studied the creativity of Japanese people in the early 1990s he concluded that, like other South East Asians, their main characteristic was elaboration, meaning they tended to improve on existing products rather than transforming them into completely new ones.

Condensation

Jackson and Messick described condensation as “the capacity to allow continued contemplation without exhausting meanings and implications.” This criterion seems more appropriate for great works of art, music or literature, rather than, for example, an invention. Perhaps this is the most culturally transferable of Jackson and Messick’s four criteria.

Appropriateness

This concerns the extent to which a product is appropriate to its context. Paletz and Peng used an implicit theory approach to explore the validity of *appropriateness* and *novelty* amongst over 400 students from Japan, China, and the United States. To do this they used repeated measured scenarios of cooking and textbook products. They concluded that appropriateness was more important for Americans and Japanese for evaluations of creativity and desire for products. They also concluded that whilst novelty was important for them all, the Chinese were more swayed than the Americans by the novelty manipulation with regard to their degree of desire for the product.

The Social Context of Creativity

The fact that creativity does not exist in a vacuum, but in a social context has long been stressed both by Stein and Cropley. Cropley (an Australian who spent much of his career working overseas) argued that society is ambivalent about creativity and that two opposing forces are operating: conserving forces which resist change and innovating forces that favor it. Importantly he noted that that not all conservation is reactionary or undesirable and not all innovation is beneficial. Furthermore, creativity can be achieved through evolutionary as well as revolutionary change.

Evidence that societal goals and cultural values influence the focus of creative endeavor was put forward by Razik who argued that economic needs and the political situation have tended to influence assumptions about creativity. He pointed out that in the United States even though the Progressive Education Movement, which focused attention on the creative qualities of children, was widespread as early as the 1930s, it was only after the Second World War "in the presence of the Russian threat, creativity could not be left to the chance occurrence of the genius . . . it had to be a property in many men . . ." Razik stated that it was when the need for creative individuals was great, that people began to entertain the possibility that perhaps anyone could be creative and that creativity was amenable to education. Cropley described how in the United States, the National Defence Education Act adopted a concept of creativity which went beyond its earlier aesthetic definition, to one in which creativity was seen as a key factor in society's prosperity and survival, thus launching the age of social creativity.

'Eastern' and 'Western' Perspectives on Creativity

Raina articulated what many literature reviews strongly suggest, that "theories of creativity derive from cultures' creation myths." The word *derive* seems important here since (if he is interpreted correctly) he was referring to the religious basis of creativity in each culture, whether Indian, Greek, or Judaic, for example. Hussain also emphasized how Islam laid the cultural and scientific foundations of the modern world.

It may, therefore, seem easy to simplify the cultural differences in creativity by grouping them into roughly Eastern and Western cultures, but this is not what Raina was arguing since he pointed out that: "creative thought in the Oriental traditions cannot be treated as a single, undifferentiated entity . . ."

So, whilst there are some significant differences between East and West in terms of creativity and culture, the situation is really more complex than this. This argument is also backed up by Kapur, Subramanyam, and Shah who drew attention to the similarities between Indian and Western scientists.

Furthermore, Hussain argued for the importance of understanding how people see creativity in order to help them improve and to do this it is important to understand the traditional bases for their creativity. He pointed out that Eastern philosophies like Buddhism and Taoism suggest that there is a need to loosen control and let the mind be free, because as soon as a person tries to create, 'to do,' they start controlling. Instead of forcing it they need to give it a chance to 'come,' although in his view this does not work for everyone.

According to Lee, in his controversial thesis *Why Asians are less creative than Westerners*, Singaporean Ng Aik Kwang described Asian society as hierarchical, tightly organized and collectivist. There is an emphasis on social order, harmony and gaining approval and a negative view of conflict in society. By contrast, he argued, Westerners are loosely organized with fewer social rules and norms to adhere to. They are individualistic and egalitarian, encouraging open and democratic exchange of ideas between individuals to develop creative potential. They are less negative about conflict in society. Therefore, he concluded, Asians are less creative. However, in her book, *Creative Malaysians*, Lee provided a series of examples of creative people in Malaysia and other countries in South East Asia. Therefore, she argued, it is too simplistic to assert that Asians are less creative than Westerners. Co-author Yong studied 16-year-old Malaysian students and found (not surprisingly) that their creative abilities were comparable to American students of similar age.

Yong believes that Southeast Asians also tend to display a similar type of creativity to Japanese people, who he argued are good at elaboration, or building on existing ideas. The idea of Southeast Asians as elaborators is also backed up, according to Lubart, by Westwood and Low who cited examples of creativity in a Hindu perspective, in which traditional truths are revealed in a new way, and classic Chinese visual art, in which a well-known topic represented with a certain style is explored in a new way.

According to Hussain, whereas the West relies on a scientific approach of hypothesis building and the search for evidence, the traditional Eastern system places great emphasis on building a solid foundation and then building up basic knowledge step by step. But he maintained the downside of this approach is an over-emphasis on the foundations and rote learning – something which he suggested has "robbed people of the initiative to make bold hypotheses about new situations and new problems." Another distinctive trait of Eastern culture he identified is humility in learning.

In Confucianist-influenced societies, such as China, Taiwan, Singapore, Malaysia, and to some extent Japan, the teacher is seen as the master of knowledge who must be respected, and challenging those views can be seen as inappropriate. According to Sharma, in India school children are expected to comply with authority, and follow their teachers' (gurus') instructions. The unwillingness to question the authority of teachers has emerged in a number of countries, although of course this is not universal within or across cultures.

Other researchers have drawn attention to features of Asian cultures which can foster creativity, including an emphasis on collectivism which can encourage working together for incremental innovations. They also highlighted the fact that Asian cultures often encourage long-term goal setting and perseverance which would be beneficial to creativity.

Hussain highlighted the incredible creativity and inventiveness of Chinese society as well as the outstanding works of great thinkers like Confucius. But despite all these achievements, he suggested that there have been no similar breakthroughs in the last 1000 years. He ascribed this change to a lengthy period of feudalism and the "rigid and deeply entrenched Imperial Examination System." He contrasted this

with a much shorter period of feudalism in Europe followed by the Renaissance, and later the Industrial Revolution. He concluded that the historical conditions in the West over the past few centuries have been very favorable to creativity and inventiveness, whereas in the East the historical conditions have been less favorable. But, he argued, the Western emphasis on individual achievement over collective effort also has its disadvantages: although it can spur people on to greater accomplishments, it results in self-centred individualism which indirectly affects creativity.

One of the ways researchers have tried to make sense of all these contrasting features of different cultures is by adopting categories such as those featured in Hofstede's study of IBM's international employees:

- Individualism–collectivism
- Power distance relationship
- Masculinity–femininity
- Uncertainty avoidance–uncertainty acceptance

According to Lubart, in studies of national inventiveness and innovation, it appears that societies which feature individualism, low power distance, and low levels of uncertainty avoidance are more likely to be inventive and innovative. However countries with high levels of individualism may struggle with idea implementation, as this stage often requires a team effort.

Obviously the picture is more complex and individual cultures cannot be classed as simply as Hofstede's criteria might suggest. Within every culture there will be pockets of creativity as well as sections of society who resist creativity. For example, citing Lau, Hui, and Ng, Lubart explained that "Chinese culture is complex and cannot be reduced to being simply 'collectivist'."

But as Hussain pointed out, both Eastern and Western cultures and civilizations have made outstanding contributions to the arts, mathematics, science, and technology which influence our thinking and our lives, alluding to the role religion has played in this, whether Buddhism, Christianity, Hinduism, or Islam.

But what Hussain stressed most strongly is the benefits to society of a synergy between Eastern and Western thinking and creativity:

[By drawing on] the essence of Eastern and Western cultures, and seeking a new direction amidst the clashes and contradictions, we can achieve a greater breakthrough in creativity for the mutual benefit of both East and West. (Hussain, 2004: 96)

Rasekoala, a Nigerian chemical engineer and champion of science education for young people, pointed to the way in which unfavorable conditions (in Africa) undermine creativity. This time Eurocentric values have, in her view, 'denied, undermined and marginalized' African perspectives on creativity and innovation which, she suggested comprise the:

crucial starting point in understanding the demise of advancement on the continent. Africans are still trying to come to terms with the trauma of the arrested development of their societies, through the often brutal interface of so-called Western civilisation. (Rasekoala, 2004: 11)

Their imposed values, she argued:

interrupted [Africa's] development path along cultural, spiritual and value systems that were uniquely theirs, having been handed down through generations. (Rasekoala, 2004: 11)

Such value systems, she suggested, had been the driving force for their creativity and innovation – in science, technology, and numeracy, for example.

Rasekoala provided examples of earlier African creativity, underpinned by their cultural and spiritual value systems, such as the Benin bronzes, the Ishango Bone and the Yoruba Number System. The driving force behind such achievements, she suggested, was the "cultural and spiritual need to pay homage to spirits and natural phenomena . . . deemed to be the powerful forces behind the creation and sustainability of the Earth such as the Sun, Moon, Stars, Thunder and Rain." But Christian missionary zeal, which converted many Africans to Christianity, labelled these cultural and spiritual systems as primitive and forms of paganism to be eradicated. This had a profoundly negative impact on the development and creativity of many Africans, she argued.

Paletz and Peng reached an important conclusion, which is to understand that:

Implicit theories of creativity may go beyond stereotypes about East – West differences . . . the nature of creativity is multifaceted: if we view it through the eyes of people across the world, we can better understand which aspects are universal and which are culture specific. (Paletz and Peng, 2008: 299)

Both Hussain and Rasekoala emigrated as children from their native countries (Pakistan and Nigeria respectively) to Britain. This in no way invalidates their perspectives, but the next section charts the views of indigenous creativity researchers about creativity in their own countries.

Perspectives of Indigenous Creativity Researchers

The famous researcher, Oppenheim, maintained that if you want to know something, sometimes the best way is simply to ask people. This is what has been done here, by contacting a number of creativity researchers around the world and asking them all the same questions. Not all were able to participate, but the answers of those who did are included below. This section includes snapshots of creativity and its development in eleven countries, Australia, Estonia, India, Japan, Malta, Poland, Portugal, Romania, Singapore, Spain, and the United Kingdom – personal views provided by distinguished creativity researchers from each country. Their perceptions could provide a valuable starting point for a more comprehensive comparative study since some interesting similarities and differences are revealed.

Please note that the summary from Estonia was based on students' views collected by their professor and the Japanese account was based on Fryer's experiences, in consultation with Japanese colleagues, together with the work of Torrance and Safter.

The questions asked were:

- How is creativity perceived in your country – what sort of definitions are used?

- What, if anything, is unique about creativity in your country?
- Is creativity valued in your country, if so why and if not why not?
- Is it valued only in particular contexts, for example, the arts, education, or at work?
- Have you undertaken any recent research which reveals more about the cultural approaches to creativity in your country?

Below is a summary of the responses received.

Australia – David Cropley

Australia has a strong tradition of invention and the cultural tradition of creativity is regarded as the first step in the process of innovation – something which probably links to early European settlers and those living in remote areas in modern times who had to invent out of necessity. However, most Australians would link creativity with art and culture rather than novelty.

In business and government, however, there is extensive interest in innovation, but rather than being seen as involving the generation and exploitation of new ideas and products, innovation tends to be seen as doing new business. So the focus seems to be mainly on the business and commercial aspect as opposed to things that are created and exploited or the characteristics of those involved in that. There is also a widely held belief that Australia is very good at coming up with novel products and processes but usually fails to exploit them, possibly because of a lack of scale and resources to do so.

Creativity is valued in an artistic sense and in schools. It is seen as enriching, and part of a diverse, mature, and healthy society. The Australian population is very diverse with a large proportion having been born overseas. The policy of multiculturalism, as opposed to integration, has enabled new immigrants to fit in whilst retaining their own cultural identities. But in a nonartistic sense creativity is undervalued because it is not well understood. This includes a weak understanding of how it leads to new products, processes and services and the factors that affect this.

Estonia – Eda Heinla

A recent survey of students' views on creativity revealed their perceptions about the extent to which they felt creativity had been supported in Estonia over the last decade. Results indicate that the regaining of independence of the Estonian Republic was considered most important for creativity. For example:

Responsibility for your life has become greater, since there is nobody any more directing you and telling you how to do things. People need to use their creativity in order to use their freedom.

Estonian society has moved in the direction where creativity is promoted at school and at work . . .

At the same time they also perceived inhibiting factors such as “state economic policy: insufficient funding in the areas of culture, education and leisure activities, as well as the use of networking out of self interest.”

Other enabling and inhibiting factors they perceived include an increase in self confidence amongst Estonian

people, independence in decision making countered by a tendency to be overly influenced by Western views and behaviors, and to become more materialistic – which was seen as “the most dangerous restraint on creative self-realization.” As one student put it:

In recent years there is much less of the experimenting spirit, open mind, looking for new opportunities in the Estonian cultural landscape. People do things that are guaranteed to bring in money. Has the comfort phase arrived?

At the same time, the students regarded Estonians as being “very flexible thinkers . . . open to unconventional solutions.” They attributed this to “historical quirks and cultural peculiarities of the Estonian nation.”

India – Rehka Sharma-Sen and Neerja Sharma

India is a highly multicultural society and every region has its traditional arts and crafts, quite often woven into people's everyday lives – in the clothes they wear, the motifs they draw on their walls, and so on. Thus, amongst the traditional rural, semi-urban people creativity is perceived as the skill to create artefacts which they believe need not always be original. But amongst the urban educated, the Western notion of creativity implying novelty and originality is accepted.

In India creativity is valued. What it means to people depends on their tribal/rural/urban residence, socio-economic status, and level of formal education. However, in the realm of formal education it is not valued over and above intelligence or wisdom. The uniqueness or need for autonomy of the creative person (as in the Western context) goes against the Indian cultural value for familism/collectivism. When creativity threatens group cohesiveness it is discouraged, as getting along with others is considered very important.

The school system generally does not support creative expression as it can only be nurtured in a democratic environment. In India, school is experienced as a space that commands compliance to authority and as a place for following teachers' (gurus') instructions. Within that, art, craft, music, and dance may be encouraged. But only the *best* ones are rewarded. Others do not see themselves as creative. It is not seen as a quality everyone can have.

At work, some of the modern institutions reward creative ideas – these may be in the fields of business, technology, education, or the arts.

Japan – Marilyn Fryer, in Consultation with Japanese Colleagues

The approach taken by the Japanese has much to offer the West. As well as their unique approach to creativity (outlined below) much value is placed on collaborative work. As is the case in many Asian countries there is some evidence of a reluctance to challenge the teacher's views. As far as artistic creativity is concerned, there is increasing interest in making this accessible to a wider population both in terms of the practice and appreciation of the arts.

According to Tatsuno, a Japanese author cited by Torrance and Safter, the Japanese can reach higher levels of creativity and invention by looking inward – grounding themselves in the

bedrock of Japanese tradition – instead of scouring the world for ideas and inspiration. He regarded the linear Western processes as being ill-suited to the Japanese, although those educated in the West take on Western characteristics. Tatsuno used the words ‘pathos’ and ‘logos’ to describe the differences between the way Japanese people and Westerners process information.

One method which illustrates the Japanese approach well is the KJ method. According to Susumu Kunifuji, this is very popular in Japan (more so than an alternative approach, the NM method, which is rather like Synectics). The KJ method was developed by Kawakita Jiro, an anthropologist, who used it as a means of organizing the vast amounts of data he collected during his explorations. Akira Onda reported in 2000 that a survey conducted by the Sanno College Creativity Development Group indicated that the KJ method was more popular in Japan than brainstorming, checklists, or Synectics. Brainstorming and checklist methods of idea generation had been popular in Japan in the 1960s.

The KJ method is a means of integrating data or ideas. It is a connection-making strategy that allows participants to create new meanings. They write a brief description of ideas or observations on cards. They can only put one piece of information on a card, so some ideas have to be cut up. Akira Onda described how this can help people change their views about others, since they have to separate positive statements about people from negative ones. It can also help people overcome fixed ideas.

The participants then spread the cards on a table and collate them according to similarity of information. This can serve as a memory aid. They give each group of cards a title and arrange them spatially. Giving groups of cards a title is seen as a way of consciously manipulating the data for future use.

Participants should gather the cards according to emotional feeling about the information or idea. There is no right way to group the data – it is personal and need not be hurried. Akira Onda suggested that if a spatial arrangement can be smoothly explained in words, then it is appropriate; if it is not an appropriate arrangement, it will not be easy to explain in words.

Malta – Shirley Pulis Xerxen

In an everyday sense, creativity is very much associated with the arts and this is the main focus of the St James Cavalier World Centre for Creativity. Edward de Bono is Maltese and his work is well known in Malta. State primary schools have a thinking skills program and at the University, the Edward de Bono Institute runs an annual Masters in Creativity and Innovation which attracts both local and international students.

Creativity has achieved a higher status over the years and it is particularly valued in the arts. In education there is greater emphasis on creativity and thinking skills than on rote and passive learning. Employers are also realizing that the *weightless economy* relies on employees who demonstrate a degree of independence of thought and creativity. This respondent’s 2006 survey of Maltese teachers’ perspectives on creativity in education revealed that, despite very many constraints, they value creativity as an educational goal and a student trait.

Poland – Joanna Kwasniewska

Historically, culture and creativity have been very important in Poland. During the time that Poland was not on a map, culture and creativity integrated the Polish nation.

There is a saying, *Polak potrafi*, which means that a Polish person can cope in every situation. When the shops were empty and life was hard, Polish people tried untypical methods to achieve what they wanted and they also had to be innovative in making things that they could not buy.

In Poland creativity is valued especially by educated people and in large cities, in the arts and by managers of large corporations, in which it is often a core value. However, it is not valued enough in everyday life (where it is associated with being insane, maladaptive, or antisocial), at school (where creativity is rarely a criterion for evaluating children’s work) or at work (in the lower levels of an organization).

Portugal – Fatima Morais

Ten years ago, the concept of creativity was almost unknown in every context in Portugal. Now, the situation is different, although there are still misunderstandings about the concepts of creativity and giftedness. Teachers and educators in general are more and more interested in creativity and strongly participate when events are organized. However, problems remain. For example, despite creativity being formally considered in the Portuguese education system, this is not supported financially by the government.

Universities are beginning to offer formal courses, for example, *Psychology of Creativity* and *Creativity and Innovation*, but there are few such courses. Instead creativity is included within other courses such as *Psychology of Intelligence* and *Cognition and Learning*. However, a Masters Degree *Creativity, Innovation and Human Development* will begin this year in a private college. At the same time, there are some major problems such as a lack of motivation and institutional acknowledgment in some universities with regard to the field of creativity and the small number of researchers working in this field.

Some research is also being done, mainly in the educational domain (creativity in different school levels and years; creativity and other variables like reasoning, self concept, academic achievement; teachers’ perceptions and practices; elaboration of some tests like insightful thinking, problem finding, pupils’ self evaluation; the beginning of Torrance Tests’ validation).

There are three professional Creativity Associations:

- AEDC – Association for Education and Development of Creativity – oriented to teachers
- Apgico – Association for Creativity and Innovation in Portugal – oriented to enterprises
- Torrance Center Portugal – (recently created) oriented to education in general.

These associations provide training sessions, organize conferences, and provide information about national and international events and publications. In addition, some enterprises invite creative problem solving trainers. There are also two national newsletters about creativity, but few academic publications.

Romania – Ana Stoica-Constantin

Creativity in Romania is still feeling its way as a social and individual phenomenon and as an area of study. Following a promising epoch, two world wars and the communist regime, psychologists today have not developed their own great theories and ideas, but they have maintained interest in creativity as a field of study. What they have done is to adapt and disseminate Western, mainly American, theories and research in Romania. They have also carried out their own empirical studies, whether original or replicating other research. And they have developed practical investigations and edited programmes for training in creativity as well as issuing practical guides for the development of creativity in education and business.

Creativity has been openly declared an *education* goal, and steps have been taken toward this aim despite problems in terms of incoherent legislation, poor endowment of schools and low motivation amongst some teachers. Generally, Romanian people tend to be individualistic – they hardly work in groups one reason for this could be the competitive nature of education. Presently, courses in creativity are held in at least four universities, creative groups of students are trained, and a large movement for promoting talented children is sustained by the association *RO-talent*.

In the *arts*, too, creators enjoy, and turn to good account, the liberty of expression and the access to information. In *business*, creativity is valued postfactum by successful entrepreneurs, and the fact that they make public the importance of creative thinking is beneficial to the others, and to the field of creativity. Having no previous experience, the managers have to create both their business, and their style of management, and that makes them more creative.

Two kinds of problems exist, which are not just evident in Romania. These include a certain inertness in attitudes and behavior in some quarters and the *brain drain* to highly developed Western countries along with the emigration of disadvantaged people.

Spain – Petra Perez and Neus Sandra Mefford

In Spain, creativity is understood as the ability to find solutions. Artistic creativity is also very important in Spain. Generally speaking, creativity is defined as *something new and valuable*.

In Spain creativity and the creative person are highly valued, perhaps because Spanish people are accustomed to improvise. Inflexibility is not valued. Creativity is particularly valued in the arts, advertising, business, and education, especially with regard to promotion.

Singapore – Henry Tio

In Singapore creativity is envisaged as *thinking outside the box*. As well as *creativity*, the terms used include *innovation, entrepreneurship, enterprize, invention, design, research, and development*. Creativity is usually approached from a practical, pragmatic point of view – to come up with useful, new products and services that can be produced and marketed in Singapore and exported. Creativity is frequently perceived as an economic activity in the sense that the outcome is beneficial

and has some tangible rewards – a return on the investment of time, money, talent and energy. It is best that it serves a purpose and creates value-added aspects for both the developer and the end user. But things are also changing in the sense that an element of fun, relaxation, enjoyment and personal enrichment are now also entertained, so there does not always have to be a monetary reward.

In Singapore there are diverse religions, cultures and value systems with people coming from all over the world to live and work. This provides a platform which makes people more open with one another and enables them to think differently. A lot of ingredients for innovation are in place. More money is being poured into science and technology. There are growing investments in creative industries, which have developed very well in recent years, and for designing centers of excellence around them. These include:

- Advertising
- Antiques and art dealership
- Architecture
- Broadcasting
- Computer software
- Design
- Digital entertainment
- Films
- Music
- Performing arts
- Publishing

Creativity is highly valued. The Singapore government has also been very supportive and proactive in promoting creativity and innovation as there are no natural resources and human capital is the country's only asset. Furthermore, there is a wish to attract foreign talent – for people to settle in Singapore with their families. The arts and entertainment scene has also been developed, so as to be a culturally vibrant city. Creativity is valued in many contexts as Singapore develops into a global city – a hub of excellence in many things with a very diverse, cosmopolitan population. In education both for young people and in higher education, creativity modules are included. The respondent teaches *Creativity and Applied Thinking Skills (CATS)* and this module is taken by all first year students. The aim is to help them develop a more open mindset and to take all kinds of possibilities into consideration. They are encouraged to use various brainstorming techniques, thinking tools and processes to solve real life challenges. They have to use both divergent and convergent thinking to come up with viable solutions.

United Kingdom – Marilyn Fryer

In the United Kingdom, creativity has traditionally been associated with the arts, but increasingly it is being recognized that people can be creative in other fields of endeavor. Creativity is now being taken very seriously across the whole school curriculum and increasingly in higher education the need for both staff to operate creatively and students to develop their creative skills is being made more explicit.

The situation was very different when Fryer began researching this area in the mid 1980s. At that time it was only really being addressed in some arts, management, and engineering courses. This is partly because in the 1960s creativity education had been wrongly regarded as synonymous with permissive education. In many instances this led to a *laissez-faire* approach to education and eventually to the demise of creative education until late into the 1990s, at least as far as government policy was

concerned. Between the 1960s and the 1990s, very few people were working in the area of creative education either formally in HE or informally in school. In the late 1980s there was great concern amongst teachers that the introduction of a National Curriculum and the *red tape* which accompanied it would make it even more difficult for them to enable their students to be creative. In fact many excellent teachers left the profession.

But by the late 1990s public opinion was changing and there was an increasing recognition that creativity education would be vital in the twenty-first century. This view was adopted by the then Secretary of State for Education – and later by the government as a whole. The publication of a government report, *All Our Futures: Creative and Cultural Education* was the catalyst for a whole series of initiatives and this report was hailed by the arts establishment as legitimizing arts education and its role in the development of creativity. In some quarters it was felt that the arts establishment had ‘hijacked’ creativity education, and this is still somewhat reflected in the government’s definition of *creative industries*. Despite this, the number of initiatives to promote or develop creativity and innovation in business, education, the arts, and the community as a whole has increased.

In Europe, the interest in creativity has been significantly boosted by the designation of 2009 as the *European Year of Creativity and Innovation*. But, as can be seen from the above extracts, although creativity is being increasingly encouraged in different cultures, there is also some ambivalence about it and this is the focus of the next section.

Why Some Cultures May Discourage Creativity

In some cultures creative people are viewed negatively, at least in certain contexts. According to Lubart, Lim and Plucker found that in Korea creative people are characterized by a set of deviant features – ‘indifferent to others’ opinions, headstrong, makes conflicts in working groups, is rude, is abnormal.’ He also cited a study of Chinese teachers by Chan and Chan which suggests that nonconformity, expressiveness, and assertiveness are seen as characteristics of creative students, but viewed negatively in terms of rebelliousness, being opinionated, and being self-centered.

But, as the snapshots in the previous section demonstrate, this phenomenon is not the prerogative of the East. Another example came from a Swedish study. Eriksson found that Swedish educators expressed ambivalent and negative attitudes toward the students they regarded as creative. They described them as a worrying element, wanting to do everything differently, unwilling to cooperate, adjusting badly to conventional tuition, troublesome in class, egocentric and egotistical, listless at the prospect of some subjects, cheeky, careless, coming up with strange ideas, and disobedient.

Similarly, Torrance’s classic cultural study of teachers’ attitudes to creative students revealed that, whilst all the cultures sampled had some values which supported creativity, teachers in the United States, Germany, Greece, India and the Philippines unduly valued characteristics associated with deference and making children easier to teach. Also employing Torrance’s Ideal Pupil checklist, Ohuche found that the Igbo teachers in Nigeria highly valued industry,

sincerity, obedience, consideration for others, and self confidence but neither nonconformity nor timidity. Using the same measure, Fryer, exploring over 1000 UK teachers’ views on creativity in the mid to late 1980s, found that no single personality characteristic was selected for particular encouragement by even half her sample. The most popular were *considerate* and *socially well-adjusted*, followed by three characteristics normally associated with creativity: *self confident*, *independent in thinking*, and *curious*. It is possible that both practical considerations and cultural factors have a role to play in coloring teachers’ views. Certainly a mistrust of imagination appears to have been deeply embedded in Western culture at least until the late eighteenth century. But as reported above, with the slimming down of the UK’s national curriculum, increasing autonomy for schools and a heightened interest in creativity, education for creativity is now formally required and assessed in state schools in England (www.qcda.gov.uk).

Cross-Cultural Assessment of Creativity

With regard to cross-cultural assessment of creativity, many of the measures used in the past have had their origins in the West, in particular the United States. Examination of the extent to which this biases the results of any testing of non-Western cultural groups has been woefully neglected, but is now being considered more seriously. As far as the East is concerned, it is important to be aware of the possible distorting effect that using Western measures of creativity may have on findings. Furthermore, Raina pointed out that “our concept and understanding of creativity may not have claims to universal legitimacy since our skewed discussions of the phenomenon are largely based on studies of societies which are homogeneous and uniform.” So it is important to be cautious when designing and conducting cross-cultural research and interpreting findings.

Conclusion

The subject of cross-cultural differences in creativity is very complex with many areas for debate, which this article has aimed to summarize briefly. The fact that creativity research appears to be becoming more cross-cultural is a good thing for the field, but it is essential that researchers do consider the effect of using measures devised in one country for conducting research in another. It is possible to loosely categorize features of cultures as supportive or not supportive of creativity, but the traditional distinction of grouping cultures as Eastern and Western is too simplistic and masks the vast number of differences between one culture and another. There are hints that colonial oppression, or a totalitarian regime, inhibits a culture’s creativity and this would tie in with the theory that countries with a small power distance would be less creative. But it is also true that sometimes these conditions can help creativity flourish, for example in Poland, where it became part of the national identity when the country was subsumed under communism. There is also evidence that the predominant features of creativity within a culture appear to tie in with that culture’s creation ‘mythology’ or stories. Internationally,

it appears that the interest in creativity from governments and business is increasing, which is helpful for its development, despite some resistance from those who see creativity as a threat to stability.

Glossary

Cognitive style The method in which an individual is able to process information, acquire knowledge, and evaluate experiences through mental activities, such as thinking, reasoning, and problem solving. There is a diverse array of cognitive styles as a result of individual differences, which are a product of genetic and environmental or cultural experiences.

Creativity A multifaceted human experience involving the interaction between predisposing genetic factors and environmental or sociocultural influences. All individuals have the potential for some form of creative expression. However, creativity is manifested in ways that are unique to the personality of the individual as well as consistent with his or her cultural context. Creativity may be studied in terms of personality characteristics, ways of processing, specific domains, and subjective outcomes and objective products. This article emphasizes the influence of culture on all of these aspects of creativity.

Culturally and linguistically diverse Individuals who are immigrants or who have attained varying degrees of acculturation, but whose traditional culture continues to exert an influence on their values and styles of thinking and behavior.

Culture Defined as the organization of values, ideas, and behaviors shared by a particular group of people. As a group, people use modal patterns for perceiving, interpreting, and relating to their environment.

Developmental stages Developmental stages identify behaviors at particular age levels and attempt to account for gradual changes of an individual's behaviors (cognitive, emotional, motor, and social) by describing a progress based on a specific theoretical framework.

Divergent thinking As defined by Guilford, divergent thinking is the generation of information from given information, where the emphasis is on the variety and quantity.

Diversity, cultural Factors (and related linguistic and cognitive style differences) that influence the development and manifestation of creative abilities in individuals.

Linguistic diversity proficiency In a language other than standard English. The various stages of language proficiency may move from monolingual dominance of native language to incipient second language learning and may advance into balanced dominance of both native and host country language (English). Linguistic diversity is related to differences in style of creative expression (e.g., content and nature of verbal humor). Balanced bilingualism has been associated with cognitive and creative advantages.

Multiple intelligences Gardner's theory of multiple intelligences is a multifaceted approach to describing intelligence. Gardner proposes that there are various types of intelligences including linguistic, logical–mathematical, spatial, musical, bodily kinesthetic, intrapersonal, and interpersonal.

Tests of creativity The main uses of creativity tests are for identifying creatively gifted individuals for specific enrichment programs, for research purposes, and for career counseling. Formal evaluations of creativity that have been cross-culturally validated include the Torrance Tests of Creative Thinking and Mary Meeker's Structure of Intellect (SOI), a measure based on Guilford's Model.

Creativity and Cultural Diversity

Culture has a significant impact on the conceptualization, definition, and identification of creativity. Although there are similarities across cultures in how creativity is conceived, measured, and developed, cultural values influence preferences for specific talents and abilities and how these are nurtured and expressed. For example, Westernized (e.g., European, Soviet-Russian) views of creativity are generally associated with novel and innovative ideas or products, while other cultures (e.g., German) value the creative process itself, and some emphasize the practical application of creative solutions to simple everyday life problems or complex societal problems (e.g., Latin Americans, Turks).

Understanding the origins of cultural diversity within the construct of creativity is complex. It is important to acknowledge the varying philosophical, religious, historical-political, psychological, and sociocultural factors that surround the concept of creativity within a particular society. For example, due to political instability and economic crises in Latin American countries, solving public health, educational, and poverty-related problems have been the focus of creative endeavors rather than conducting research in understanding the phenomenon of creativity. Furthermore, creative practices have also influenced cultural groups that have immigrated to a particular region. This is evident when examining the African influence in music of South America; bossa nova in jazz of Brazil and tango in Argentina.

Similarly, the daily lives of people impact how creativity is expressed in a culture. For example, in Turkey there is much poverty and oppression toward women. As a consequence of the arduous farm life experienced by Turkish women, artistic creativity is expressed in the form of embroideries, folk art, and song. Tales of happiness, love, and friendship are intricately interwoven into colorful embroidered traditional clothing, while tales of pain and sorrow are incorporated in their songs. In some East Asian countries such as India, creativity is highly associated with spirituality. Creativity is viewed as a personal journey of self-actualization and transformation of self which may not create a tangible visible product. Therefore, creativity is highly valued across cultures but differs in its manifestations.

Another important consideration that has been recently addressed in research (i.e., Runco, Sternberg) is implicit theory of psychological concepts. Implicit theories of creativity are beliefs and expectations held by parents, teachers, schools, and communities that determine whether a particular behavior or characteristic would be deemed as creative and therefore may elicit or inhibit certain creative behaviors. Implicit theories reflect cultural values, traditions, beliefs, and norms. Although implicit theories are hardly ever discussed, they significantly impact our daily lives. Parents will foster certain creative behaviors as well as teachers with their students. Accounting for implicit theories is very useful in understanding the commonalities and differences that exist in how creativity is perceived across diverse cultures and how individuals judge and assess whether traits or behaviors are considered creative. However, implicit theories are not stable and may change over time. Although there are general agreements about what characterizes creative traits across cultures, there are some differences. For example, some collectivist cultures value traits such as being courteous, orderly, and socially competent – traits that have been more associated with noncreative behaviors. Similarly, teachers also mistakenly characterize creative children as conforming and cooperative and fail to recognize creative children who are impulsive and nonconforming.

Although we have briefly touched on a small aspect of cross-cultural views of creativity, awareness and understanding of the cross-cultural literature on creativity facilitates our understanding of cultural diversity and creativity in the United States. The United States is a pluralistic and multicultural society where manifestations of creative endeavors vary and where implicit theories of creativity affect how we value, assess, identify, and encourage certain creative behaviors.

Research in the United States continues to remain limited in understanding creativity among culturally and linguistically diverse individuals. However, research is beginning to place more emphasis on examining bilingualism and linguistic and cognitive style diversity in relation to creativity. Some major developments in this area may be originally attributed to E. Paul Torrance whose pioneering work on cultural views of creativity led the way for future studies linking cultural diversity with creativity. Although creativity is manifestly a universal human experience, it is important to study how and to what extent culture influences its expression, without neglecting commonalities and within-group differences. An understanding of creativity from a multicultural perspective is critical, given the value that is placed on it and the desire to foster creativity among American youth in a democratic, pluralistic society.

Theoretical and Research Perspectives

Culture and Creativity

The critical role of culture on creative abilities went unrecognized prior to the 1960s. Before that time, creativity was closely identified with the study of high intelligence, which, in turn, was attributed primarily to hereditary factors. The work of Francis Galton, as reflected in *Hereditary Genius*, published in 1869, emphasized the genetic aspects of individual differences in intellectual functioning. Similarly, Lewis Terman's longitudinal study of gifted children, begun in the 1920s, was based on a definition of giftedness and creativity as high performance on standardized tests of intelligence. In 1926, Leta Stetter Hollingworth defined intelligence as the top 1% of intellectual ability, although she believed that giftedness manifested itself in a variety of ways such as in music, art, literacy, abstract reasoning, and mechanical aptitude. However, the beginning of a formal shift from a unidimensional to a multidimensional perspective of intelligence may be attributed to Louis Thurstone, who posited in 1938 that there were multiple talents or primary abilities that could not be measured by a single test of intelligence. Furthermore, J. P. Guilford's structure of intellect model in 1956, which included the concept of divergent thinking abilities, provided an important turning point for viewing creativity as distinct from intelligence. His model of creativity included flexibility, fluency, originality, and elaboration in divergent thinking, which was the major theoretical framework Torrance used in 1974 to develop a highly popular test adapted across many cultures – the Torrance Test of Creative Thinking.

The concept that creativity is a discrete construct was advanced by Getzels and Jackson in their 1962 landmark study. These researchers found that adolescents who were considered highly creative were not necessarily high academic achievers or the most intelligent. The role of nonintellectual factors on creative abilities, including sociocultural and environmental influences, continued to be studied in the 1960s by other researchers (e.g., Sato, Strang, Taylor). An often cited quotation from Torrance's writings, "What is honored in a culture will be cultivated there," concerns the influences of cultural differences on creativity. Torrance studied a number of diverse cultures and found differences in how creativity was defined, valued, and expressed. Based on his observations of economically disadvantaged African American (then referred to as Black) children, Torrance found that they exhibited unique creative characteristics. The creative positives of these children included the abilities to express feelings and emotions, improvise with commonplace materials, articulate effectively in role playing activities, engage in creative movement and dance, exhibit richness of imagery in language, figural fluency, and flexibility, and express enjoyment and skill in group problem solving.

Other researchers since the 1970s and today, such as Baldwin, Bernal, Chen and Goon, Kitano, and Maker and Schriever, have continued to focus their research on identifying gifted and creative characteristics among specific cultural groups. Among Hispanic Americans, gifted characteristics included rapid acquisition of the English language, leadership abilities in both dynamic-expressive and quiet influential ways, street-smarts, and risk-taking behaviors. For Native Americans, gifted and creative behaviors included valuing

traditions, heritage, and cultural beliefs; effective ability to communicate the collective idea of the tribe, creating stories and poems; generating original ideas and solutions; unusual sensitivity to expectations and feelings of others; and encouraging others to explore and develop their abilities. The ability to work diligently, demonstrate social competence, and excel in mathematics was regarded as characteristic of giftedness among Asian Americans. Furthermore, current research has indicated that bilingualism may have an advantage on creative abilities – cognitive flexibility that allows for multiple perspectives of problem solving. As demonstrated cross-culturally and within the pluralistic context of US society, cultural diversity in creativity comprises a variety of ways of expression and manifestations – from visible measurable outcomes to more subtle, but highly influential creative behaviors. Research on cultural diversity in creativity is of growing importance as analyses of gifted programs within the United States reveal an underrepresentation of culturally and linguistically diverse groups as members of programs in the public school system.

Additional theorists, such as Robert Sternberg, have emphasized the contextual components of intelligence and the role of sociocultural environments on the human expression of abilities, including creativity. Howard Gardner's theory of multiple intelligences (i.e., linguistic, logical and mathematical, visual and spatial, kinesthetic, interpersonal, and intrapersonal) also has enhanced the concept of sociocultural factors that contribute to determining the diverse manifestations of intelligence and creativity. Further, contemporary emphasis is placed on how creativity is expressed in various specific domains rather than on the absolute level of creative ability. Specific attention is being given to the diversity of talents, distinctly different styles of creative problem solving (e.g., Kirton, Feldhusen, Treffinger, and Selby), and specific forms of expression in culturally and linguistically diverse (CLD) populations (e.g., Bernal, Esquivel). Finally, it is important to consider the impact of individual diversity and culture, specifically in terms of language and cognitive style.

Although significant strides have been made in expanding the knowledge base on the impact of culture on creativity, the identification and assessment of creativity among culturally diverse populations continue to lag behind.

Bilingualism and Creativity

Research in the area of linguistic differences and bilingualism has taken a similar course in relation to the study of cultural factors on creativity. Studies prior to the 1930s tended to perpetuate the view that there were negative effects associated with bilingualism and cognitive and academic functioning. However, beginning in the 1960s, studies by Pearl and Lambert, and others, began to reflect the opposite of the deficit view of bilingualism. Bilingual students showed a number of cognitive and creative strengths. In 1970, Landry examined creativity in bilingual children and found that when a second language was learned at a critical age, performance on measures of figural and verbal fluency, flexibility, and originality was significantly better than for the monolingual group. In 1974, Carringer studied divergent thinking in bilingual children for whom Spanish was their first language and found similar results. Earlier studies failed to account for the different

degrees of bilingualism resulting in methodological flaws. Furthermore, early studies may have utilized measures of functioning that were internally biased against individuals whose second language was English. Recent research has continued to substantiate the fact that students who become 'balanced' bilinguals or proficient in more than one language show higher metacognitive awareness, originality, divergent thinking, cognitive flexibility, linguistic humor (e.g., in the form of puns), and other signs of creativity.

Simonton uses historical evidence to examine the association of bilingualism with creativity. He reported that higher incidences of creativity and creative geniuses were evident when civilizations were composed of bilingual or multilingual cultural groups (e.g., Golden Age of Greece) rather than having one official language. For example, higher probabilities of creativity were apparent when Japan opened its doors to foreigners such as Chinese Buddhist monks, Korean artists, and Christian missionaries. Other researchers have found a high percentage of famous creative geniuses who were first and second generation immigrants. Therefore, given the cultural and linguistic diversity of the United States, the potential for creativity to thrive in this country is significant, if recognized and nurtured.

Beyond the advantages of bilingualism, it is important to study the effects of linguistic style differences on creative expression. Catherine Collier suggested that some languages (e.g., Romance) lend themselves to greater embellishment and elaboration, whereas others (e.g., Germanic) are more precise and direct. These differences may manifest themselves in ways of processing verbal information and in the quality of creative products. For example, creative writing of Hispanic students may be characterized by ornamentation. Additionally, humor, a creative characteristic, may vary across cultures based on cultural meaning and semantic differences. In general, research in psycholinguistics (e.g., Cummins, Krashen) points to a strong link with affective, cognitive, and creative processes. The study of bilingualism is increasingly relevant as the numbers of bilingual and ethnically diverse students increase in US schools.

Cognitive Style and Creativity

Facets of diversity may also be examined through the interaction of culture and creativity in the area of cognitive styles. A cognitive style is the method in which an individual is able to process information, acquire knowledge, and evaluate experiences through mental activities such as thinking, reasoning, and problem solving. A cognitive style is a unique characteristic, or a personality trait that develops as a result of an individual's genetic inheritance and the experiences and interactions of the individual in the external environment and, more specifically, culture. Creativity is linked to cognitive style in the sense that creativity is an expression of the ways in which information in the environment is processed and manipulated. In *The Geography of Thought: How Asians and Westerners Think Differently ... and why?*, R. Nisbett provides convincing evidence of modal cultural patterns in cognitive style. Cognitive style among Asians is generally characterized by affective factors, interdependence, circularity, harmony, field dependence, and holistic conceptualization. Westerners tend to be more analytical, cause and effect, linear, and independent in thinking style.

Originally, the concept of cognitive style has roots in the cognitive-developmental theory of Jean Piaget. In the 1950s, Piaget's research focused specifically on mental intelligence and cognitive development. Piaget viewed development as a continuous process that begins when an individual enters the world and, thus, environment and culture have an impact on the ways in which individuals perceive the world and interact within society. Stemming from Piaget's work, further research began to examine the diversity of cognitive style and to define these styles primarily in terms of a bipolar continuum. Work exploring the polarity of cognitive styles began in 1958 with the work of Jerome Kagan. Kagan defined conceptual tempo as a specific cognitive style that was rooted in the notion of reflection (the tendency to reflect on alternative solutions) versus impulsivity (the tendency to respond impulsively without sufficient consideration of the problem). According to Kagan, it is conceptual tempo that can be considered a source of individual differences. Other work examining the polarity of individual differences in cognitive style continued throughout the 1960s and 1970s. In 1962, Herman Witkin and colleagues formulated the theory of field dependence versus field independence, which refers to how an individual utilizes the perceptual field in organizing information. Additional research by A. R. Luria in 1973, examined how information is processed either simultaneously or sequentially. In 1975, Das and Moll found how the selection of the cognitive process is dependent on not only the type of task involved but the individual's preference for informational processing and the range and variety of past experiences. This early literature has attempted to define cognitive style as the methods in which an individual processes information from a dichotomous perspective. Research in the 1980s and 1990s turned from evaluating cognitive style on a bipolar level to a multidimensional level, as cognitive processing began to be viewed as more complex in nature. Robert Sternberg's three facet model of creativity incorporates intelligence, cognition, and motivation. In 1988, Sternberg defined cognitive-learning style as a preferred way of utilizing abilities and not simply the possession of actual abilities. Preferences may be highly influenced by social learning and cultural differences.

Utilizing theories of individual differences within human cognition, research involving individuals of different cultures and ethnicity began to attempt to identify unique styles of cognition among culturally diverse populations. In Torrance's 1967 study comparing Anglo and African American children on divergent thinking, it was found that African American children scored higher than Anglo children on measures of figural fluency, flexibility, and originality. This study was further supported by Price-Williams and Ramirez in 1977. These researchers found that Mexican-American and African American males scored higher than Anglo males on fluency and flexibility measures.

The emerging sociocultural perspective of the research literature in the area of cognitive style is based on the notion that there is a relationship between society, culture, learning, and development. This perspective is translated into studies by Rita Dunn and her associates, which established that there are numerous cognitive and social variables that influence learning in diverse populations. In 1990, Dunn, Dunn, and Price developed the comprehensive Learning Style Inventory (LSI) as a tool for understanding diversity in learning and

cognitive style. According to Dunn and Dunn in 1993, cognitive style is composed of an individual's unique reactions to elements of instruction when learning information. These elements include the immediate environment, emotionality, sociological preferences, physiological traits, and cognitive-psychological inclination. In general, the construct of cognitive style has progressed from being viewed as a simple independent variable toward a conceptualization of style as part of a cultural process.

Research has been further stimulated by the high rate of academic underachievement among minorities in the United States and the assumption that culturally diverse populations learn differently. In 1990, Dunn and Griggs reported distinct cultural differences using the LSI in terms of preferred cognitive strategies. These researchers analyzed the learning styles of at-risk high school students and found that these students utilize a processing style and instructional strategies that differ significantly from those who are more successful academically. Overall, differences in learning style, specifically the patterns of used and preferred strategies, have been found in the form of modal patterns, although there may be more within-group than between-group differences. Additionally, creativity profiles across cultures have been found to be similar within a specific domain (e.g., science) and different across domains (e.g., music, mathematics, sports). Current research focuses on understanding distinct homework styles of creative behaviors in the classroom settings through the use of the Hong and Milgrams's The Homework Motivation and Preferences Questionnaire. Practical implications suggest that performance of creative behaviors can be supported by creating learning environments that are congruent with learning styles, thus reducing talent loss. The stability of learning styles has been debated, some arguing that learning changes according to developmental, environmental, and cultural factors.

Furthermore, according to Collier, cultures tend to reinforce certain learning styles through socialization. For example, in the educational system, rewards are given for analytic rather than relational forms of learning. Students who do not exhibit analytic style in their academic performance and have an alternative style that may contrast with the teacher's style will be at a distinct disadvantage in the classroom. Societal influences affect development of particular cognitive styles and preferences for methods of processing information. The role of culture also has been considered by Sternberg and Lubart, who believe that cognitive style is a component of creativity. Just as cognitive style may be influenced by socialization and environmental factors, so may creative style. Research by Darcy in 1989 focused specifically on the link between cognitive styles and creativity. In reference to Witkin's field dependence-independence theory, it was found that independent individuals were considered to be more creative, in that these individuals were better able to function independently of the perceptual field. This was further supported by a 2006 cross-cultural research by Hongli and Yulin in China among urban and rural high school students in liberal arts and science. Creative individuals have more cognitive flexibility in the ways in which they process information and solve problems.

Cultural blocks, such as rules, traditions and social norms, may hinder the expression of creativity and the development

of flexible cognitive style. Learning and cognitive style research is one approach to understanding individual differences and creativity.

Currently, research needs to continue to explore cognitive style because the concept is quite relevant to psychological constructs. In particular, it is important to consider cultural diversity and the degree to which an individual identifies with his or her ethnic background in considering the relationship of individual differences to cognitive style and creativity.

Identification

A central assumption in the identification of creativity in culturally and linguistically diverse (CLD) individuals is that environmental, sociological, cultural, and linguistic differences affect the way in which creativity is expressed. Consequently, when attempting to identify creative ability in CLD students, there is a need to use approaches that are capable of tapping into the unique creative strengths and into the ways in which creativity is manifested in diverse populations. These approaches, however, should be used with flexibility to avoid stereotyping individuals.

In general, CLD students, including African Americans, Hispanic Americans, Native Americans, and Asians Americans, particularly those of lower socioeconomic status, are underrepresented in programs for the creative and gifted. Reasons for this underrepresentation specifically include the narrow way in which creativity and giftedness have traditionally been defined, inappropriate methods and test procedures utilized, and the limited focus of the identification process itself. More and more researchers are advocating that the identification of creativity should be based on a broad definition of what it means to be creative. In terms of CLD individuals, special consideration needs to be given to cognitive style and cultural factors that affect the expression of creative abilities. In essence, all individuals possess diverse creative abilities. Therefore, the aim is not to 'identify' only the highly creative according to one set standard of what it means to be creative (e.g., high intelligence), but rather to assess in a suitable manner the diversity of creative abilities according to a variety of domains (e.g., visual and spatial, kinesthetic, mathematical).

Creativity within a multicultural perspective is more broadly defined as a multifaceted construct that may be exhibited through (a) diverse characteristics, (b) different ways of processing information and problem solving, (c) a variety of domains (e.g., music, dance, sports, or science), and (d) a wide range of subjective outcomes (e.g., sense of fulfillment, self-worth, spirituality, resilience) and objective products (e.g., a painting, musical score, or literary composition). Based on this definition, the assessment and identification process for CLD students will include multiple criteria, a variety of sources of nomination (e.g., bilingual and English as a Second Language (ESL) teachers, parents), and pluralistic assessment methods. There are numerous ways in which creative characteristics may be assessed in CLD students, including the use of culture-specific behavioral observations in various settings, anecdotal reports from a number of sources, biographical inventories, acculturation scales, and sociometric measures, including same-culture peers as raters. The assessment needs to be

accomplished with an understanding of the culture of the individual or group in question. For example, some cultures value personality characteristics of humor and cleverness in a social context over independent behaviors. Other cultures reinforce kinesthetic forms of expression (e.g., loud laughter, touching) that may be considered rude and disruptive, rather than creative channels, in mainstream culture.

Some cultures (e.g., Asians) show regard for quiet but influential leaders over assertive leadership styles. Current methods of identification could overlook these culturally different characteristics as signs of potential creativity. In reference to past literature and research studies in the field, creativity and the creative process have been assessed in terms of divergent thinking, problem solving, cognitive flexibility, critical thinking, ideation, fantasy, visual imagery, and other information-processing modes. The issue of preferences is also important to be considered in the realm of diversity and creativity. For example, some individuals are more creative (i.e., offer many ideas) in cooperative learning situations than in situations that are competitive in nature. Additionally, some individuals prefer to solve problems in a reflective and systematic manner, whereas others prefer a more intuitive and spontaneous approach. Learning style inventories may help determine the modalities of strength and the preferred cognitive styles and learning modes of the individual and of specific cultural groups; lending itself to creating learning environments that support diverse creative behaviors. Furthermore, tests that measure real-life problem solving (e.g., Creative Real Life Problem-Solving and Real World Divergent Thinking Test) may identify creativity of a practical nature.

Very few paper-and-pencil tests are relatively free from cultural bias. However, the Torrance Tests of Creative Thinking have been effective in identifying creativity in CLD students and have been translated into various languages; developed in 1966 with the most current version available in 2008. However, research has indicated mixed results with Hispanic Americans (e.g., Garcia) scoring better on nonverbal tasks, while others found no significant differences. It is important to account for bilingual language skills. Code switching, or shifting between two languages in various ways, has been said to reflect exceptionality in linguistic abilities. Bilingual administrations, untimed tests, and nonverbal forms of tests are useful for students with limited English proficiency. Use of Multiple Criteria Method such as the Bilingual Talent Portfolio (BTP) is a strength-based assessment approach that evaluates individual's interests, abilities, expression-style preferences, and potential talents in their primary language. In addition, level of acculturation must be accounted for given that less acculturated individuals often perform lower than highly acculturated individuals.

In addition, methods for assessing subjective outcomes and experiences may include personal and parental interviews and self-report measures. Self-reports of creative behaviors include the Creativity Achievement Questionnaire developed in 2005 by Carson, Peterson, and Higgins to assess various domains in drama, writing, humor, music, visual arts, dance, invention, science, culinary arts, and architecture. Ivcevic and Mayer used a method that examines both creative behaviors and personality to identify five types of creative individuals: conventional, everyday creative individuals, artists, scholars, and renaissance.

Again, it is important that this assessment be conducted with cultural sensitivity and understanding. Products, portfolios, and other objective outcomes in a variety of domains (e.g., art, creative writings, or science projects) may be reviewed and assessed by content experts who also have cultural expertise or by individuals with input from cultural consultants (individuals familiar with the culture in question). The Consensual Assessment Technique (CAT) is a method used by experts to rate creative products such as poems, stories, collages, and narratives. Kaufman, Plucker, and Baer indicate that this method can help identify creative talent that may be overlooked by traditional measures. Consideration needs to be given to culture-specific aspects of the content and quality of outcomes. For example, there may be sociocultural difference in materials used (e.g., commonplace versus expensive), aesthetic values (e.g., choice of colors), manner of expression (e.g., poetic versus analytical writing style), functional utility (e.g., for the common good versus the individual advantage), or emphasis on process versus product (e.g., value on subjective versus objective outcomes). Criteria for what is considered creative needs to incorporate cultural components as well as account for implicit theories of creativity. However, the intent is not to stereotype but to consider cultural factors with flexibility, showing respect for different levels of acculturation and individual differences.

In general, the identification process needs to be closely linked to intervention and implementation of enrichment programs. Caution needs to be taken in considering the role of diversity, particularly when implementing educational programs and identifying creativity in children. The main purpose of identification should be to provide students with opportunities for enhancing their creative development.

Educational Implications

The assumptions that all individuals have the potential for creativity, that creativity may be expressed in diverse ways, and that creative abilities may be enhanced have implications for more comprehensive educational approaches. Globally, creativity has been a fundamental mission in education, particularly in training creative thinking among students. Generally, educational initiatives in creativity have involved creative development through play, arts, direct instruction, and teacher training. Examples of educational programs include the 'Aprender para Crear' (Learning for Creating) and 'Aprender a Pensar' (Learning to Think) in South America. The 'Proyecto Inteligencia' (Intelligent Project) from Stanford University has been implemented internationally. Preschools in countries such as France and Germany have been successful in nurturing creative stimulation through storytelling, art, musical improvisation, and artistic expression. In India, drama is used to increase children's imagination, creativity, concentration, communication, self-expression, organizational skills, and disciplined behaviors.

Globally, training in creativity is incorporated in high schools, higher education, science, technology, engineering, art, and business organizations. Effective training programs are primarily based on the Creative Problem Solving or Osborn-Parnes Model which uses divergent thinking to

brainstorm a number of possible solutions to a problem. Treffinger et al. developed the VIEW which is a Problem Solving Style measure of creativity, with language translations, cross-culturation validation, and application for training in problem solving. Other related methods include brainstorming, the Art of Inquiry (method of questioning that allows the integration of disparate ideas), and Creative Synthesis (combining unrelated elements or subject matter into a cohesive whole). Innovative methods in business include using computer-based systems in industrial design tasks or cell phone applications. Phone application programs include tracking people or your position via GPS, listening to your own audio tour guide of London, or using your phone as a metro-nome as you practice a Rachmaninoff piano concerto.

In the United States, educational efforts are represented by such models as Joseph Renzulli's schoolwide enrichment triad model and John Feldhausen's talent identification and development in education model, both of which attempt to reach a greater number of students in order to enhance their areas of strength. Donald Treffinger has emphasized the need for educators to develop and support independent learning methods and for instructional environments in the regular classroom to be more responsive to the development of talent and creativity in all students. Similarly, Ernesto Bernal has suggested that CLD students be provided with in-class accommodations, and other diversified opportunities that are sensitive to their cultural and linguistic background. In addition, unique characteristics of learning style are found in the 'gifted' as well as in underachieving learners, students in special education, and others at risk for school failure. For students to achieve their potential, they should be taught in an environment and with the approaches that complement their specific talents, potentials, and learning styles.

There is limited research on creative development interventions specific to CLD students, but a number of researchers (e.g., Bernal, Castellano, Cummins, De Avila, or Ortiz) recommend pedagogical approaches that incorporate bilingual interaction, dual language instruction, a multicultural curriculum component, experiential methods, mentoring from cultural role models, special guidance, and parental involvement. Promoting partnerships between bilingual education and gifted and talented programs will broaden the experience of all students. Education in the United States should be sensitive to the linguistic and cultural differences of the students and be flexible to enable all students to develop their creativity potential.

In 2008, Hong and Milgram made the following educational recommendations to help reduce talent loss: use differentiated curriculum that focuses on a variety of creative abilities (e.g., political leadership, business, art, and drama); integrate technology with learning (e.g., television, computers, distance-learning, teleconferencing, email); individualize instruction tailored to diverse creative abilities; provide warm, nurturing, supportive, and creative school environments; emphasize teacher training in the areas of giftedness and creativity; and use mentors to guide the cognitive and social-emotional development of disadvantaged CLD students. The above researchers advocate technology integrated education to "eliminate the need for complex processes of identification and selection ... to no longer need expensive special education programs of all kinds ... offered to all levels, for all domains,

and for children of all ages in all schools.” Therefore, an open admissions policy is recommended to allow access to gifted and talented programs to reduce talent loss.

Conclusion

Cross-cultural research on creativity allows a greater multidimensional understanding of the concept of creativity which widens the cultural lens of the United States. Different cultures view creativity along a variety of dimensions. The value placed on creativity may be attributed to the reward system and socialization process of the particular culture. Although it has been supported that diversity in creativity and cognitive style exists between and among ethnic and cultural groups, research also suggests that there are as many within-group as between-group differences. Continuing research needs to focus on determining the universality of the creative process and the ways it is expressed in differing cultures and countries. In general, as the understanding of creativity continues to grow, it is important to consider the diverse manifestation of creativity, including the role that culture plays in its expression. In essence, attending to cultural diversity in creativity is another way of being sensitive to the uniqueness of each individual.

Marie Sklodowska Curie 1867–1934

Physicist

Awarded Nobel Prizes for Physics and Chemistry

B J Thurston, University of Hawaii, Hilo, HI, USA

© 2011 Elsevier Inc. All rights reserved.

This article is reproduced from the previous edition, volume 1, pp 465–468, © 1999, Elsevier Inc.

Marie Sklodowska Curie was one of the first woman scientists to win worldwide fame and one of the great scientists of this century. She had degrees in mathematics and physics. Winner of two Nobel prizes, she performed pioneering studies with radium and polonium and contributed profoundly to the understanding of radioactivity.

Perhaps the most eminent of all women scientists, Marie Sklodowska Curie is notable for her many firsts. She was first to use the term "radioactivity" for this phenomenon. In 1903, she became the first woman to win a Nobel Prize for Physics. She was also the first female lecturer and professor at the Sorbonne University in Paris (1906). In 1911, she won an unprecedented second Nobel prize (this time in chemistry) for her discovery and isolation of pure radium and radium components. She was the first mother–Nobel Prize Laureate of a daughter–Nobel Prize Laureate; her oldest daughter, Irene Joliot-Curie, also won a Nobel Prize for Chemistry (1935). She received 19 degrees, 15 gold medals, and many other honors.

Marie Curie. (Copyright WideWorld Photo.)

In 1995 Marie Curie's ashes were enshrined in the Pantheon in Paris; she was the first woman to receive this honor for her own achievements.

Background

Marie Sklodowska was born in 1867 in Poland, the fifth and youngest child of Bronsilawa Boguska, a pianist, singer, and teacher, and Wladyslaw Sklodowski, a professor of mathematics and physics. Descendants of Catholic landowners, her parents were intellectuals whose opportunities were restricted by the Russian domination of Poland. At age 10, Marie was left motherless.

Her father took boarders into his home; Marie helped with housework and became a governess for six years so that her sister Bronie might study in Paris and become a medical doctor. In 1891 Marie also went to Paris and after several years of spartan living and intense study she received a *licence*, or master's degrees, in physics and mathematics at the Sorbonne.

Marie was married to Pierre Curie, also a physicist, in a civil ceremony in 1895, followed by a honeymoon which was a three-week bicycle tour. Living near poverty they gave up social contacts and recreation for their dedication to research. Marie's first scientific work was on the magnetic properties of tempered steel (1893). Then, learning of Becquerel's discovery, she selected the radiation from uranium for her doctor's thesis. After observing that uranium ore (pitchblende) was several times more radioactive than uranium, the Curies came to believe that the ore contained a new element or elements more active than uranium.

Working under miserable conditions in a shed, the Curies carried out the chemical concentration of some 100 kg of uranium ore supplied by the Austrian government to obtain a specimen from which spectroscopic identification was made of a new element which they called "polonium." Marie later discovered a second element in pitchblende, which she named "radium."

By 1902, she had isolated 1 g of pure radium salt and had determined the atomic mass of radium as 225 (226 is now accepted). In 1903, Marie, her husband, and Henri Becquerel received the Nobel prize in physics for their work on radioactivity. It was not until 1910 that she finally obtained 1 g of the pure radium metal. The Curies also determined that the beta rays emitted by radium were negatively charged particles (electrons).

The birth of her two daughters, Irene and Eve, in 1897 and 1904 did not interrupt Marie's intensive scientific work. She was appointed lecturer in physics at the *École Normale*

Supérieure for girls in Sévres and introduced there a method of teaching based on experimental demonstrations. In 1904, Marie was finally named as Pierre's assistant at the *Faculté des Sciences* where she had long worked without pay.

Confident of medical and industrial applications, a French industrialist constructed a factory near Paris for the extraction of radium from pitchblende. The Curies took out no patents and claimed no royalties, thereby renouncing a fortune. The sudden death of Pierre Curie in a road accident in 1906 was a bitter blow to Marie Curie, but it was also a decisive turning point in her career. Marie's life became even more devoted to continuing her research and raising her daughters.

In 1906, the physics chair created for Pierre was bestowed on Marie and for the first time a woman taught at the Sorbonne. As had Pierre, Marie declined the recognition of the *Légion d'Honneur*, asking only for the means to work. Albert Einstein once said of her that "Marie Curie is, of all celebrated beings, the one whom fame has not corrupted." Five years after her husband's death, Marie received the 1911 Nobel prize, in recognition of her work in isolating radium in its pure metallic form and developing the first international standard for measuring the substance. She was nominated for the French Academy of Sciences that year, but was rejected by one vote after a slanderous campaign was waged against Marie by a competitor. Marie's supporters and co-workers were shocked by this defeat but she made no comment on her rejection.

In 1910, Marie worked with the Radiology Congress in Brussels to establish official standards for radium needed in therapy and research. The Congress defined the "curie" as the unit of radioactivity. During World War I, Marie, with the aid of private gifts, equipped ambulances (which she could drive) with portable x-ray equipment; she became head of radiological services for the Red Cross. Her wartime experience led her to write the book, *La Radiologie et la Guerre*.

In 1914 Marie Curie helped found the Radium Institute in Paris, and was the Institute's first director. Through the Radium Institute, the Curie Foundation, and her membership in the Academy of Medicine, Marie Curie pursued goals such as "curie therapy" and the establishment of safety standards for workers. Marie Curie has been honored more than any other scientist on the postage stamps of many nations; many picture the benefits of x-ray diagnosis, the use of radium in the treatment of cancer, and the gift of 1 g of radium to Madame Curie by grateful women of America.

Madame Curie's health declined partly due to the lethal effects of her prolonged exposure to nuclear radiations. She had cataract operations, and suffered from lesions on her fingers and from leukemia. She died in a sanatorium in the French Alps in 1934. After her death the Radium Institute was renamed the Curie Institute in her honor.

Creativity And Eminence

For decades, scholars have studied creativity by examining eminent individuals and those factors that appear to influence or be related to creativity. Marie Curie demonstrated many of the personality characteristics common to eminent individuals and she experienced many of the environmental and social factors frequently encountered by eminent individuals.

Personal Characteristics And Creativity

Scholars do not know whether personal qualities can be a direct cause of creativity, but it does seem clear that they are intimately involved in the process. Marie Curie demonstrated the following personality characteristics common to eminent individuals: propensity to persevere, intellectual competence, academic propensity, risk taking, force of character, and independence.

Marie Curie's perseverance, intellectual competence, and academic propensity are unquestioned. She spent six years as a governess so that her older sister Bronie might study in Paris and become a medical doctor, knowing that when Bronie obtained her licence, Marie would have the opportunity to attend university. Marie spent four years of spartan living and intense study so that she could receive a master's degree in physics and a year later, a master's degree in mathematics. From childhood, Marie was remarkable for her prodigious memory, and at the age of 16 she won a gold medal on completion of her secondary education at the Russian lycee. Her intellectual competence and academic propensity were also evident in her later academic accomplishments. Among those taking the *licence es sciences* exam Marie ranked first, and among those taking the *licence es mathématiques* exam she ranked second.

Marie Curie was not afraid to take risks and her forceful character led her to a level of independence unusual for her time. In France during this period, women, especially gifted women, were scorned. The Belle Epoque writer Octave Mirbeau wrote during this period that a woman "is not good for anything but love and motherhood. Some women, rare exceptions, have been able to give, either in art or literature, the illusion that they are creative. But they are either abnormal or simple reflections of men." When studying in Paris, Marie lived alone for almost three years. It was a life which, as she wrote later in *Autobiographical Notes*, gave her a sense of liberty and independence.

Later, Marie showed incredible strength of character when she foresaw the immense labor necessary in attempting to chemically concentrate uranium in order to study radium. Knowing the small means to accomplish this task at her disposal, she plunged into the adventure wholeheartedly.

Environmental Influences

Marie Curie was influenced by many of the environmental and social factors common to eminent individuals: she came from a culturally and intellectually advantaged family; she had the presence of many adults other than her parents; she was exposed to eminent adults during her formative years; and she experienced an early parental death.

Marie's family came from the peculiarly Polish form of landed gentry known as *szlachta*, nobles who in previous centuries had fought for the republic but who valued their independent authority and participated with equal voice in the parliament of the land. During Marie's time, both sides of her family had been reduced to the position of minor *szlachta*. Though very poor, the family, like many of the intelligentsia, viewed education as a powerful weapon, an unlimited resource which could fundamentally change and ennoble society.

Many members of Marie's family were teachers and the overall welfare of the children was primary.

"My father," Marie's brother remembers, "was concerned about our health, our physical development, our studies and even our free time, for which he tried to provide us with ideas and games." In the Sklodowski household, play was learning and learning was play. Although women were excluded from university in Poland, Marie and her sisters grew up assuming higher education was their right.

While growing up, Marie and her siblings had the presence of many adult role models, especially female role models. Marie Curie could look to her own family for examples of female independence. There had been her mother, the forceful headmistress, and there was Uncle Zdzislaw's wife, Marie Rogowska, the tall blonde who founded factories and ran the family estates, defying the rules of dress and decorum along the way. But the most pertinent example may well have been Aunt Wanda Sklodowska, "the most educated of all" the women, according to Marie's brother; she had attended university in Geneva and developed a "literary career." Later, Marie may have been influenced by another remarkable woman, Jadwiga Szczinska-Dawidowa. Dawidowa, responding to the yearnings of young Polish women for higher education, began to organize a clandestine academy for women. Marie was apparently involved in the secret academy almost from its inception.

Along with these adult role models, Marie was exposed to eminent adults during the formative years of her career. While at the Sorbonne in Paris she followed the lectures of Paul Appel, Gabriel Lippmann, and Edmond Bouty. There she became acquainted with other physicists who were well known—Jean Perrin, Charles Maurain, and Aimé Cotton.

Research suggests that the experience of an early death of a parent and/or an older sibling is not necessarily an impediment to the achievement of creative achievement and eminence. Such an event can be an opportunity and a challenge to healthy ego development. At age 7 Marie experienced the death of her cherished oldest sister Zofia from typhus, and that of her beloved mother at age 10 from tuberculosis. It may have been these premature deaths that in Marie evoked the agnosticism that would later bolster her faith in science.

History is replete with geniuses. Their contributions to the advancement of knowledge and enhancement of the arts has greatly embellished the human adventure. There is, however, a division of genius. Those individuals who have contributed to the field of science have not made a comparable contribution to the field of art and vice versa. Only one individual—**LEONARDO DA VINCI**—in the entire historical record has been able to bridge the two fields of art and science and make Nobel-prize quality contributions to both. An examination of the unique way that Leonardo's brain was wired holds the clue to his genius.

Leonardo da Vinci, self-portrait. Used with permission from Alinari /Art Resource, NY.

Introduction

History is replete with remarkable men and women, but only once in the historical record has there appeared an individual who has no peer: such a one was Leonardo da Vinci. The quintessential Renaissance man, Leonardo made his mark as a theorist, an engineer, an artist, and a scientist. While there have been many famous thinkers, engineers, inventors, artists, and scientists whose work could be compared to Leonardo's, what makes Leonardo unique is that one would be hard pressed to find another thinker, engineer, inventor, artist, or scientist who also made significant contributions to the other fields mentioned. In terms of sheer creative intensity across the spectrum of human endeavor, Leonardo has no equal.

Historical Biography

Born in 1452, Leonardo was the illegitimate child of an illiterate peasant woman and a Florentine lawyer. He was

initially raised by his mother; then, before the age of five, he was separated from his mother and brought into the household of his father, a man of means who apparently did not care much for the young Leonardo. Leonardo had few friends during childhood and developed a highly sensitive, dreamy nature. Like many creative people he enjoyed his solitude.

As young man, Leonardo had a penchant for exotic practical jokes. Using a connecting tube, he once attached some bellows to the shriveled dried intestines of a bull and placed the guts in one room while he stood with the bellows in another. When people arrived in the room they barely noticed the prunelike coils, but were soon discomfited and then stupefied as a huge balloon suddenly started to fill the available space, crowding them against the opposite wall. Leonardo's fecund imagination poured forth a constant stream of discoveries, gadgets, engineering marvels, and far-sighted contrivances. He invented the helicopter, parachute, submarine, turn screw, and tank. Leonardo was extremely visual and expressed his ideas primarily through drawings. He made many contributions to science, both in theory and in application, but paradoxically he is principally studied in art history classes. He believed in pure mathematics as the highest expression of the human mind and stated, "There is no certainty where one can neither apply any of the mathematical sciences nor any of those which are based upon mathematical sciences." The subject of motion intrigued him and he made significant contributions to the field of mechanics. Leonardo's compelling studies of the muscular movements of men and horses, exemplified in his cartoons from his *Battle of Anghiari*, are the most detailed anatomical descriptions of men and animals in motion that have ever been produced. He published a book that still remains the definitive study of equine anatomy. His interest in the principles of movement carried him deep into the field of anatomy so that his contributions changed forever the way future students of this subject would be taught. The first modern medical textbook, Andreas Vesalius's *De humani corporis fabrica*, published in 1543, owes an enormous debt to Leonardo's earlier anatomical studies. Leonardo also attempted to understand the concept of inertia and came astonishingly close to the central clue that allowed Isaac Newton to elaborate his laws of motion two centuries later. Leonardo wrote, "All movement tends to maintenance, or rather all moved bodies continue to move as long as the impression of the force of their motors (original impetus) remains in them." The principle of inertia was called the Principle of Leonardo until Newton published his *Principia*.

Leonardo, the artist, analyzed the visual world with a scientist's eye. In a sampling of his precepts one finds,

When you have to draw from nature, stand three times as far away as the size of the object that you are drawing. . . . Every opaque object that is devoid of color partakes of the color of that which is opposite to it, as happens with a white wall. . . . The shadows cast by trees on which the sun is shining are as dark as that of the center of the tree. . . . The sun will appear greater in moving water or when the surface is broken into waves than it does in still water.

Leonardo was a pioneer in the study of light, and he revealed revolutionary insights about its nature. Leonardo understood that images were reversed upon the retina. He is generally credited with the invention of the camera obscura, upon which the principle of modern photography rests. He studied optical illusions and his explanations for them still apply today. He sketched an instrument to record the intensity of light that differed little from the one developed by Benjamin Thompson, an American, three centuries later. Leonardo was also fascinated by shadows and worked out the geometrical details of the umbra and penumbra that are still in use by present-day astronomers. He was familiar with eyeglasses and suggested in the 15th century the possibility of contact lenses. He investigated the phenomenon of the iridescence of peacock feathers and oil on water. He was the first person in the historical record to make the all-important surmise that light traveled through space and time. Extrapolating from water waves and sound waves he wrote, Just as a stone thrown into water becomes the center and cause of various circles, sound spreads in circles in the air. Thus everybody placed in the luminous air spreads out in circles and fills the surrounding space with finite likenesses of itself and appears all in all and all in every part.

Leonardo, the most visual of scientists, waxed poetic when describing the sense of sight by which we perceive light:

The eye, which is the window of the soul, is the chief organ whereby the understanding can have the most complete and magnificent view of the infinite works of nature. Now do you not see that the eye embraces the beauty of the whole world? . . . It counsels and corrects all the arts of mankind. . . . It is the prince of mathematics, and the sciences founded on it are absolutely certain. It has measured the distances and sizes of the stars; it has discovered the elements and their location. . . . It has given birth to architecture and to perspective and the divine art of painting.

Oh, excellent thing, superior to all others created by God! What praises can do justice to your nobility? What peoples, what tongues will fully describe your function? The eye is the window of the human body through which it feels its way and enjoys the beauty of the world. Owing to the eye the soul is content to stay in its bodily prison, for without it such bodily prison is torture. O marvelous, O stupendous necessity, thou with supreme reason compellest all effects to be the direct result of their causes; and by a supreme and irrevocable law every natural action obeys thee by the shortest process possible. Who would believe that so small a space could contain all the images of the universe. . . .

His most enduring contributions to our knowledge of light were not written in words, however, but rather they can be seen in his paintings. Leonardo was able to coax out of brush and paint a rare quality of light. No artist before or since has achieved the mysterious opalescence of the distant atmosphere. His ineffable vistas of faraway mountains, the wordless interplay of ethereal light upon a woman's smile, and the rippling fasciculations of a horse in motion, all are bathed in a light that at once is representative of the visual world and at

the same time contains a sfumato that gives his works an almost otherworldly quality.

Leonardo's technical innovations and scientific discoveries are insufficiently acknowledged by science historians because Leonardo was so ahead of his time. His imagination so far outstripped the technology of the 15th century that many of his most brilliant inventions and theories could not even be tested. Leonardo was also interested in the nature of abstract designs. In his *Treatise on Painting* (not published until 1651), he spoke of a method "of quickening the spirit of invention." He advised artists,

You should look at certain walls stained with damp, or at stones of uneven colour. If you have to invent some backgrounds you will be able to see in these the likeness of divine landscapes, adomed with mountains, ruins, rocks, woods, great plains, hills and valleys in great variety; and expressions of faces and clothes and an infinity of things which you will be able to reduce to their complete and proper forms. In such walls the same thing happens as in the sound of bells, in whose stroke you may find every named word which you can imagine.

Leonardo's interest in images without things led him to be the first European artist to draw a landscape. In so doing, he took the important step away from concrete and symbolic representation toward abstraction. Pure landscapes were utterly unimaginable to Greek, Roman, or Christian artists because they did not include the usual hierarchy of man-made things or people; instead they are the beginning of a recognition of patterns rather than objects. His interest in abstract pattern intensified until Leonardo became preoccupied with pure geometrical designs. His notebooks are filled with pictures that have no identifiable image. Later in Leonardo's life, he composed many drawings for his *Eruption of the Deluge* (1514), that second coming of the flood that would purify the sins of humankind with water. In these drawings, the complex shapes of massive walls of falling water achieve a level of art-without-an-image that anticipated by 400 years the abstract works of Wassily Kandinsky, Kazimir Malevich, and Piet Mondrian. Although Leonardo never published a single book, his writings were extensive. The scattered and disarranged pages of notes he left behind have been indexed somewhat haphazardly over the ensuing centuries, resulting in the *Codex Atlanticus*, which contains 1222 pages bundled together, evidently not in the order Leonardo wrote them. In these pages are some of the astonishing revelations of the Renaissance's most incisive mind. In one line Leonardo states with conviction, "The sun does not move," thereby anticipating both Copernicus and Galileo. The many pages of notes include an astonishing array of drawings of aerial maps, swirling water, plants, grand irrigation schemes, anatomical studies, and the ever-present profiles of faces of every physiognomic variation.

Rivalry with Michaelangelo

Like most historical geniuses, Leonardo had to contend with a rival artist, Michelangelo, who also excelled at engineering but cannot compare to Leonardo in the scientific endeavors. The living presence of an artist who could challenge Leonardo led to an inevitable confrontation. According to the Renaissance

art historian Vasari, Leonardo and Michelangelo disliked each other intensely. Leonardo, who enjoyed wearing the latest fashions, had frequently made belittling comments about the coarse and peasant-like appearance Michelangelo presented in his sculptor's working clothes and his ever-present pale patina of marble dust. Leonardo's remarks made their way back to Michelangelo and they did not endear the painter to him. When Michelangelo learned that the Duke of Sforza, the ruler of Milan, had commissioned Leonardo to cast an equestrian statue, he sneered contemptuously, believing that the diletante painter could never complete such a project. Leonardo, of course, was up to the task. There had been many man-on-a-horse monuments and Leonardo was determined to create something the likes of which the world had never seen. He set out to create an object not only of great beauty, but also the largest, most daring equestrian statue ever conceived.

When Leonardo finished making a model in plaster, it was so magnificent the townspeople urged him to place it outside in the piazza for all to behold in the sunshine. Meanwhile the artist busied himself with the engineering details of the proposed casting and informed his patron, Sforza, he would need 200,000 pounds of bronze. Sforza dutifully began to accumulate such a large quantity of the expensive metal, but not without a nagging doubt about the wisdom of commissioning such a large and expensive statue. Shortly thereafter Sforza found himself pressed by the armies of the French at his gate. He directed the bronze he had put aside for Leonardo's statue to be cast into cannons instead. Depressed, Leonardo departed for Florence. The horse suffered the fate of the martyrdom of St. Sebastian. When the French mercenaries forced the gates, they were confronted by a piazza deserted save for a towering clay horse, which must have appeared to them as a Trojan horse in reverse. In the victory celebration that followed, drunken soldiers began shooting arrows at the vulnerable *cavello*, and continued to do so into the night. In the morning, the arrows were removed and the mortally wounded horse was exposed to the elements. Rainwater seeped into the arrow tracks, and within a few months the erosive effect caused the horse to disintegrate.

One day soon after in Florence, Leonardo passed a group of young men in the piazza who were discussing Dante's *Inferno*. They asked Leonardo for his interpretation just as Michelangelo, who was also living in Florence, deep in thought, rounded the corner. Michelangelo was known to have studied Dante zealously. Leonardo, in a gentlemanly fashion, said, "Here is Michelangelo; let us ask him as he will know." Michelangelo, however, misunderstood and thought Leonardo was making fun of him. Michelangelo exploded: "Explain them yourselves! You made a design for a horse to be cast in bronze, and, unable to cast it, you have in your shame abandoned it. And to think that those Milanese capons believed you!" Leonardo flushed deeply but made no reply, turned on his heels, and strode away. These two titans never spoke to each other again, but Leonardo, as best we know, never again spoke or wrote ill of Michelangelo.

Paradox Of his Personality

Leonardo had a penchant for secrecy and loved to decode and write in cryptograms, and he enjoyed trying to decipher occult

messages from the past. In Leonardo's voluminous writings, personal statements are curiously absent. Upon learning of his father's death, for example, Leonardo made the following dispassionate entry in his journal:

On the ninth of July 1504, Wednesday at seven o'clock, died Sen Piero da Vinci, notary at the palace of the Podesta, my father, at seven o'clock. He was 80 years old, left ten sons and two daughters.

Despite his personal reserve, Leonardo was the exemplary Renaissance man. By reputation, he was gentle and generous, and he was an accomplished musician and a pleasant, witty conversationalist. Leonardo developed a philosophy akin to St. Francis of Assisi's early in his life. He had a reverence for all living things and frequently bought caged birds just so he could set them free. He became a vegetarian because he did not believe one should ever kill a living creature. It is a paradox that Leonardo, who was reputed to be unable to harm a fly, nevertheless expended considerable amounts of his genius designing engines of war. In the course of his career, he invented some of the most gruesome devices to grind and rend the flesh of enemy soldiers. Without the faintest moral compunction, he solicited employment from the infamous Cesare Borgia and left his post as Borgia's military engineer only when he discovered that a fellow worker of his, also in Borgia's employ, had been strangled to death for some unknown reason by their mutual patron.

How Leonardowas Unique

To highlight the fact that Leonardo stands alone, imagine that in every year of human history a Nobel prize committee had granted an award for the outstanding artistic achievement as well as for the most meritorious scientific one. To be fair, let us broaden the scope of the word "scientist" to include everyone whoever pondered the nature of "nature," including Pythagoras, Plato, St. Augustine, Aquinas, Kant, Dalton, Darwin, and Freud.

Despite the numerous artistic titans and the many giants of science, the fact that leaps out of the historical record is how rarely anyone would have ever qualified for *both* awards. While there have been artists who dabbled in science and scientists who displayed an artistic bent, there is almost no one who was able to make an outstanding contribution to both fields. Brunelleschi and Alberti would certainly be nominated. In the realm of art, Michelangelo, Voltaire, Goethe, and Wagner spring to mind, but their scientific contributions would not be considered Nobel prize material. Correspondingly, not a single artistic creation of Nobel prize caliber has ever issued forth from any of the men or women who applied their talents primarily to solve the problems posed by science. How odd that in all of recorded civilization only one person could lay clear-cut claims to both prizes. It speaks to the sharp divisions in our culture between art and science that we have produced only this one indisputable exemplar of the total integration of creativity's dual aspects at such high levels. The existence of even this one individual, however, points the way to the possibility and the importance of healing the artificial rift between these two sides. Somehow Leonardo

merged the processes of seeing and thinking, and the profusion of images and insights that emerged from that cross-fertilization was cornucopian.

Left Brain–Right Brain Split

To better understand this amazing Italian's creativity, we must take a short excursion and examine how the human brain processes information. All vertebrates from fish onward have a bilobed brain, that is, a right hemisphere and a left hemisphere. In all animals with this configuration, each side of the brain performs in a mirror image fashion the same tasks as its opposite side. Only humans have sharply diverged from this arrangement. While each side of the human brain is similar in appearance to each other and resembles the configuration of other animals, each lobe of a human's brain performs functionally different tasks. This specialization is called hemispheric lateralization. (Some other higher mammals and birds exhibit brain lateralization but none approach the extent to which this feature is present in humans.) The evolutionary reason for this arrangement is nature's decision to dedicate one hemisphere primarily for language. This then became the left hemisphere in right-handed people. Slightly over 90% of the population is right handed and 90% of their language centers reside in their left hemisphere. (The arrangement is not so lopsided in women, homosexual men, and lefthanded people of both sexes.) The other hemisphere, the right side, then became the primary location for functions that used to reside in both lobes, but because of space requirements now had to be squeezed into the right lobe. Since language is processed one word at a time, one sentence at a time, and one paragraph at a time, the left hemisphere functions primarily in time. All of the other human abilities and concepts that are time dependent, such as arithmetic, causality, determinism, logic, and rationality, require a well developed linear sequential time sense.

The left hemisphere controls the act of willing through its agent the right hand, which carries out the commands of this hemisphere. The right hand is the agent of action and aggression. In battle or the hunt, the right hand swings the club or sword, throws the spear, and pulls the trigger. It is the right hand that hammers the nail while the left one steadies the nail. As such it is more dominant than the left hand. The four cardinal abilities of the left hemisphere are language, numeracy, abstract thinking, and doing. All the human abilities that depend on holism and simultaneity, such as the recognition of spatial relationships, were crowded into the remaining right hemisphere. Pattern recognition, identifying faces, manipulating three-dimensional objects in space, appreciating a 70-piece orchestra, or deciphering inner emotional states through a person's expressions or gestures fall under the purview of the right brain. The left hand, controlled by the right brain, is often the one that cradles a baby, carries what the right hand has gathered, and wards off blows. Its function is more protective and nurturing. The four cardinal features of the right hemisphere are perceiving patterns, recognizing faces, synthesizing music, and creating the existential state of being. Immanuel Kant proposed that human beings have two innate dimensions built into their brains which they use to construct their

perception of reality. Kant imagined these two parameters as time and space. In many ways, the hemispheric lateralization scheme recently elucidated by neuroscientists seems to confirm Kant's speculation. The right hemisphere is predominantly a spatial hemisphere. Driving, dancing, skiing, and seeing the relationships of the parts to the whole are better handled by this hemisphere. On the left, every function that takes place there is time dependent. One could almost say that the left hemisphere is a new sense organ designed by evolution to perceive time. It differs from our other conventional sense organs in that it does not have an opening to the outside world through skin or skull.

Because the loss of speech results in a catastrophic effect on human communication, the left hemisphere has been commonly referred to as the "dominant" hemisphere and the right hemisphere is called the "nondominant" one. Researchers have identified the right hemisphere as the side best suited to process novel information; the left side is better at organizing and retrieving information that has already been learned. One could say that creativity is more a right brained function than a left one.

While not scientifically proven, it is also fair to say that the right hemisphere has those attributes that are commonly associated with the feminine and the left has those that are traditionally thought of as being masculine. Intuition, holism, synthesis, simultaneity, and emotions have been traits we usually associate with the feminine. Linearity, sequence, reductionism, analysis, and duality are concepts traditionally associated with the masculine. In a similar duality, science is traditionally associated with the left hemisphere and the masculine, and art is traditionally associated with the right hemisphere and the feminine.

This background discussion of right–left brain dichotomies is necessary to understand the unique creativity of Leonardo. To integrate so seamlessly the two hemispheric functions, Leonardo must have been born with some very peculiar wiring in his brain. We know several startling things about his mental faculties, the most striking of which was that he was ambidextrous and could write with equal facility forward and backward (mirror writing). Some of these features are found in people with dyslexia, a gender cognitive syndrome (affecting boys over girls 9:1) in which the letters "b" and "d," and "p" and "q" are frequently transposed. Many neuroscientists theorize that dyslexia may be due to a failure of brain dominance. In the dyslexic child, both hemispheres have nearly equal responsibility for the generation and understanding of speech, written language, and hand dominance, instead of the conventional arrangement in which hand preference and the preponderance of speech centers lie in the dominant lobe. Although today dyslexia is generally considered a learning disability, it did not hinder Leonardo. Perhaps his near equilibrium between his lobes allowed him to range back and forth between two different mental processes, one rooted in space and the other in time. In this way he achieved a depth of understanding about this world that has rarely, if ever, been equaled. The equality of Leonardo's hemispheres enabled this dual man to perceive space and time differently from any artist or scientist before him. Spatially, Leonardo elevated the artistic practice of sfumato to its apogee. It was his vision of deep space and the way atmospheric conditions changed distant light that revealed the

subtleties of depth to all viewers of his art. This feature of reality had gone unnoticed by previous artists. In the most famous painting in the world, his *Mona Lisa*, Leonardo imbued this obscure young woman with an eternal aura of mystery. A significant part of her inscrutable countenance lies just at the edges of the viewer's perception, for on either side of her head Leonardo created different distant landscapes that do not coincide: One is painted in a perspective that makes it closer than the other. While few people are consciously aware of this slight difference in the third dimension of depth, it is not unperceived by the viewer's eye, and this paradox of space heightens the enigmatic quality of the *Mona Lisa's* smile.

Leonardo's ability to perceive time was also *sui generis*. He observed and recorded in his drawings the complex sequence of pigeons' wings fluttering in flight, as well as the patterns made by fast-flowing water. It was not until time-lapse photography was invented 300 years after he worked that anyone else could slow down these visual blurs, and then the studies photographers made confirmed what Leonardo had seen. He alone, among all the world's artists, was able to see time in slow motion, and in the case of his flowing water drawings he was able to transfix time so that it stopped. He worked out a bird's wing's sequence of flight and the still frame pattern of rivulets capturing the motionless complex whorls and eddies. Perhaps the nondominance of his hemispheres allowed Leonardo to envision time as an "all-at-once" phenomenon, rather than perceive it in the conventional "one-at-a-time" sequence. Further evidence that Leonardo's time sense was different from other people's is his reputation for procrastination. In one case, Leonardo set an all-time record for time elapsed between accepting a commission and delivering the finished painting—23 years! In another, Pope Leo X commissioned Leonardo to paint any subject he wished. Absorbed as always in technical matters, Leonardo started to compound a special varnish for the finish of the unpainted picture. The pope, checking on the progress of his commission, threw up his hands in disgust and exploded, "This man will never accomplish anything! He thinks about finishing the work before he even starts it!" If Leonardo did not envision time as a linear sequence running from beginning to end, perhaps for him the end was the same as the beginning. Aware of his unusual ability to see time all-at-once, he once remarked, "We know well that sight, through rapid observation, discovers in one glance an infinity of forms; nonetheless, it can only take in one thing at a time." In ancient mythology the wisest figures were hermaphrodites. For example, Tiresias, the hermaphroditic blind seer in many Greek dramas, was the one character who could see the clearest. On the continuum of masculine to feminine, homosexuality falls somewhere in the middle. If the left hemisphere represents the masculine in both men and women, and the right hemisphere represents the feminine in both men and women, then someone who had a near equilibrium between the two cortical sides would likely be homosexual. Besides his ambidexterity, Leonard's homosexuality was well recorded. In his case, considering his genius and ability to see into the future, perhaps it would be more appropriate to think of Leonardo's balanced brain as the factor that made him one of history's nonfictional hermaphrodites. Although he lived more than 400 years ago, the achievements of Leonardo continue to fascinate a populace that still operates

primarily out of either one or the other side of the psyche. In *The Innocent Eye*, Roger Shattuck reports that for a stretch of 50 years— from 1869 to 1919—a time characterized by a burst of artistic and scientific creativity in the West, there was an average of one full-length book per year published on the subject of Leonardo—more than about any other individual. This literary outpouring came from such diverse authors as Bernard Berenson, Jakob Burckhardt, Sigmund Freud, and Paul Valéry, to mention but a few. The number of books still being published about the life and work of this phenomenal artist / scientist suggests that his combination of artistic humanism and scientific curiosity attests to the public's continuing awe of Leonardo. If Leonardo could integrate the two halves of his divided psyche, then how might the rest of us learn to do so? Perhaps the left hemisphere, the language lobe, has been given too much weight in Western culture. Perhaps dependence on left brained thinking and a denigration of right hemispheric thinking prevents us from being more creative. Clearly, Leonardo's brain differed from the ordinary in that he had a more balanced outlook. The following analogy will help to illustrate why the full integration of the attributes from each hemisphere will enhance a new way to see and think, which in turn is the essence of creativity.

Nature of Integrated Paired Sense of Sight and Hearing

One of the most compelling features of our sensory apparatus occurs as the result of the quirk of overlapping fields. When a paired sense such as vision or hearing appreciates the same perception from two slightly different positions in space, something unique emerges. For instance, since both our eyes face forward, we see essentially the same picture with each eye at any given moment, but because the distance between the skeletal orbits of the two eyeballs is minimal, each retina registers its impression from a slightly offset point of view. When we view an object with one eye, we perceive only two vectors of space: perpendicular height and horizontal length. However, when we open our second eye, we provide our brain with information from a slightly different angle. Somewhere within the matrix of the visual cortex, the brain overlaps the information from these two angles to create, almost magically, the third dimension of depth.

Our brains operate in the same sort of way with our hearing. Each of our ears listens to the same sounds; however, each takes in auditory information from a different point in space. Again, this distance between our ears, though small, is enough to create a third dimension of sound that we perceive as depth. Everyone knows this who has listened to music through a pair of stereophonic earphones and heard the sound as if it emanated from a point directly above the head. This occurs even though the listener *knows* that the sound from each speaker is entering each ear on the head's opposite sides. We can also discover a new dimension when we attempt to understand art and science in terms of each other. Our language certainly recognizes this, which is why, when we say a person is "well rounded," or that he "has depth," we commonly mean he can see the world through the different lenses of art and science and, by integrating these perspectives, arrive at a deeper understanding of reality. These colloquial

expressions indicate that, unconsciously, we realize that someone who has the ability to knit together two basically different hemispheric points of view is richer for it. We refer to them in words evocative of depth— “multifaceted” or “multidimensional.” The right and left hemispheres offer overlapping viewpoints of the same thing. Using both hemispheres allows us to see it in the full glory of three dimensions and understand its existence in an extended “now.” The synthesis will produce a heightened awareness and appreciation of the world we live in, two preconditions for creativity. Meister Eckhardt, the medieval mystic, wrote, “When is a man in mere understanding?” I answer, “When he sees one thing separate from another.” And when is a man above mere understanding? That I can tell you: “When a man sees All in all, then a man stands beyond mere understanding.”

Conclusion

Using both brush and pen, Leonardo changed the way we see the world, and this subtle shift in mind-set prepared people to

be receptive to the changes in perception that were destined to bring forth the modern world. This extraordinary individual was arguably the most creative individual in history. He created the sobriquet “Renaissance man” because of the outstanding contributions he made not to just one field but across a spectrum of fields, beginning with art at one end and science at the other.

Glossary

Aesthetics From the Greek root word, aisthese; applied to something that incorporates perception, feelings, and sensation; usually manifested in art, culture, and nature.

Chi Kung Also known as Qigong; Chinese term applied to all forms of exercise which works with one's chi (chi is vital energy or breath and kung is to work with or to train); simply translates as breathe work that incorporates active and passive training.

Classical dance Ballet – theatrical classical Western school of dance that has evolved over six centuries and is known for its codified movement vocabulary.

Classical dance kathak Classical dance of India known for its brilliant rhythms, fast turns, and foot work that combines Hindu and Muslim influences in perfect harmony.

Convergent and divergent thinking Convergent thinking is a process that moves toward one point; whereas, divergent thinking is a process that moves away from one point.

Cortical The outer layer of the brain, also considered the higher regions of the brain.

Flow state To move freely and effortlessly; a state that is achieved when the challenges of the task match the skills of the performer.

Phenomenology Philosophical and qualitative research study that examines 'the thing itself.'

Phylogenetic The history of the evolution of a species as opposed to ontogeny which is the history of the development of an individual organism.

Reasoning Inductive reasoning is a process of separating, bringing together and reaching a conclusion versus deductive reasoning is a process of taking away to reach a conclusion, moving from the general to the particular.

Shaman A priest of Shamanism; found in any religion that believes gods and spirits work only through the shamans who provide healing and wisdom to the tribe members.

Dance and Embodiment

Jose Limon, dancer and choreographer, once observed that dancers are fortunate because their instrument is the most eloquent and miraculous of all instruments, it is the human body. Dance is an ancient and enduring practice, a nonverbal act of expression that embodies imaginative feeling and being. It is a mind–body experience that expresses and reveals the archetypal themes of humanity. Performed by dancers and viscerally experienced by viewers, dance springs from and resides within movement that exists in an immediate interpersonal time–space continuum.

Dance sits at the center of human expression, indeed, according to Hindu legend, Shiva, the Lord of the Dance, created heaven and earth when he performed his Dance of Creation. Curt Sachs claimed that dance is the mother of the arts since the creator and the thing created, the artist and the work, remain one and the same thing. Humans are able to use their bodies in dance to create rhythmical patterns through movement in time, to engage a flexible sense of space, and to evoke vivid representations of a world seen and imagined. The dancing body was the first medium of expression; later, substances such as stone, paint, musical instruments, and spoken and written language were utilized to

enhance expression. Dance continues to be a vehicle for the ecstatic practices of spiritual rituals, for the exhilarating liberation of imagination, visions and repressed emotions, and for the delight of sharing social events. Ancient civilizations regarded dance as sacred, primal, and essential.

Dance was and continues to be an activity that involves rhythmic motions and gestures that recreate things seen and heard, giving form and substance to intangible and irrational perceptions, and expressing the divine and the mundane. From the beginning it was believed that dance represented cosmic harmony; it remains a dynamic activity that resides completely within the present-moment. Though dance could easily be mistaken for any movement, including the everyday actions of work and play, it exists as something separate. What differentiates dance from other forms of movement is its singular intention towards an aesthetic that reveals itself through itself. It is immediately recognized by the youngest child and by anyone who visits a foreign culture. Dance, in its immediate visceral potency, breaks down the distinctions of body and soul, social norms and individual expression, and emotion and intellect. Dance is defined as the rhythmic pattern of movement but it is much more – it is an aesthetic experience that moves easily from the domain of spiritual practices and social celebrations to artistic forms.

Dance Forms

The origin of dance is almost impossible to determine with accuracy; however, ancient paintings and writings do provide clues. We can surmise that dance was deeply integrated into all aspects of communal living. It was part of ceremonial practices, story-telling, and spiritual rituals. Dance and acting were indivisible in the beginning, although early in dance evolution it separated as a unique and different form of expression. Movement patterns performed by individuals were orchestrated into group choral dances, organized around rhythmic structures and spatial patterns such as rounds, chains, serpentines, and squares. Over time dance became more codified and with these stylized demands dancers required formal training and protracted periods of practice. Regardless of region or continent, dance developed along several tracks: (a) social celebrations and ecstatic expressions of pleasure, (b) religious rites, (c) healing and shaman practices, (d) folk dance, also known as world dance, (e) ballroom, (f) dance as theatrical or operatic interludes, (g) concert dance forms such as jazz, contemporary and tap, (f) classical dance such as ballet or Kathak.

Although dance forms change and develop over time, original dances are maintained with great authenticity. Historical dance societies and performing groups operate as living museums in which dances are preserved through a practice of examining (a) original music, (b) art work or photos from the time period, (c) dance notations, and (d) written critical reviews of the dances. Further, the long tradition of dancers handing down dance steps from one generation to the next, although not an authentic documentation, does keep indigenous and classical dance alive. These organizations, companies and groups are dedicated to preserving the authenticity of dance, while in less formal settings small communities and tribes retain and regularly practice their dances at family gatherings and community celebrations. The preservation of dance tradition is counterbalanced by the passion and commitment of dancers and choreographers who strive to push the boundaries of physical limits and the constraints inherent in any dance form. The advancement of dance forms evolved within many settings such as the courts of royalty, where all classical dance forms around the world developed, or in small cafes, urban streets or small studios, where social dance, tap, jazz, modern, stepping, folk dances or urban street dances emerged as a way to express the socio-political world of the people. Many dance crazes, started by small groups of individuals, preceded larger socio-political shifts in behaviors and values. For example, Argentine tango grew in the barrios and cantinas of South America. It expressed the passions, tensions, and struggles of a community and even when it was outlawed it persisted. Soon dancers in other parts of the world adopted the tango. Rather than being quelled it progressed into formal theatrical companies that toured the world. Similar dance crazes have unfolded within folk dance traditions and classical dance. This was certainly the origins of Modern Dance, a dance form that rejected classical ballet and celebrated the struggles of the human spirit, including the unrelenting pull of gravity on all movement. Today world dance traditions are both preserved to ensure authenticity and fused into new forms that can express the diversity of our world. They can be readily viewed on the internet (YouTube or the Dance Channel), television and

film, in the traditional settings of theatres, studios, site-specific spaces, dance halls, restaurants, casinos, cultural community centers or in the school halls and even on city sidewalks.

Choreography

The word choreography is a compound word of Greek origin, literally meaning dance and write. The practice of choreography and the leadership provided by a choreographer (those who create new dances) seems to have evolved concurrently with dance development. Although dance notation only existed since the early fourteenth century, choreographers began by designing their compositions on the actual dancers who performed the work, and this practice continues today. The choreographer's function is to conceive and make dances. They (1) select the music, dancers, and other performers that may be involved in the work; (2) establish the style and specific steps of the dance; (3) determine the design elements such as sets, props, lighting, and costumes; and (4) they share in the responsibility of producing the dance (where it will be performed, promotion and advertising of the performance, and managing budgets and revenues). The choreographer may be the dominant figure in a theatrical event, especially if they are also the artistic director of a dance company, or they may be part of a creative team when a theatrical work includes dance such as in musical theatre, opera or dramatic plays. Choreographers also work in large and small productions that are not dance-specific, for example, half time shows during games, opening and closing ceremonies of sporting events, fashion shows, circuses, or cultural festivals. Choreographers work in film, television, and other electronic media whether for the purpose of creating advertising, adding dramatic or physical variety to a work, or as the major focus of the show.

Choreographers are first trained as dancers, although most express an interest in making dances as well as performing dance early in their career. Today there are choreographic training programs offered in conservatories, universities, and professional dance companies; however, many choreographers still learn to create dances by witnessing others in the process. Unlike composers and playwrights, choreographers generally do not write a score or a text, although some choreographers will have their dances notated after the work is set. The majority of choreographers compose new works on the mobile bodies of dancers who will then share in maintaining the memory of the new work. Since this process is collaborative, dancers frequently join in the creation of the dance. The quality of how they move, the technical skills that they possess, and their unique physical appearance all influence the creation of a dance work; most choreographers will cast dancers with these elements in mind. The dancer is the choreographer's instrument and may even be the inspiration for a new work. Like the other performing arts, dance requires daily practice to maintain the skills essential to give life to the dynamic expression of the work and since a dancer's instrument is the embodied imagination they must cultivate both physical skills and a vivid imagination. Choreographers who share in this same training practice expect dancers to provide these ingredients. The dancer and choreographer are completely interdependent; they bring an aesthetic understanding that springs from

their collective kinesthetic imagination and they give present-moment life to the artistic expression inherent in dance.

Dance and Healing Practices

Although dance is primarily regarded as an aesthetic art form, there is a long tradition in the healing arts and spiritual practices to include it. For example, ancient shaman practices incorporated dance as a means to communicate with spirits and to activate transformative energy necessary to excise unwanted spirits. Formal spiritual practices frequently require specific physical postures to be assumed during meditation or prayer, the same postures that are repeatedly found in dance forms around the world. Many ancient healing traditions such as yoga and chi kung have clearly prescribed sequences of dance-like movements that are practiced in a state of mindful awareness. Since around 3000 BCE until today, these ancient movement arts offer relief to human suffering by activating physiological and psychological energetic release, and by providing hope to those seeking enlightenment and wisdom. As Western medicine began to depart from these ancient practices, dance and movement were devalued and gradually disappeared from medical treatment. However, in the United States in 1940, dance therapy became a distinct profession and in 1966 the American Dance Therapy Association was founded. Not surprisingly, dance therapists in the West reintroduced practices similar to those of the shamanistic, tribal, and Eastern traditions. They asserted that the body and mind were interrelated and that psychotherapy could use movement to further emotional, cognitive, physical, and social integration of the individual. With increased Western cultural awareness of ancient healing traditions, native tribal rituals were once again given credence and in some communities these healing practices were reinstated. For example, the Northern Canadian Inuit communities are now treating their depressed and addicted members with ancient healing practices; practices that incorporate movement and dance. Many treatment centers that offer an integration of Western and Alternative medicines prescribe some form of dance or movement therapy such as in the rehabilitation of patients suffering strokes, neurological disorders, or heart disease. Dance as a healing art continues to be incorporated into programs that treat babies, children, adolescents, adults, and geriatric populations. Many experienced dancers are actively working in the healing arts and conducting research in this field of study.

Creativity and Neurobiology

It can be readily argued that dance and creativity have co-existed since the beginning, even though the product (dance) disappears as rapidly as it appears. Given this transient quality, any study of creativity and dance must focus on process as much as product. Traditionally, creativity is defined as a process in which original or meaningful new ideas, forms, interpretations, or methods transcend traditional ideas, rules, patterns, or relationships that results in a product that is unique and original. An older term, imagination, is defined as the faculty of forming memories, mental images or concepts of what is not actually present to the senses. The merging of

these two terms, creative and imagination, has come to mean not only the memory of actual events but the transformation of these memories into something that has never existed before. In neurobiological terms, the retrieval of memories is a process which reconfigures images that were previously consolidated and stored in multiple regions of the brain. Memory retrieval is a form of imagination but what distinguishes any imaginative memory from creative imagination is how we use these images.

The brain is dynamic and continually generates neural maps, neural networks, and neural systems to support life. When we engage our creative imagination, neural activity is even more complex. According to neuroscientist, Walter Freeman, creative activities require the most chaotic and unstable brain activations and yet this chaos is organized and balanced by high levels of global cooperativity in the brain. This cooperativity is managed in multiple association areas located throughout the higher and lower cortical and subcortical structures of the brain. Antonio Damasio, a neuroscientist, states in his book, *The Feeling of What Happens: Body and Emotion in the Making of Consciousness*, that there are two levels of neurobiological description, one for the mind and one for the brain. This separation is not intended to be reductionist but rather reflects different degrees of complexity in neural activation and patterning. Damasio places the body and emotion at the apex of making unconscious material conscious. Like choreographers and dancers, he claims that the body and emotion express our inner feelings and intentions. He posits that the mind, a much more complex term, captures the mystery of the imagination; whereas, the brain, a physical organ, opens up the discussion of where, and to some degree, how the imagination and creativity operate. Although creative individuals have long known the power of the creative imagination, today scientists are attempting to understand its neurological process.

There are many theories that describe the creative process but one of the most applicable to today's neurobiological findings is a biphasic model of creativity. The biphasic model is a recursive model in which global imaginings are detailed and elaborated. This biphasic activation pattern can occur with high global cooperativity that regulates chaotic neurological patterns or it can work with less flexibility, ease, and regulation. The poet, Samuel Taylor Coleridge, described his notion of a biphasic model and named the two phases, primary and secondary imagination. He believed that primary imagination was the most direct living power and prime agent for all human perception. As a creative process, primary imagination worked as the instant act of organizing global images into meaningful patterns. Coleridge's secondary imagination, an echo of primary imagination, was not a spontaneous process but coexisted with conscious will and analytic thought. With the effort required to employ his secondary imagination he noticed that his images tended to dissolve or become diffuse. Their primacy dissipated with the effort to create them. Although different in kind, both primary and secondary imagination processes inevitably operate in any creative enterprise.

Primary and secondary imagination activations employ different cognitive and affective strategies. Often primary imagination is comprised of divergent thinking, inductive reasoning and broad global focus. These cognitive strategies allow artists to make remote associations (drawing material that may seem unrelated and bringing them together). In order to

facilitate this form of reasoning and focus, less frontal brain activation occurs as is evidenced by increased theta wave rhythms, a rhythm state that is associated with deep reverie. Decreased frontal cortical brain activity facilitates disinhibition of the sub-cortical (deeper and lower regions) of the brain which then releases more emotional and sensory information during the creative process. Furthermore, during primary imagination the usual pragmatic daily activities that demand more language-centered left hemispheric dominance are reduced, thus both hemispheres interplay. When the left hemisphere is no longer dominating right hemispheric activations diverse and bountiful associational information is detailed and elaborated. Secondary imagination consists of convergent thinking, deductive reasoning, and focused attention. These cognitive activities are critical for detailed selection and engage more prefrontal and frontal cortical activation. With the activation of higher cortical regions there is greater inhibition of sub-cortical regions and thus less emotional interference occurs. Literature on right and left hemispheric specialization supports and adds to our understanding about creative integration. For example, the right hemisphere generally holds autobiographical memory as well as an ability to contextualize events through a process of balance, focus, self awareness, self-reflection, and self-monitoring, while the left hemisphere applies learned rules, specificity, complexity, and reason. Perhaps Coleridge's ideas contained an intuitive knowledge about how primary imagination resembled right hemispheric processes while his secondary imagination paralleled the activities of left hemispheric activations. The creative imagination flexibly engages both the right and left hemispheres to create content and form that shapes creative meaning.

For the dance artist it is helpful to recognize and understand these recursive biphasic states. To engage more primary imagination it is necessary for the artist to reduce external stimulus in order to enter a state of deeper receptivity, a state that facilitates internally generated remote associations. This occurs as a result of reduced cortical activation. Further, it is helpful to recognize that when the frontal cortical regions are quieter, there is less inhibition of the lower brain regions that store more intense emotional memories. Since the higher cortical regions regulate the intensity of emotional responses, when these regions are quieter more unbidden memories and sensations emerge, an experience that may be quite unsettling for artists if they do not have the skills to tolerate and regulate them. During secondary imagination, the detailed complexity of higher cortical regions, especially from the left hemisphere, operates in a more sequential linear progression, a process that is much slower than global right hemispheric activations. Artists must also learn to tolerate and regulate this slower process since it can heighten anxiety and doubt. The more artists learn how to recognize, activate, and fluidly shift between primary and secondary imagination, the more they experience a sense of control and security. Twyla Tharp stated in her book, *The Creative Habit*, that what is most important for any dance artist is to repeatedly engage in the act of creating and dancing; it is a daily practice, a habit that is maintained throughout a dance artist's career. Knowing how to activate and respond to primary and secondary imagination is a learned skill that requires trust and patience. With practice a dance artist learns to experience a sense of creative efficacy and

with it comes an abiding faith that the creative imagination can be activated, tolerated, and regulated.

Dance and Neurobiology

We have gained some knowledge about the neurobiological processes operating during creativity and great understanding about how movement is organized. We know that our brain is biased to respond to sensory stimuli, especially sensing motion in others, whether it is a baby responding to the loving smile of a mother, a child imitating the actions of older children, adults empathically engaging with others, or members of a social gathering swaying and rocking to music. These responses are classified as fixed action patterns; they are phylogenetically innate neural network patterns of behavior that integrate movement and emotional activation. When we participate in movement sequences that are intrinsically congruent with the outside world we experience a knowing that is personal and individual. The sensori-motor-emotional associational regions of our brain and body are designed to resonate with the actions of others. We engage in mind-body experiences that are always immediate and visceral and when aesthetic intention is added to movement, dance emerges.

Science now confirms that we have multiple neural maps of our body that react in real time while anticipating future actions and intentions. Sandra and Matthew Blakeslee, in their book, *The Body has a Mind of Its Own*, clearly describe how our brain maintains body-maps that extend and blend into space. In short, our self does not end where our flesh ends, but extends and blends with the world, including other beings. They describe this as peripersonal space, a flexible elastic aura-like space that expands and contracts to meet our goals and needs. Our perceptions of our body expand while driving a car, holding an object, in an embrace, or dancing with another. Our profoundly plastic body-maps are located throughout our body (skin surfaces, joints, and muscles) and our brain (central, autonomic, and peripheral nervous systems). This allows for complex dynamic engagement with the world and an embodied sense of agency and meaning.

Our body schema (a felt sense based on physical properties of our body) is ideally matched with our body image (learned attitudes about our body). In dance this is one of the most delicate convergences because many trained dancers acquire great skill at managing body schema activations; however, their body image may become distorted by the ideal notion of what a dancer's body is to resemble. Body schemas operate almost entirely outside of our conscious awareness. For example: (a) proprioception (meaning perception of one's own) provides a sense of body motion, (b) the vestibular system provides a spatial awareness while we are moving, (c) our senses of touch, sight, sound, and smell provide further information, and (d) muscle memory (procedural memory) facilitates an organized and coherent motor action. Multiple regions within our brain coordinate our body schemas and organize and mobilize conscious and unconscious intentional actions. What is most intriguing is that our perceptions of the world and our actions are primarily predictive. Our brain is constantly creating models of our body and the world, continually updating these models as new information is received and

extrapolating and predicting action intentions so that we can effectively respond. For great dancers and athletes this predictive power is what gives them a decided advantage over those with less neurologically dynamic body schema facility. In fact, research studies have shown that physical practice maintains and may even improve cognitive ability. According to Glenna Batson, a dance scientist and physical therapist, through dance training, accuracy of proprioceptive inputs are strengthened. This suggests that dancers develop an augmented inner body sense compared to nondancers. Research findings also demonstrate that when greater technical skill level is attained, brain activation is more efficient and precise. As a result of long hours of training, the modifications to body schemas are rapid and require less metabolic energy. These findings explain why beginners may get discouraged; they employ more brain activation and achieve less accurate body schema feedback. Only with practice does this improve. The brain manages the learning of new skills much differently than the activation of old skills. This is precisely why Twyla Tharp claimed that creativity must be a habit and why dancers around the world know that they must dance regularly if they wish to dance with ease.

The discovery of mirror neurons is one of the most intriguing neuroscientific findings, especially when applied to our growing understanding about how dance engages others. These specialized neurons, located in major cortical regions of the brain, allow us to mimic an action that is performed in front of us. They rapidly link perception, action, and intention in order to facilitate the acquisition of new motor behaviors. Not only do these mirror neurons help us learn new skills but they also form strong neural circuits as we practice and witness these skills. Perhaps this is why members of an audience who have danced gain greater pleasure when watching others dance and why they are less kinesthetically involved when they watch football players. Mirror neurons help us learn and they improve with practice. Along with mirror neurons we are also neurobiologically biased to empathically sense the emotional state of others. Even in newborn infants this ability is evident. When one baby cries in the nursery a contagion effect results and soon all will be crying. The limbic regions in the brain detect the emotional states of others and mobilize actions and intentions that are congruent. This is why we can laugh with another and why we feel sad when someone else is crying. Further, as we respond emotionally, our interoceptive awareness activates visceral sensations. We can feel light-hearted or sick to our stomach when we experience emotional states. The insula, a region situated between the prefrontal cortex, the limbic system, and other subcortical regions, integrates emotional, motor and somatic signals allowing us the capacity to fully feel what is happening around us. Our body schemas blend with our interoceptive and emotional sensations and they all give us appropriate feedback so that we can engage effectively. These felt exchanges occur between dancers and between dancers and their audiences.

Our brains are wired so that we can effectively interact with our environment. Dance, as an activity and as an art form, engages these social neurobiological systems. For the dance creator these complex neurobiological processes are embedded within the tapestry of the creative imagination. Howard Gardner suggested that dance artists may have greater kinesthetic intelligence. This may be in part because they have

trained and refined their body schema systems, systems that include mirror neurons and interoception. Neurobiological processes that operate during the creative moments of dance are rich resources that are enhanced by training, and heightened by flexible and fluid state shifts that adapt and respond to the demands of the creative moment.

Dance, Creativity, and Research

Dance research falls into several large groupings. The majority is theoretical and qualitative: (a) anthropological studies of world culture and indigenous dance practices; (b) descriptions of historical trends within specific dance genres such as ballet, tap, modern, African, or ballroom; (c) historical-biographical accounts that investigate individuals, how they were influenced by their socio-political environments and how they shaped dance; and (d) critical inquiry studies that analyze the shifting patterns of dance. Although important and rigorous scholarship has been produced, within the historical-biographical genre, a pattern of idealizing and glamorizing dance artists prevails. Despite this tendency many excellent biographical books, such as those written on Serge Diaghilev, Vaslav Nijinsky, Martha Graham, Fred Astaire, or Tatsumi Hijikata, inform the reader of the unique creative gifts inherent in the artist and the specific contributions they made to the field of dance.

More anthropological-based and critical inquiry subjects on dance are included in essays found in dance journals. One of the major journals dedicated to such topics is the *Dance Research Journal*. It offers essays on issues such as transnational migration patterns in the arts, especially theories and methods for understanding patterns of individual and mass human movements across world stages and the social-cultural experiences that such movement migrations engender. In this journal topics are examined with great care and detail. For example, writings suggest that the effects of human migration on dance in particular, and the arts in general, help researchers investigate issues such as citizenship and statelessness, labor refugeeism, border wars, religious and political occupations, and environmental displacement. Anthropological fieldwork studies document how dance is integrated into religious and ritual traditions and how these traditions inevitably influence subsequent dance practices. This line of research provides contextual insight into today's urban street dance practices such as hip hop, popping and locking, house dance, capoeira, krumping, and break dancing. Critical studies, a field of study within aesthetics, provide a format to critically investigate new approaches to understand and interpret interdisciplinary dance performances. They claim that collaboration and cross-fertilization between forms of dance, theatre, visual art, film, and technology are growing. Researchers in critical studies suggest that increasing multi-layered performances demand new approaches to critically analyze dance and to frame new works in ways that will enhance awareness, understanding, and enlightenment in audiences, researchers, and performers.

Empirical and anecdotal research in dance therapy presents findings on treatment outcomes such as how dance contributes to (a) elevated mood in geriatric treatment centers, (b) promotes appropriate adolescent emotional expression in juvenile delinquent homes, and (c) augments physical therapy

treatment practices in patients with neurological disorders such as Parkinson's disease and related movement disorders. Scientific dance research investigates the implications of dance training and dance styles on the type, degree, and rate of injuries, as well as the psychological make-up of dancers working in this frequently brief and stressful profession. These investigations also examine the specific biomechanics and motor learning employed during the execution of dance skills. Research topics that remain at the forefront include investigations on the distinction between perfectionism and neurotic perfectionism; denial of pain and exhaustion that frequently cause career ending injuries; and body image and eating disorders, especially in the adolescent dancer who is vulnerable to disruptions in normal hormonal and bone development. Researchers such as Donna Krasnow, Linda Mainwaring, and Gretchen Kerr have demonstrated a clear link between excessive perfectionism and dance injuries and multiple articles address the need for dancers to maintain adequate nutrition to achieve optimal physical and psychological balance. The topic of effectively treating dancers as a population with unique needs and specific treatment approaches is another major focus of investigation. Dance practitioners, dance educators, and dance scientists all share similar concerns regarding the need for trained practitioners in performance psychology and dance medicine. They claim that effective treatments will only be developed with specific understanding about the physical and psychological demands of dance and how dancers respond to treatment interventions as compared to other patient populations.

A topic that has received robust research is the application of imagery and mental practice to improve performance. Consistent findings suggest that elite dance artists tend to use more elaborate images to improve the quality of their performances. When images are effectively used performance improves, in particular, when motivational mastery imagery is employed self-confidence is enhanced. Cognitive-specific imagery significantly predicts the direction of somatic and cognitive anxiety symptoms. According to Eva Monsma and Lynnette Overby, motivation-specific and motivation-general imagery improves performance. They recommend that motivation-general imagery practices should be avoided when linked to cognitive arousal images but not when linked with somatic arousal imagery. Other studies suggest that more elite dancers have more frequent experiences of working with teachers who offer metaphorical images. Although it is unknown whether imagery is the major factor for improving performance these dancers are able to engage in movement with more complexity, control, structure, deliberation, and sensory involvement. Further, findings suggest that dancers tend to be skilled and talented in a range of mental imagery strategies, hence they frequently engage in imagery as part of their training (to avoid overuse injuries) and for healing when injured.

Dance research is a strong international field of study but most dance artists and dance educators have minimal contact with these findings. One area that does have cross-over influence is the popular work on flow states. Findings suggest that dancers actually have more flow experiences in part because they have enhanced autotelic abilities (Greek word meaning something that is an end unto itself); dancers are able to

become absorbed in the present-moment of dancing where autotelic experiences reside. They are also able to maintain an optimal balance between skill level and performance challenge. Achieving flow states is pleasurable and desired and most dancers, whether in professional, spiritual or recreational settings, seek and embrace them.

Research that specifically examines creativity in dance remains scant, although this is gradually changing. One of the challenges in studying creativity is determining the criteria that constitute a creative product and a creative individual. One way to manage this dilemma is to select artists or scientists that have been designated as creative on the basis of their level of achievement and success and then to compare them to individuals who have not worked or trained in these domains and who have not demonstrated any creative productivity. This approach has provided rich information about creative personalities, findings that can be generalized to some degree. What makes dance a challenge to investigate is that it is both an individual and group process. Hence, creativity in dance must be examined through a model that includes individual and contextual factors. Mihaly Csikszentmihalyi and Howard Gardner proposed such a model, an interactive model on creativity, in which three elements or nodes are regarded as central in any consideration of creativity: (1) the individual artist; (2) the domain or discipline in which the individual is working; and (3) the surrounding field that judges the quality of individuals and products. They argue that creativity is best viewed as a dialectical or interactive process in which all three of these elements participate. Keith Sawyer claims that an integration of two approaches, contextualist (sociological, cultural, and historical elements) and individualist (personality, cognitive psychology, biology, and computational approaches) best explains the nature of creativity. Certainly, in the domain of dance, all approaches must be considered in order to acquire a deeper understanding about this art form. Any individual artist, either dancer or choreographer, operates within a dynamic group setting, which includes interactions with their audience. Perhaps because of the communal nature of dance, more contextual writings currently exist, especially in the disciplines of dance history, dance criticism, world-dance, dance computer notation systems, and dance education. Less is known within the individualist approach that examines the dance artist's personality, cognition and biology, although case study and phenomenological papers have attempted to capture the ephemeral nature of dance.

Although more limited in number, many studies do lend greater understanding about the creativity of dance artists and how they are influenced by the environments that surround them. Gregory Feist, a major figure in the creativity research field, noted that dancers, as well as other performing artists, scored significantly higher than control subjects on anxiety, guilt, and hypochondriasis, and that dancers were more achievement-oriented. Jane Piirto suggested that dancers tend to suffer physical injuries and psychological disorders, such as eating disorders, low self-esteem, and self-image distortions and that their personalities were more akin to those of athletes (discipline, high-standards, perfectionism kinesthetic, and emotional intelligence). Paula Thomson, E. B. Keehn, and Thomas Gumpel found that dancers and choreographers were

similar in their level of fantasy proneness, a finding that reinforces the belief that dancers and choreographers are generally cocreators in any new dance work. This research team also found that dancers employed more dissociative absorption states, perhaps as a cognitive and somatic strategy to engage in heightened kinesthetic awareness, and that dance artists had elevated levels of pathological dissociation as compared to nonperforming artists. This finding supports the theory that performing artists are vulnerable to psychological disorders but the research team also found that dancers were significantly better able to tolerate and regulate intense emotions.

The diverse range, scope and volume of research in dance makes it an easy field to gather information but one of the major problems is a lack of integration within and between research fields and a fundamental lack of interest by the actual practitioners working within dance. In order to spread these rich research findings to the dancers and their audiences, research practitioners must explore new ways to engage wider audiences. Perhaps electronic media formats are doing just that. More viewers are now able to see dance and maybe they will read more articles if they are listed as links provided within the websites.

Dance Artists Communicate: Writings and New Media Tools

Despite the fact that dancers remain suspicious of more academic approaches, as a group, they seem to gravitate toward writing about the actual creative process. Maybe because dance is so difficult to capture in words these same artists are drawn to articulate their process in writings or interviews. Further, dance remains frustratingly illusive to capture on camera, in part because the human eye is able to maintain complex focal patterning that far exceeds the limited range of the camera lens and editing choices. Perhaps dancers write about their process as a way to preserve the meaning, significance, and beauty of their works – dances that may have been seen by only a small audience during a brief performance season. Regardless of the intent, what is striking and inspiring is the magnitude of writing on this topic and the force of these accounts. Writings by dance artists such as Martha Graham (*Blood Memory*), Doris Humphrey (*An Artist First*), and Paul Taylor (*Private Domain*) provide insight into the brilliant creativity of dancers. Dancers write about their professional experiences including the technical training regimes that were practiced; dance educators provide books on pedagogical concepts for effectively training young dancers in school and community settings; dance therapists recount effective treatment practices for specific patient populations; and dance specialists offer books on specific genres such as flamenco, folk dance, ballroom dance, classical ballet, or Kathak dances of India. Dancers also write about their struggles as they transition from a career in dance to a new profession. Whether as a result of injury or age, the inevitable transition from dance is a topic that is shared through personal memoirs and interviews. Yes, dance is a nonverbal art form but much has been written on this topic and certainly more will be generated.

With technological advancements most of these works will include DVD documentaries to support the written texts. Electronic media carriers are offering even more documentation about the creative process in dance and the personal journeys of dance artists.

Conclusion

Dancers love to dance and they display this passion early in development. As young children they respond kinesthetically; they move when music is played and they express their emotions through movement. This desire to move, and to move within a rhythmic pattern, is one of the intrinsic motivating factors that drew them to dance. As Twyla Tharp stated, dance is a habit. Dancers embrace the demands of daily classes, long rehearsals, and public performances. Although their careers tend to be short they self-identify as dancers long after they have left the profession. For those who never had the opportunity to formally study dance, their intrinsic desire to dance can be seen whenever an opportunity presents itself. Family celebrations, cultural events, and clubs are all places and times where dance can be experienced. Dancers relish the kinesthetic pleasure of expressing ideas through movement. Dance, whether performed in clubs, streets, studios, film sets, or theatres, is a dynamic and immediate form of expression. It lives in the present moment of the embodied dancer and is viscerally experienced by the viewer. A preeminent choreographer and dance artist, Martha Graham, claimed that dancers offer a blood memory, an archetypal presence that far exceeds any single dancer. Since dance and creativity are intrinsically tied to embodied expression the dance artist must give kinesthetic life to any creative idea. The process, according to Martha Graham, is a blessed unrest that keeps dancers moving and exploring. This kinesthetic manifestation of the creative imagination is demanding and compelling.

Dance is regarded as an ephemeral art form; it exists within the present moment and then disappears, but the immediacy of expression is palpable and tangible. Dance was present at the dawn of civilization and remains today. Regardless of political upheaval, religious persecution, or social restriction, dance endures and prevails. The impulse to give expression and find meaning through movement is a fundamental human response that persists – this is where dance lives.

Glossary

Aesthetic Creativity Creativity in which the focus is primarily on the generation of novelty.

Benevolent Creativity Creativity intended to result in positive and/or self-actualizing outcomes.

Disruptive Innovation The exploitation of unprecedented, effective, and novel ideas.

Functional Creativity Creativity in which the primary concern is the generation of effective, useful novelty.

Incremental Innovation The exploitation of relatively small, but effective and novel, changes to existing artefacts.

Malevolent Creativity Creativity intended to result in deliberate harm or damage of others.

Negative Creativity Bad or undesirable outcomes resulting from creative processes.

Positive Creativity Good and desirable outcomes resulting from creative processes.

Introduction

In psychological research Mel Rhodes introduced the four Ps approach to creativity, looking at it from the point of view of Person, Product, Process, and Press (environmental support). Typically, discussions have regarded all four facets of creativity in a positive light. For instance in the case of Person creativity is typically associated with positive properties of the individual such as openness, courage, or high ego strength, and with favourable psychological development such as achievement of a high level of self-actualization, personal fulfilment, or improved mental health. The creative Process involves procedures like seeing the known in a new light, combining the disparate, producing multiple answers, shifting perspective, transforming the known, generating alternative or multiple solutions, initiating new lines of attack, giving surprising answers, or opening up new possibilities, all thought to be highly beneficial for achieving peace and prosperity at both local and global level. Where outcomes (Product) were discussed, the main interest was usually in artistic, literary, musical or other aesthetic products, in discoveries in science or medicine or in innovations in technology, manufacturing, or business systems. All of these are usually regarded as inherently good.

The essence of creativity is going against the crowd. In the case of Person this involves "creating" an individual self and a unique identity. This process is also at the core of normal personality development, which can thus itself be seen as a creative process. However, as James Averill has pointed out, at some point, in some cases, the process can go awry. The positive, desirable "creation" of a unique personality can cross the line and become pathological or antisocial, manifesting itself in, for instance, personal maladjustment and neurosis, or in crime. Various writers such as Nancy Andreasen and David Schulberg have demonstrated the existence of a link between creativity and both mood disturbance and also cognitive disorders. In a recent review, Dean Keith Simonton examined this relationship and concluded that there is some truth to the idea that creativity is connected with mental illness. However, there is no simple, linear causal relationship.

While it is true that processes such as combining the disparate may in themselves be neither good nor evil, it is clear that

under certain circumstances these processes, usually referred to as "divergent," can have a dark side. In the school classroom, to take a single example, they have the potential to lead to disruption of order and to introduce intolerable levels of uncertainty. A striking example is that of the French mathematician, Evariste Galois, who was expelled from secondary school despite being a brilliant and, as is now known, highly creative mathematics student who was keenly interested in learning and greatly admired his mathematics teacher. He was simply too disruptive to be tolerated. In business or industry too, divergence can go too far, for example, if a new product or process is simply too divergent for customers and consumers to accept. Clayton Christensen points out that disruptive technologies – in other words, those that embody high degrees of divergence – can actually prove fatal, even, or perhaps, especially to well-managed, mature companies. The Sinclair C5 electric vehicle, launched in the United Kingdom in January 1985, embodied many novel ideas, including technological breakthroughs in motor design, aerodynamic performance, chassis and body design, and also anticipated a move to hybrid vehicles, and yet led to the bankruptcy of Sinclair Vehicles less than one year after launch, due to poor sales volume. Similarly the famous DeLorean DMC12, launched in 1981, exemplified divergence in automobile design, with novel materials, body and chassis design, industry-leading use of electronic fuel injection and advanced safety features, but, like the Sinclair C5, sales were poor and the company folded in 1983.

More recently, some writers have turned their attention to Product, the results of creativity, rather than the processes or the personal properties that foster the processes. Such products include aesthetic creations such as artworks or literary or musical compositions, but they also encompass structures, machines and devices, production, distribution or marketing techniques, and complex systems. It does not require much effort, however, to see that creativity – in the sense of the generation of effective, or useful, novelty, whether aesthetic or concretely useful – can also be used for purposes that, to some people at least, might be considered undesirable, for instance to obtain undeserved benefits, discomfort or harm other people, or get away with crimes, that is, the outcomes (products) of creativity can also have a dark side.

This dark side of creativity is found in a wide variety of domains, some obvious, and some less so. In the fields of advertising, marketing, politics, technology, agriculture, entertainment, literature, and even art, it is possible to identify manifestations of the dark side of creativity. For example, creative advertising campaigns encouraged people to smoke cigarettes despite the adverse health effects of smoking. In Australia, agricultural innovations that have facilitated the development of highly efficient and intensive farming in areas lacking in sufficient natural rainfall have also now led to the breakdown of the country's Murray–Darling river system. The impact of irrigation, drawing water out of the river system in upstream parts of the country, has resulted in excessive salinity, acidification of soil, and toxic algal blooms in downstream regions that may yet result in the complete breakdown of the ecosystem in these areas. The beneficial effects of creative approaches to irrigation in some areas are driving farmers off the land in other areas and literally rendering some farmland unusable.

Defining Creativity: Novelty and Usefulness

If one accepts the widely used definitions of creativity (see elsewhere in this volume) that regard novelty and usefulness as its core criteria, then one must first ask the question: "Useful for what and for whom?" The term implies that creativity is undertaken with some particular purpose in mind. This purpose is often captured through the idea of problem-solving. Indeed "creative problem-solving" is a common phrase and is associated with the application of techniques for the generation of novel ideas. Well known examples of these include *Brainstorming* devised by Alex Osborn in the early 1950s and *Synectics*, formulated by William Gordon in the same decade. The problems that people seek to solve through the application of these techniques and methods may be conceptualized more generally as *needs*. In a conventional sense the need might, for example, be that of a motorist for a more economical automobile, or the need of a doctor for a means to "see" inside a patient's body. The solutions to these needs, in the former case an electronic fuel-injector, and in the latter case a Magnetic Resonance Imaging (MRI) machine, would, when first introduced, have been seen as novel – that is to say original and new – and continue to be seen as useful and/or effective in addressing the need today.

Creativity and Business

It is also a widely held belief nowadays that creativity, along with its offspring innovation, is an essential ingredient of competitive businesses. Whether this innovation takes the form of small improvements to what already exists (typically referred to as *incremental innovation*) or of radical changes to the *status quo* (usually called *disruptive innovation*) there can be no doubt that recognizing and responding to the needs of customers, in the sense of solving their problems through the generation of effective, novel solutions, is a key activity for businesses. Those organizations that are good at this activity prosper, while those that are not may stagnate or perish. In 2002, the *Economist Technology Quarterly* reinforced this fact by

pointing out that, at the turn of the twenty-first century, more than half of economic growth is accounted for by creative products. Paul Pilzer has described the concept of *economic alchemy* whereby novel technologies continue to override the limitations of finite resources. Creativity and innovation in the automotive industry continue to improve the fuel efficiency of automobiles, for example, and in so doing reduce dependence on oil. This has the effect of extending the life of that finite resource. Pilzer argues that humans are not constrained by finite resources, provided that technological creativity and innovation continue to drive businesses.

Creativity and Competition

Does this competitive model apply only to businesses? "Competition" can be conceived of more broadly by recognizing that opposing armies, for example, are engaged in a form of competition. Similarly, opposing sporting teams are competing in a more readily recognizable way. It is also possible to think of doctors as competing with diseases, in this case for the health of people, or even law enforcement agencies as competing with criminals.

These latter examples, however, open up a somewhat different perspective on creativity and competition. To understand this it is necessary to return to the notion that creativity embodies novelty and usefulness. It is easy to see, in a business context – for example, two rival manufacturers competing to sell washing machines – that usefulness means the same thing for both parties. Usefulness is about providing customers with clean clothes. It is about performing a function. If a novel idea, for example, using an electric motor to agitate a container full of clothes, rather than manual labor, is also useful (in this case the task is performed more effectively by a motor than by a human) then this creative idea is both new and useful and offers a competitive advantage. Both rival manufacturers wish to provide their customers with a machine that helps in the process of washing clothing, and both seek to do this effectively, efficiently, and at an affordable cost. The one that can do so *most* efficiently, and *most* effectively, and at the *lowest* cost, will typically capture the lion's share of the market.

Competition in a Broader Sense

What about the case of a law enforcement agency *competing* with criminals? In this case the competition is of a fundamentally different nature. One party, the police, is seeking to do something that most people would have no hesitation in categorizing as laudable, desirable, and good, while the other party, the criminals, is seeking to do something that most would regard as undesirable, or indeed, illegal and overtly bad. In this example it is now no longer the case that the two competitors share the same basic, benevolent objective (i.e., to satisfy a customer need). Rather, one competitor is doing something regarded as good, or benevolent, while the other is doing something bad, or malevolent. Whether this latter example is labelled "negative" creativity, in contrast to the positive, benevolent creativity embodied in the example of the competing businesses, or "malevolent" creativity, one

must examine and seek to understand what it is that makes the process and the outcomes of some creative activity desirable and good, of other kinds of activity bad.

A Dark Side to Creativity

A good starting point is to return to the key criteria of creativity – novelty and usefulness. Novelty presents fewer problems. It is widely agreed that novelty captures the notion that something is original and new. More colloquially it might be said that a novel solution to a problem has “never been seen before”, in contrast to a solution that is already well-known. This is not to say that an established solution is not desirable. One may speak of *routine* solutions, whose primary criterion is that they are effective – they solve the problem – even if they lack novelty. Creative solutions, namely those that are both novel and effective, may elicit a reaction of surprise from an observer. “Why didn’t I think of that!” or “What a neat idea!” are phrases that are often heard in response to creative – that is surprising and effective – solutions.

Effectiveness, or usefulness, however presents a moral dilemma that manifests itself in some of the examples cited earlier. If one moves from the idea of rival businesses competing with each other to meet a customer need, and returns to the idea of law enforcement agencies *competing with* criminals, or even security forces competing with terrorists, the problem is more obvious. While it might casually be said that “most people” would regard the idea of hijacking a plane and crashing it into a building as bad, if not overtly evil, and therefore not at all useful or effective, it cannot be denied that there are some people who would see this situation differently. There is no doubt that the 9/11 hijackers believed that what they were doing served some noble purpose, and that, in the light of what actually happened, it was highly useful and effective. That their method of attack on that day was also, by definition, surprising and therefore highly novel – commercial airliners had not previously been hijacked and crashed into buildings – is not in question.

Similarly, the conman who devises a new method for defrauding an organization, or the thief who finds a new way to defeat a security system, may develop solutions that exhibit high degrees of novelty, and presumably they do these things because they solve a problem that the criminal has – in this case, the desire to obtain more money.

This leads to a situation in which it seems that the current lexicon of creativity is not fully equipped to describe these situations, and that the lack of a term to classify these cases – where the goal of the creative process is to achieve harmful, illegal, or immoral ends – hinders one’s ability to analyze them and take action against them. This is one aspect of the Dark Side of creativity – the use of creativity deliberately to damage or harm others.

Characterizing the Dark Side of Creativity

Two pairs of concepts have already been articulated in the field of creativity and help make sense of this dark side of creativity. Keith James and his colleagues Karla Clark and Russell Cropanzano have been using the term *negative creativity*, in

contrast to *positive creativity*, to describe the undesirable, or indeed harmful, consequences of creativity since the late 1990s. These terms provide a more general classification of creativity with respect to the nature of the outcome, or product. Good products and outcomes, in other words those that are beneficial and affirming, are labeled “positive.” Those that are undesirable, harmful and/or damaging are negative.

A more differentiated classification of product and outcome is yielded by the pair of terms *malevolent* and *benevolent* creativity. Coming into use more recently than *positive* and *negative* creativity, these terms provide a secondary, more explicit and more precise level of classification. In contrast to negative creativity, the critical factor that differentiates malevolent creativity from negative creativity is the *intent* of the actor. Malevolent creativity *must* involve not only a harmful or damaging outcome or product, but also a *deliberate intent* to cause harm or damage. Negative creativity, by way of contrast, may feature no deliberate intent. In the case of negative creativity, the harmful or damaging outcomes may be merely an unfortunate by-product that results in unintended consequences such as the discovery of microorganisms leading to germ warfare. Benevolent creativity, in comparison to positive creativity, involves both a positive outcome and positive intent.

The Many Faces of the Dark Side of Creativity

Negative Creativity

At least two factors can therefore be said to contribute to the dark side of creativity. The first is the product or outcome of the activity. This is typically the generation of an effective or useful, novel solution to a problem. The second is the intent of the actor – that is, the individual, or possibly the organization, generating the effective novelty.

Robert McLaren’s seminal work on the dark side of creativity contains many instructive examples of negative products and outcomes that may be differentiated from malevolent creativity through the absence of intent. It seems unlikely that medieval clergy, for example, set out to impoverish the laity by commissioning elaborately decorated, expensive, and undoubtedly artistically creative, cathedrals. And yet there is no denying that the money and resources lavished on these religious monuments might, as McLaren points out, instead have been used to satisfy more earthly needs. Thus the products of artistic creativity embodied in these structures were, as McLaren describes them “merely aesthetic exercises in self-indulgence,” and although they constitute an example of negative creativity, since they harmed many people, they cannot be regarded as malevolent. **Table 1** identifies the primary differentiator for the dark side of creativity. In straightforward terms, bad outcomes/products arising from the process of generation of effective

Table 1 Negative–positive creativity and product

<i>Product/outcome</i>	<i>Primary label</i>
Bad	Negative
Good	Positive

novelty are labeled “negative creativity” and good outcomes/products are labeled “positive creativity.”

The changes, cited by McLaren, to the way that the function of art was perceived, during the age of Enlightenment and beyond, also help distinguish between different aspects of the dark side of creativity. Whether art, as a form of creativity, becomes “a substitute for reality,” or a rival “to faith,” or indeed that it leads “nowhere except to the aggrandizement of the isolated artist and his will” these arguably negative outcomes are difficult to see as intentionally damaging or harmful. The dark side of creativity thus manifests itself again as an undesirable or bad outcome/product, but not one that is malevolent. The preceding example also once again highlights a difficulty posed by the dark side of creativity – namely, how to decide what is bad and what is good. Some might see artistic works that call religious faith into question as liberating and progressive, in the same way that some see acts of terror as vital steps on the path to freedom.

Technology is also not free of examples of the dark side of creativity. Deborah Cadbury described examples of technological and scientific creativity that gave rise to an explosion of new products, processes, systems, and services from the late eighteenth century onwards. The changes wrought by the industrial revolution, however, created as many problems as they solved. The advent of steam locomotion, for example, resulted in the need to build tunnels to facilitate the development of rail networks. Often these tunnels were pressurized during construction to prevent flooding. This elegant solution – tunnellers could continue to work unaffected by water leaking into the works – resulted in the cases of the “bends.” A similar problem occurred in the construction of the foundation of large bridges which used pressurized caissons to allow workers to dig foundations and pour concrete on the beds of rivers. When workers finished their shifts and returned to the external environment they began to suffer the effects of nitrogen bubbles released in their bloodstream. It took some years and a number of deaths before the problem was understood and a solution found. Once again, it is impossible to ascribe any evil intent to the engineers who devised the creative procedure of using pressurized air to facilitate this kind of work. Their solution to the problem of digging bridge foundations and tunnels was both effective and novel, and yet it also resulted in a harmful outcome. It was negative, at least with regard to the health of the workers, but it was not malevolent.

Malevolent Creativity

Introducing the concept of malevolent and benevolent creativity expands the available classifications of creativity, including those representative of the dark side, from two categories to four. This serves a purpose that is more than merely technical. In particular it makes it possible to turn attention from the output of the creative process or activity to its *inputs*, and indeed, to the process itself. **Table 2** adds the *intent* of the actor in the creative process, to the nature of the product or outcome of **Table 1**. This permits more precise differentiation than is possible when using the labels “positive” and “negative.” When a creative process, for example, the development of a novel form of terrorist attack (like the attacks on 9/11 previously mentioned), results in an outcome that is undeniably negative, it

Table 2 Outcome and intent – malevolent creativity

<i>Product/outcome</i>	<i>Intent</i>	<i>Secondary label</i>
Bad	Malevolent	Conscious malevolence
Good	Malevolent	Failed malevolence
Bad	Benevolent	Failed benevolence
Good	Benevolent	Conscious benevolence

can now be further examined and an attempt made to understand the intent of the actor(s). Where the intent is deliberately to cause harm to others, as was the case on 9/11, the label “negative” creativity is replaced with *consciously malevolent creativity*. The terrorists in question set out to create a novel “solution” to their problem that would, if successful (i.e., effective and useful), undeniably and without any shadow of doubt, result in the deaths of many innocent people and the widespread destruction of property. This negative outcome was not the result of an accidental set of circumstances, nor was it an unfortunate by-product of some other activity, both of which might cause us to label it as *failed benevolence* (good intent, bad outcome). Because it was both novel and effective, it was creative, and because of the nature of the intent it was not merely negative creativity, but *consciously malevolent creativity*.

Similarly, when benevolent intent results in a positive outcome or product, then the label positive creativity is replaced with *consciously benevolent creativity*. However, addition of the factor *intent* also now acknowledges the possibility that malevolent intent may, serendipitously, result in a positive outcome. In this latter case one can now use the label *failed malevolence*. In other words, in comparison to **Table 1**, there are two possible situations in which the result is positive, and two possible cases where the result is negative. **Table 2** allows us to express these cases with greater precision.

Table 2 illustrates the value to be gained in the more differentiated understanding that results from an analysis of the dark side of creativity. At a primary level, negative creativity recognizes that the product of the creative process *may be* bad. Thus the invention of the internal combustion engine, leading as it has to pollution and many deaths in automobile accidents (and notwithstanding the many positive aspects that have also resulted from its invention and that of the automobile), is an example of negative creativity, but not malevolent creativity. It seems certain that Karl Benz, who designed and built the first four-stroke engine, did not do so with the intent of polluting the environment or killing people. Indeed, it is almost certain that he envisioned only positive outcomes for society, including massive improvements to economic prosperity, mobility, and development. In a more differentiated analysis, an appropriate secondary label for this invention, at least with respect to the polluting/safety aspects of the engine, would be *failed benevolence*. The negative aspects of the invention are unintended, and unforeseen, consequences of the primary problem which the device was created to solve.

The Four Ps of Creativity and the Dark Side

The addition of the factor intent has enriched the understanding of the dark side of creativity. Negative outcomes may be

deliberate, but they may also happen, as it were, accidentally. The literature of creativity, however, points to other factors that could enhance this understanding further, and lead to a more highly differentiated model of creativity. The traditional model of creativity in psychology is the 4Ps approach: The social/psychological factors involved in creativity are the Person, the Process, the Product, and the influence of the surrounding environment (the Press). These factors were originally proposed by Mel Rhodes in the 1960s. Although Person covers a range of factors including motivation, feelings, and other personal properties, such as willingness to take risks, it is sufficient for present purposes to use this factor to address intent. The factor Product is what has already been labeled under the same name, or alternatively the outcome. If Process and Press are now added to the table of factors leading to creativity, the categorizations available grows from four (Table 2) to eight (Table 3).

For the purpose of differentiating the dark side more precisely, I will treat Process and Press together as representative of those factors that influence what happens between the formation of intent, and the realization of the end product. These will be categorized again using two poles. Either the Process and Press act to *support* the activity for which a useful, novel product is the output, or they act to *undermine* it. The former will be labelled *supportive*, and the latter *obstructive*.

Table 3 introduces four new categorizations that are distinct from those discussed in the previous section. In Table 2, on the dark side of the creativity ledger, *conscious malevolence* and *failed benevolence* arise where the outcome, or product, is negative, but where the intent is, respectively, malevolent and benevolent. In Table 3, the addition of Process/Press now distinguishes between creative activities that take place in circumstances that are either supportive of the intent, or that attempt to act against the intent.

Thus, while intent may be malevolent, and a negative outcome may result, one can conceive of two pathways to this result. One arises from a situation where both the Process and the Press act in concert with the intent, whereas the other arises from a situation where Process and Press act in opposition to the intent. Put more plainly, malevolent intent that achieves a negative outcome *in spite of* the process and press is *resilient malevolence*, in contrast to *conscious malevolence* that succeeds *because of* the process and press. The terrorist attacks on 9/11 again assist us in understanding the different forms of the dark side of creativity. It can be argued that the hijackers of the aircraft involved in the Twin Towers attacks, and the Pentagon attack, succeeded *in spite of* an *obstructive* press. In other words, the normal security measures that were part of the

environment in which those attacks were made failed to prevent them. The creativity of the attacks was therefore not only intentionally harmful, but it was resilient enough not to be deterred. It is interesting, however, to note that the attack on United Airlines Flight 93 did not possess the same resilience. It may be argued that the reason for this “failure” of the terrorist attack was that it was no longer novel (and therefore no longer creative to the same degree as the other attacks). There is evidence from phone conversations with some of the UA93 passengers that they were aware of the other attacks that had taken place. This means that the novelty of the attack on UA93 was already different, and lower, than that on the other flights. The starkly different reaction of the UA93 passengers to the hijacking was almost certainly a direct consequence of this decline in novelty. In other words, they were not taken by surprise in the way that the passengers on the other flights seem to have been. When the passengers on UA93 fought back, this obstructive environment turned the resilient malevolence of the terrorist attack into *frustrated* malevolence. In this case, one has to admit that there is a degree of relativity in this discussion. The terrorist attack was still successful, particularly for the people on board the flight, but it was clearly not nearly as successful as is generally believed was the intent. Thanks to the bravery of the people on board, the UA93 attack did not succeed to the degree that it might have.

The discoveries of Jenner and Pasteur in the field of immunology can be used to illustrate different combinations of Product, Person, Process, and Press. There is no doubt that both scientists set out with the intention of treating harmful diseases and alleviating illness and suffering. In both cases they developed “products” consistent with their intent. Thus the intent was unequivocally benevolent, and the product good. If undertaking these activities in an environment that supported their goals, and using a process that positively aided in their achievement, then we can label the outcome as *conscious benevolence*. Even if the process and/or press was obstructive in some way, for example, they may have struggled to obtain financial support, or they may have been undermined by jealous competitors, the positive outcome and good intent simply means that the resulting benevolent creativity was *resilient* and able to succeed in spite of some adverse factors.

The same example, however, can also be used to illustrate a combination of factors leading to negative outcomes. Maria Zaitseva writes about the activities of scientists in the Soviet Union who participated in the development of biological weapons. She argues that some of the scientists may have deliberately blinded themselves to the dark side of their

Table 3 Product, Person, Process, and Press – types of malevolent creativity

<i>Product</i>	<i>Person (intent)</i>	<i>Process/Press</i>	<i>Secondary label</i>
Bad	Malevolent	Supportive	Conscious Malevolence
Good	Malevolent	Supportive	Failed Malevolence
Bad	Benevolent	Supportive	Failed Benevolence
Good	Benevolent	Supportive	Conscious Benevolence
Bad	Malevolent	Obstructive	Resilient Malevolence
Good	Malevolent	Obstructive	Frustrated Malevolence
Bad	Benevolent	Obstructive	Frustrated Benevolence
Good	Benevolent	Obstructive	Resilient Benevolence

work, either through a fascination with their work, or as a result of unquestioning political obedience, or even through deliberate deception or coercion by the state. Thus, under the right set of deceptive and coercive circumstances, the same apparent positive intent and supportive environment, instead of leading to cures, could lead to harmful biological weapons, changing *conscious* benevolence to either *failed* or *frustrated benevolence*.

Dealing with the Dark Side

The latter examples pave the way for a final question. That question is “so what”? Why is it necessary, important and/or useful to develop a more precise, more highly differentiated model of the dark side of creativity? Is it not sufficient to recognize that creativity – the generation of effective or useful novelty – can sometimes lead to bad outcomes? There are two answers to these questions. First, it is entirely consistent with the progress of science to seek to understand a phenomenon in progressively greater detail. The contrast between negative and positive creativity opens our eyes to the fact that creativity does not have to be only about beneficial, desirable self-actualization. Creativity is an ingredient of competitive success, and it does not have to be confined only to those activities that are inherently good.

Second, the more precise, and more highly differentiated, the model of the dark side of creativity, the more likely one is to find ways to counteract it. In the same way that the positive aspects of creativity are highly valued, for example, in business – a great deal of time and effort is spent trying to enhance the creativity of individuals and organizations – one needs to invest time and effort in learning how to minimize the impact of the dark side. Whether this is used to prevent terrorist attacks, or to prevent criminal acts, or simply to guard against the accidental negative consequences of a new technology, a detailed model is the first step in equipping society to deal with the dark side of creativity.

The three factors that characterize the dark side of creativity – Product, Person, and Process/Press – allow researchers to formulate approaches to counteracting the dark side of creativity. The example of the 9/11 attacks highlights the potentially disruptive impact that an obstructive Press can play with regard to frustrating malevolent creativity. By the same token, strategies that attempt to disrupt the Person (including their intent) or the Process may offer opportunities to turn a negative outcome into a positive one.

Concluding Remarks

The concept of a dark side to creativity, at least explicitly stated, is fairly new. It arises when attention is turned from studies of creativity based on outcome measures that focus on positive ideas, solutions, products, and outcomes, to outcome measures that focus on negatives. Acts of terrorism, as well as fraud, theft, and deceit bring into focus the fact that creativity is by no means limited to the production of useful or effective novelty for universally positive purposes. James et al. resolve the qualitative dilemma this poses by recognizing that while

the decision of what is good or bad requires a subjective judgment, where a creative product achieves an outcome that is good for some, but bad for many, it is not unreasonable to label this as negative. Negative outcomes, or products in a general sense, that result from creativity give us the starting point for studying the dark side of creativity. If one adds to that the *intent* of the actor then it is possible to differentiate more precisely on the nature and kind of dark side creativity involved. Once other social and psychological factors are added to this model – simplistically the Person and the Press – then additional categorizations of the dark side of creativity are possible.

Thus the dark side of creativity is first characterized by the nature of the outcome. Bad outcomes, at least those that are bad for the majority, resulting from the generation of effective or useful novelty give rise to negative creativity. If the nature of the intent of the actor is added to the model, then one may speak of malevolent creativity resulting from intentionally harmful effective novelty. Where the intent was positive, but the outcome was negative, one can now distinguish creativity that is unintentionally (or perhaps accidentally) malevolent and call this failed benevolence. If one adds a dimension to capture the nature of the process and press that support the generation of effective novelty, then one arrives at the most differentiated model of the dark side of creativity. In this case a supportive environment reinforces the deliberate production of harmful, effective novelty. There may be cases, however, where intentionally harmful effective novelty succeeds in spite of attempts to frustrate it. In this obstructive environment, one may speak of resilient malevolence.

Thus creativity has two basic sides – the bright and the dark. The three dimensions discussed result in eight specific manifestations of creativity. Four of these can lead to negative, undesirable and/or harmful outcomes and give us the dark side of creativity. Each of these four instances of the dark side, however, occurs through a different combination of factors, meaning that some of the negative outcomes are deliberate and some are accidental. Understanding these four faces of the dark side of creativity offers insight into how these negative consequences of the generation of effective novelty might be overcome.

CHARLES DARWIN was an English naturalist who proposed the theory of natural selection to explain the evolution of life on earth. Darwin constructed this theory in a series of notebooks that he kept during the 2 years following the nearly 5-year circumnavigation of the globe aboard H.M.S. Beagle. Although he had his basic insight into the mechanism of natural selection in 1838, 20 years passed before his theory of evolution was made public. In 1859, Darwin published *On the Origin of Species*. Though Darwin did not explicitly state in *Origin* that humans had evolved in the same manner as all life on earth, the implication was clear. This aspect of the book sparked lively debate in scientific, cultural, and religious circles as it challenged traditional views on the nature of humanity. In 1871, Darwin explicitly discussed his views on human evolution in *Descent of Man*, further fueling the controversy. In addition to the pivotal role Darwin played in the establishment of evolutionary theory, he also made substantial contributions to the fields of geology, zoology, psychology, botany, ecology, and other related fields in natural history. More than a century after his death, Darwin's ideas remain central to the biological and social sciences and continue to energize debates about human nature in cultural and religious contexts. Charles Darwin was born on February 12, 1809, in Shrewsbury, England, the fifth of six children. Charles' paternal grandfather was Erasmus Darwin, a highly regarded physician, a poet, a proponent of evolution, and a founder of the Birmingham Lunar Society, which brought together some of the most original thinkers in science and technology of the time. Charles' maternal grandfather was Josiah Wedgwood, a successful entrepreneur and innovator in ceramics technology, and a member of the Lunar Society. Charles' father, Robert Waring Darwin, was a well-respected physician in the Shrewsbury area and his mother, Susannah Wedgwood, was an intelligent woman and a knowledgeable pigeon fancier. Charles was baptized in the Anglican faith despite the tradition of free-thinking agnosticism in the Darwin line and Unitarianism in the Wedgwood line.

Charles Darwin.

Childhood and Early Adolescence: Discovering the Wonders of Natural History

The life of Charles Darwin supports a concept of creativity in which hard work plays the central role, not some special type of thinking such as divergent or primary process thinking. Interests that arose as hobbies in childhood and adolescence were gradually extended and refined to become the work of science in adulthood. As Howard Gruber has written, Darwin is best understood as an evolving system. Darwin had to organize and reorganize his knowledge, his purposes, and his emotions in such a manner as to enable him to carry on work over a long period of time. This period of long work was necessary for Darwin to construct a new point of view about nature, which was his great accomplishment. Darwin was not a child prodigy. He seems to have been a typical boy of his age, well placed by geography, social fashions, and social standing to acquire an interest in the natural world of plants, fish, birds, insects, and rocks. As a young boy, Charles' education took place at home. At age 8 he was sent to a day school. Charles' mother died when he was 8 years old. This loss has been used by psychoanalytically oriented writers to explain Charles' creativity. They propose that Charles was motivated to search for order in nature the rest of his life in response to this abrupt change in the domestic order. While no doubt a tragic event, Charles' everyday routine may not have significantly changed as a result of his mother's death. Through a combination of conventions of Charles' social class and Susannah's frequent illnesses, Charles had relatively little direct contact with his mother. Upon her death, Charles' three older sisters took charge of running the household and caring for the three younger children. Stability was also underpinned by staff members and a nanny named Nancy who were part of the household staff for years before and after Susannah's death. Charles' father, a gentle man, became rigid, depressed, and overbearing at times following his wife's death. Though a certain measure of tension existed in their relationship until Charles established himself in adulthood, Charles greatly loved and admired his father. Charles' formal education continued in 1818 at the Shrewsbury School. The education at this school was classical—study of Greek and Latin, some ancient geography and history, Shakespeare, and an emphasis on memorization, making up verses, and recitation. In his *Autobiography* Charles wrote of this school, "The school as a means of education to me was simply a blank." This statement is typical of Charles' attitude toward learning in the classroom throughout his years of schooling. Outside the classroom Charles showed zeal in pursuing his hobbies. He became an avid collector of minerals and insects, an enthusiastic birdwatcher and hunter

of birds, and an accomplished horseman. During this time, Charles also gained an appreciation for experimental science. With brother Erasmus in a homemade laboratory, the two conducted chemical experiments. This activity earned him the nickname “Gas” at school.

At age 16, Charles went to Edinburgh University where he joined his brother in the study of medicine. Charles largely dismissed the value of his classes at Edinburgh, although a course he took with Professor Robert Jameson taught him skills in how to collect, preserve, and transport specimens and provided him with field experience in geology. Charles also had access to the very fine natural history collection at the museum in Edinburgh and the university library. Charles spent 2 years in Edinburgh. During the first year, his brother Erasmus was with him. In the first year, Charles witnessed two operations, in the years before general anesthesia, one of which was on a child.

He left the operating room before they were completed and wrote in his *Autobiography* that “the two cases fairly haunted me for many a long year.” Neither Darwin brother was genuinely interested in medicine, but they plumbed the library for books on natural history and walked together to the Firth of Forth, an estuary that was rich with invertebrate fauna. After Erasmus left in March of 1826, Charles continued to walk these beaches, collect specimens, and record them in a pocket diary. He made the acquaintance of other students who had an interest in natural history and met Dr. Robert Grant, a zoologist who would become very influential during Charles’ second year at Edinburgh. Charles began taking taxidermy lessons from a freed slave, John Edmonstone, during this period, and had almost daily contact with him for a period of 2 months. John likely spoke to Charles of his life as a slave in South America and his travels with his master through the South American rain forest, and must have sowed the seeds for Charles’ later desire to travel to exotic places in pursuit of natural history.

Late Adolescence: A Turning Point

Upon his return to Edinburgh in November 1826 without Erasmus to rely on for companionship, Darwin sought the company of other students who shared his interests. Charles immediately joined the Plinian Society, a club for students and faculty interested in natural history. Darwin began accompanying the zoologist Dr. Robert Grant on walks to the Firth of Forth. Charles even went out on trawlers to collect live specimens of marine invertebrates for Dr. Grant, becoming, in effect, a research assistant. Grant became Charles’ first important mentor outside the family. The Plinian Society was the forum for two formative events in Charles’ life that second year in Edinburgh. In March 1827 a student named William Browne presented a paper supporting a thoroughly materialistic view of consciousness and mind as nothing more than the physiological activity of the brain; no spiritual agency needed to be invoked to explain mental phenomena. The minutes of Browne’s talk were stricken from the record. This censorship of a materialist view of life alerted Darwin to the dangers of proposing a materialistic explanation of nature.

At that same meeting, 18-year-old Charles made his first public presentation of discoveries he had made in natural history—that the eggs of one marine invertebrate were capable of locomotion and that the black globules contained in old oyster shells were, in fact, leech eggs. Charles had done the private work of collecting, observing, and analyzing his specimens, and he had reviewed scholarly publications to make sure no one else had made these discoveries. With this presentation, he was for the first time making his work public, a prerequisite for a life in science. Edinburgh provided an environment that nurtured Charles’ real interests in his later teenage years. The importance of the person–environment fit in the later teen years remains an underexamined question in the literature on creative thinking. Cases such as Charles Darwin in Edinburgh and Albert Einstein at Aarau suggest that it is a matter of great importance for the individual in the later teenage years to find an environment in which one can independently pursue one’s own interests in accordance with one’s own style of learning, supported by knowledgeable adults.

Taking stock of Charles as an evolving system as he left Edinburgh, his sense of purpose for a life in science had undergone significant transformation in his 2 years there, as evidenced by his presentation at the Plinian Society. His affect had changed as his love of nature and his love of science coalesced. His knowledge of natural history had been greatly expanded, especially as a result of his interaction with Dr. Grant. He left Edinburgh a very different person from when he first arrived there. In the summer of 1827, Charles and his father agreed that medicine would not be Charles’ career. Instead, Charles would attend Christ’s College at Cambridge University in order to prepare for a career as a clergyman in the Anglican church. Religious zeal was not the motivation on either Darwin’s part. For Robert Darwin, this career path held the prospect of providing respectability and a steady income for his son. For Charles, it held the prospect of a lifestyle he could enjoy. As a country parson he would have ample time for hunting, fishing, and collecting.

Darwin went to Cambridge in January 1828. There, he reconstructed a number of the circumstances that he had found helpful in the pursuit of his real interests in Edinburgh. Creativity requires the construction of a milieu in which sustained learning and work can proceed, and Charles was a good craftsman in this regard. Edinburgh had provided the natural environment and the personal support to engage in the serious study of marine invertebrates, in the form of the Firth of Forth and Dr. Robert Grant. Cambridge provided the natural environment and personal support to engage in the serious study of entomology, in the form of the Cambridge fens and the Reverend John Stevens Henslow, professor of mineralogy and later botany. Darwin formed a very close relationship with the young professor. Beetle collecting became a passion during Charles’ years at Cambridge. As he had employed trawlermen working in the Firth of Forth to collect marine invertebrates, he employed bargemen to collect beetles in the wetlands surrounding Cambridge. Charles continued this pattern of enlisting the help of others in his researches in natural history throughout his lifetime. Having successfully completed his final exams, Darwin accompanied the Cambridge geologist Adam Sedgwick on

a short geological expedition through North Wales, a trip arranged by Henslow. Henslow believed that Charles would greatly benefit from doing fieldwork with Sedgwick. Returning home from Wales at the end of August 1831, Charles read a letter from Henslow informing him that the captain of H.M.S. *Beagle*, Robert FitzRoy, was seeking a well-bred man to serve as a companion and naturalist on a voyage to survey the southern coasts of South America and Tierra del Fuego and then circumnavigate the globe. The voyage was expected to take 2 years and Charles would not receive a salary. Despite his father's initial objection, on December 27, 1831, Charles sailed from Plymouth, England, on a voyage that would last almost 5 years.

The Voyage of the *Beagle*: First Theory

The voyage of the *Beagle* should be viewed as both a remarkable personal journey for Charles Darwin and as one more journey in a tradition now known as the "voyages of discovery." These sailing expeditions were carried out for military, commercial, and scientific purposes, and include the fabled voyages of Captain Cook, the mutiny on the *Bounty*, the efforts to discover whether there was a great southern continent (Antarctica), and the search for a northwest passage from the Atlantic to Pacific through Canada. There was an established role for a naturalist on these journeys.

Darwin was now on his own. Mentors such as Robert Grant and John Henslow had played an important role in the formation of Darwin's views on nature. Deprived of easy and frequent contact with these men, Darwin adopted a new mentor, the geologist Charles Lyell. Darwin would not meet and become personal friends with Lyell until after the *Beagle* voyage, so this mentorship took place not through direct contact but through Lyell's comprehensive, three-volume, roughly 1400-page *Principles of Geology* in which the uniformitarian view of geology was explained. The crux of this point of view was that the geological forces at work in the present, at their current intensities, were the same as those that acted in the past. Lyell rejected the popular notion that great and unique cataclysms in the past could account for the present geological features of the earth. The "gradualism" in this theory—that great changes could occur through a series of small changes that continued and accumulated over long periods of time—had a profound effect on Darwin.

Darwin's letters during the voyage reveal the rapid effect that Lyell's views had on him. The power of the *Beagle* voyage on the formation of Darwin's view of nature stems from the co-occurrence of his absorbing a new point of view at the same time the raw material of nature was being directly experienced. For example, following a devastating earthquake in Chile, Charles assessed the amount of land elevation that had taken place. He found it to be several feet. Darwin saw this effect as supporting Lyell's idea that mountain ranges could be formed by gradual but continual uplift of the land on the order of inches and feet.

After spending over three and a half years in and around the southern portion of South America, the *Beagle* arrived in the Galapagos Islands. While Charles was there, he had no great insight into evolution, but his experiences in these

islands would later inform his thinking on this issue. It was during the three and a half weeks sailing from Tahiti to New Zealand that Charles made his first major creative contribution to science: a theory of coral reef formation. Gruber keenly noted in 1981 that this theory "bears a striking formal resemblance to his later work on organic evolution". It was a thoroughly gradualist theory, based in Lyell's own theory of coral reefs, but it was an improvement on Lyell's theory. Charles was able to explain different types of coral formations (fringing reefs, atolls, and islands) as structures representing different phases of a single gradual process of formation. The gradual accumulation of very small changes, the deposition of coral skeletons, over extremely long time periods created something significant in nature that had not previously existed.

The Fruitful use of Analogy: Conceiving of Natural Selection

The 2-year period following the return of the *Beagle* to England in October of 1836 marked a time of intense and productive work for Charles. By March of 1837 he was convinced that evolution had occurred and provided the best explanation for why there were different species in the natural world. This belief in evolution preceded his understanding of how it might occur and put him at odds with the great majority of scientists at the time, including Charles Lyell.

In July of 1837, Darwin opened the first notebook in what would become a series of notebooks devoted to thinking through a theory of evolution. These notebooks provide one of the best records of creative thinking in process. They show Darwin's assembling of a huge amount of information in natural history, mixing his personal observations with those of others who wrote in this field, comparing his ideas with the largely discarded views of the earlier French evolutionist Jean Baptiste Lamarck, coming to perceive the problem of explaining how species change as uniquely his own problem to solve, and eventually sketching out a series of theories of evolution only to discard them as too deeply flawed. Some of these notebooks were especially devoted to exploring issues that Darwin knew were potentially explosive, issues such as extending the theory of evolution to human beings, thereby accounting for human intellect, existence, and morality through a natural and thoroughly materialistic mechanism without invoking the concept of a Divine origin.

Within this 2-year period, Darwin also presented a paper on how topsoil was created through the action of earthworms eating, digesting, and then excreting castings of fine particles of organic material at the openings of their burrows. The analogy with the coral reef theory is clear—so-called "lowly" organisms could build large and significant features of the surface of the earth through the accumulation of tiny changes over immense periods of time.

An entry in one of the notebooks of this period, the one known as the C notebook, raises an important question for those who wish to understand creativity: What role does meta-cognition play in creative thinking? For Charles Darwin, the answer is that it played a significant role. In thinking about human evolution, Darwin wrote on page 74 of this notebook,

“The believing that monkey would breed (if mankind destroyed) some intellectual being though not MAN,—is as difficult to understand as Lyell’s doctrine of slow movements.” Here is explicit recognition of the analogy between the uniformitarian view of geology and Darwin’s emerging theory of evolution—new things can be created through the slow accumulation of small changes. He then goes on to write on page 75, “This multiplication of little means & bringing the mind to grapple with great effect produced is a most laborious & painful effort of the mind.” Darwin recognized the value of this gradualism as a strategy for problem solving. He had already used it productively in explaining the formation of coral reefs and topsoil, but he implies in this quotation that others may have difficulty in accepting this approach to explaining the natural world.

The culmination of this 2-year period of intense work came on September 28, 1838, when Darwin, writing in the D notebook, had his great insight into the mechanism of natural selection. The context for this insight was Darwin’s reading of Thomas Robert Malthus’ *Essay of Population*. This essay led Darwin to realize that the tendency toward overpopulation in human population that Malthus clearly outlined must also apply to the rest of nature, and that competition and struggle for scarce resources was the inevitable result of this situation. Combined with his understanding of hereditary principles that the traits of parents are likely to be passed to offspring and his crucial move to accept that variation was ubiquitous in nature *without* understanding or having to explain the mechanism that produced this variation (he attributed variation to “chance,” a word indicating his inability to explain the source of variation, not a belief that it was a truly random process), Darwin put it all together. Organisms which by chance had a variation that was adaptive, that is, one that helped in the struggle for scarce resources, would survive and pass this trait to offspring. Over enormous periods of time, the accumulation of these new adaptive traits would result in an organism so different from its ancestor that it would constitute a new species. It is characteristic of Darwin’s style of thought that in the same passage in which this crucial insight occurs, he uses a metaphor to capture the essence of the idea. He compares nature to “a force like a hundred thousand wedges,” some wedges forcing their way into the economy of nature and some wedges being forced out. This metaphor highlights the idea of struggle and extinction. Other metaphors Darwin used at other times include the “tree” image to capture the branching structure of nature and the “entangled bank” metaphor to emphasize the fullness and diversity of nature. Use of metaphor was an important part of Darwin’s creativity. For the next 20 years, Darwin refrained from making his theory public. Much has been written on this delay. Stomach maladies plagued him throughout his lifetime following the voyage of the *Beagle*. Explanations of Darwin’s illness and delay have ranged from psychosomatic causes stemming from fear of the reaction his theory would provoke, to hyperventilation syndrome, to a tropical disorder he picked up while on the *Beagle* voyage, to the felt need to do more work on the theory to solve problems remaining with it and to inoculate it from the criticism it would almost certainly engender. In this 20-year period, Darwin worked assiduously for 8 years to understand and

explain variation in just one group of marine invertebrates, barnacles. He also had major insights into how natural selection could work at the level of the group instead of just at the level of the individual, and how natural selection would lead to the multiplication of species (Darwin’s principle of divergence) since a local environment can support more life-forms if organisms divide resources rather than compete for the same resources.

Darwin’s long public silence on his theory of evolution came to an end in 1858 when he was set into motion by a letter he received from a young naturalist working in the Malay Archipelago, Alfred Russel Wallace. In addition to this common experience of archipelagos, Wallace also had read Malthus. In this communication Wallace outlined a theory of evolution so similar to the one Darwin had worked out over the preceding 20 years that it stunned Darwin. Darwin recognized that he could not simply go ahead and publish his own views after receipt of this letter, but a clever solution was worked out by two friends who knew Darwin’s ideas on evolution, Joseph Hooker and Charles Lyell. Darwin had formed a friendship with Hooker in 1843 and had enlisted his help in gathering information on botanical subjects. The solution consisted of having portions of an essay on natural selection Darwin had written in 1844 and part of a letter Darwin had written to American botanist Asa Gray of Harvard in 1857 explaining his views on evolution read in addition to Wallace’s paper at the July 1, 1858, meeting of the Linnean Society by the society’s secretary.

At the time Darwin received Wallace’s letter, he had completed 10 chapters in a work known as *Natural Selection*, a manuscript of over a quarter of a million words and estimated to be a bit over half completed from what Darwin intended. In light of the absence of any significant reaction to the joint presentation of his and Wallace’s views at the Linnean Society, Darwin saw a need and an opportunity to further explain his views. He set to writing an “abstract” of *Natural Selection* and the result was the approximately 500-page *Origin of Species*, one of the most important publications in the history of science and the work that reveals Darwin as a creative thinker of the first rank.

After *Origin*: Concluding a Creative Life

The publication of *Origin* when Darwin was age 50 was the signal achievement of his career. However, Darwin continued to produce important and innovative scientific books and papers, a striking example of sustained creative output throughout a full adult life. Over the final two decades of his life, Darwin’s most creative work occurred in botany, guided by the principle of natural selection. He wrote books and papers describing remarkable structures and behaviors in plants and brought a genuinely ecological approach to his analyses by focusing on insect–plant interactions. In addition to these botanical works, he published important books on variation in domesticated animals and plants and human evolution, and in the year before his death, a book length treatment of a subject he addressed over 40 years earlier, how earthworms form topsoil, reaffirming the gradualism that had worked

so well for him over his lifetime. Charles Darwin died on April 19, 1882, and was laid to rest 1 week later in Westminster Abbey amid the graves of other great creators in British arts and sciences.

Glossary

Creativity paradox The simultaneous coexistence in creativity of psychological elements that seem logically to be mutually contradictory.

Divergent thinking Thinking that yields original or unexpected ideas (contrast with 'convergent' thinking).

Effective novelty Novelty that successfully achieves some purpose or realizes some end.

Intelligence threshold An IQ score beyond which creativity is thought to become independent of intelligence.

Malevolent creativity Creativity that deliberately seeks to do harm.

Moral creativity Creativity that serves the common good.

Negative creativity Creativity leading to bad ends, whether intentionally or not.

Phases of creativity Stages in the production of a creative product.

Pseudocreativity Stereotypical behavior that is thought to involve creativity, although it does not (contrast with 'genuine' creativity).

Secondary creativity Creativity involving novel application of the already known (contrast with 'primary' creativity).

Serendipity Discovering something genuinely valuable by accident.

Sociocultural validation The acknowledgment by the social environment that a product is creative.

Sublime creativity Creativity leading to great works, major discoveries, etc. (contrast with 'ordinary' or 'everyday' creativity).

The Changing Understanding of Creativity

In his *Ion*, Plato discussed the contribution of creative artists to society, albeit in a rather sarcastic and uncomplimentary way. Over the centuries since, painters, sculptors, poets, musicians, writers, actors, and other workers in the creative arts, as well as critics and scholars, have frequently discussed creativity from an esthetic point of view, mainly focusing on works of art. The Chinese Emperor, Han Wudi, who reigned until 87 BCE, emphasized a different aspect. He saw innovative administration as a force for improving his people's well-being, and was intensely interested in giving creative thinkers high rank in the civil service, reforming the method of selection of mandarins to achieve this. Both Francis Bacon and René Descartes, two of the early seventeenth century founders of modern science, saw scientific creativity as involving the harnessing of the forces of nature for the betterment of the human condition.

Creativity has also been seen as the only uniquely 'human' characteristic, a bastion of human dignity in an age where machines, especially computers, seem to be taking over routine skilled activities and everyday thinking. It is also regarded by some writers as a force of nature that lies behind all growth and development. An extension of this point of view is to see creativity as an element of mental health: Through its perceived connection with flexibility, openness, courage, and the like – properties of personality that are seen as both prerequisites for and results of a healthy personality – creativity is thought to foster positive adjustment to life, while there is also evidence of a link between creativity and mental illness.

In a semantic sense, the term 'creativity' is used in three ways: it refers to a set of processes, a cluster of personal characteristic, and to results (e.g., a 'creative' product). Thus, creativity is treated as both a cause (creative processes give rise to

products; peoples' creative personality causes them to behave in certain ways) and also as an effect (creative products are the result of special processes and personal properties). This is the 'classic' 3 Ps approach (person, process, and product), which was soon expanded to incorporate a fourth P – 'press' (i.e., the pressure of the environment, which can either facilitate or block creativity).

However, applied discussions in the modern creativity era, which started in 1950 with the publication of J. P. Guilford's 1949 presidential address to the American Psychological Association and was strengthened by the 'Sputnik shock' of 1957, were strongly shaped by ideas from psychometrics and personality, as well as from education, largely thanks to Paul Torrance. More conceptual discussions came to be dominated by humanistic writers such as Carl Rogers, Abraham Maslow, or Rollo May, who saw its value as lying in its perceived beneficial effects on individual well-being. The result was that discussions of creativity in applied settings such as schools came to be dominated by questions of recognizing, measuring and fostering creative thinking (i.e., process), and the purpose of fostering creativity came to be seen not as production of sublime artistic works, but as promoting processes and personal properties related to creativity. The role of educators and managers was then seen as providing an appropriate environment (i.e., press). In the case of schoolchildren, because of the focus on creative thinking and creative personal properties, insistence on high quality products came to be seen as unimportant or even as inimical to creativity (see below).

Immediately after Sputnik, emphasis shifted more strongly to areas like physical science and engineering, and creativity began to be seen as a way of keeping up with the competition (especially with the then Soviet Union in the space race). The understanding of creativity was no longer largely confined to

fine art, literature, performing arts, music, and similar artistic/esthetic domains, but also included fields such as business, manufacturing, technology, medicine, administration, education, even defense, anti-terrorism, and law enforcement. Its products are sometimes abstract and essentially psychological, such as communication of a feeling, arousal of esthetic admiration, provocation of a new way of looking at such things, or development of new understandings of experience or existence (mainly artistic/esthetic or philosophical). However, they may also be concrete such as the making of works of beauty or imagination on the one hand, or on the other the design and construction of novel devices, machines, or structures, processes or systems for producing them, operating procedures, even enhancement of profits or preservation of national security. This interest has been fuelled by the perceived role of creativity in promoting social growth and justice, economic advancement, social stability, health and welfare, and peace and security.

Recent thinking thus gives more emphasis to products, especially 'functional' products (practical and useful objects and processes), which can be contrasted with esthetic products ('spiritual,' esthetically pleasing objects and processes). Although they are sometimes seen as mutually exclusive – for instance, in the foreword to his own novel, *Mademoiselle de Maupin*, Theophile Gautier argued that to be beautiful something must be useless – esthetic and practical aspects of effectiveness need not contradict each other. It is possible for a book to be commercially successful and at the same time written in elegant, even beautiful language, or for a novel technological product to look beautiful while successfully carrying out some useful practical function in a new way. Many everyday-use objects or structures such as furniture or motor vehicles or buildings seek to achieve both practical usefulness and beauty at the same time, and advertising often lays claim to both. Architecture is an outstanding example of a discipline where both beauty and practical usefulness are demanded.

Discussion of creativity has recently also become prominent in business, with an emphasis on beating the competition for markets and market shares. Research in this domain focused at first on invention of new products and production processes, for instance through studies of patent-holders. More recently there has been considerable emphasis on creative management, that is, on the fourth P of Press, especially creative leadership and the management of innovation, with research focusing on productivity, effectiveness, and the like. There has also recently been considerable discussion of the fostering of creativity in areas where it would scarcely have been regarded as relevant 25 years ago – for instance in management, technology education, sport, even counter-terrorism.

Basic Theoretical Issues

Is It Enough Simply to be Different?

Shortly after the Second World War, researchers concluded that the only constant factor in virtually all discussions of creativity is *novelty*. Novelty was later defined by Jerome Bruner in a more psychological way as the achieving of 'surprise' in the beholder. However, subsequent discussions made the important point that surprisingness alone is not sufficient for creativity.

It is possible to speak of 'pseudocreativity,' which is novel only in the sense of nonconformity, lack of discipline, blind rejection of what already exists and simply letting oneself go. These properties may be observed in many genuinely creative people, and thus be confused with creativity, but they are not actually an inherent part of it. It is also possible to distinguish what can be called 'quasicreativity.' This has many of the elements of genuine creativity – such as a high level of fantasy – but its connection with reality is tenuous. An example would be the 'creativity' of daydreams.

Genuine creativity requires two further elements over and above mere novelty. A product or response must be *relevant* to the issue at stake and must offer some kind of genuine solution, that is, it must be *effective*. Otherwise every farfetched, outrageous or preposterous idea or every act of nonconformity would, by virtue of being surprising, be creative. Thus, creativity is nowadays widely defined as the *production of relevant and effective novelty*. What is meant by 'effective' may differ from, let us say, fine art to engineering to business. In the former case, criteria such as beauty may play a decisive role (i.e., form predominates). By contrast, an engineering product – let us say a bridge built to conduct traffic across a river – must be capable of doing its job (i.e., function is paramount): no matter how esthetically pleasing its design, few people would acclaim the Tacoma Narrows Bridge as a triumph of engineering creativity even though it was beautiful to look at – it fell down in 1940, causing enormous expense and major disruption to traffic. In the case of business, increased profit provides an indicator of effectiveness, and introduction of novelty that destroyed a company's viability, as in examples given by Clayton Christensen, would not typically be regarded as creative business practice, despite its novelty. Thus, simple deviation from the usual is not enough on its own.

Can Everybody be Creative?

Creativity involves something new, different, and effective. However, this raises the question for whom a product, process or idea should be new: for all human beings throughout history, for the society or the era of the creator, or for the creator alone? Requiring that products be new in all human history would mean that a person would not be regarded as creative if someone else somewhere else had had the same idea at some time or other, even though the first person knew nothing of this. On the other hand, defining creativity in terms of the point of view of the person in question only would mean that total ignorance would guarantee creativity, since every idea would be new for someone who knew nothing! In fact, the word 'creativity' is used to refer to products ranging from being novel only in the sense that they have recently come into existence, regardless of relevance and effectiveness – such as is the case with a child's drawing on what was until a few minutes before a blank piece of paper – all the way to great works that are widely hailed as enlarging human perspectives in some way not previously seen in all history. The former involves 'ordinary' creativity, the latter 'sublime' creativity.

This distinction between the creativity of say a Leonardo da Vinci or a Johann Sebastian Bach, which changed the paradigm in an area and inspired other people to follow new pathways, versus that of, let us say, a home cook who varied the

ingredients of a well-known dish and produced an effectively novel taste effect that, however, never became known outside the family and was soon forgotten even there, is sometimes referred to in a picturesque way as involving 'big C' versus 'little c' creativity. Even in the case of sublime or big C creativity, it is possible to distinguish between two ways of producing effective surprise: by means of new applications of existing principles or by development of new principles. Some writers have contrasted 'secondary' (a different application of the already known) and 'primary' creativity (development of new principles). Other authors have distinguished between 'minor' creativity (extending the known) and 'major' creativity (going beyond the known).

A more differentiated approach in this connection is the distinction among 'levels' of creativity made by Irving Taylor: 'Expressive spontaneity' requires only the free production of ideas, without regard to their effectiveness or relevance. This has a role in some creativity training procedures such as brainstorming, and may well be helpful in the production of novelty, but may often lead to pseudo- or quasi-creativity and is not sufficient by itself for sublime creativity. 'Technical creativity' requires unusually high levels of special skills or techniques, for instance with words or paints or a musical instrument or other tools. Despite its importance in some creative activities (such as painting or playing music), technical skill is not sufficient as a universal definition of creativity. 'Inventive creativity' involves applying the already known in new ways, 'innovative creativity' requires expanding known principles, while 'emergent creativity' encompasses the development of new principles. As a general but not universal rule, children often show expressive spontaneity, but lack knowledge of a field or skill with tools or special techniques. In this sense they can be said to display creativity, but only in the form of expressive spontaneity.

About 40 years ago the idea of creativity in the person who will never achieve anything creative was introduced into the discussion by John Nichols. More recently, there has been a considerable amount of research on 'everyday' creativity. Although they may not produce innovative or emergent creativity, a high proportion of adults engage in the production of (at least for them) new ideas or products, for instance in the course of 'creative' hobbies, or simply in everyday life, as in the example of the cook given above. Thus, it is certainly possible, in the sense of everyday, minor, humble, small c creativity, to speak of creativity as a widely distributed characteristic seen in large numbers of people, although to a greater degree in some than in others.

Is a Unified Definition of Creativity Possible?

In recent writings, authors have disagreed about whether creativity can be defined in a general way or only in specific areas such as fine arts or science. There is no doubt that in specific fields special processes or personal qualifications based on, for instance, special abilities such as discrimination among tones, relevant specialized knowledge, skill in using special tools, or skill in specific techniques are important. Such abilities, knowledge, skills and techniques play a role in all fields of creativity, although the relative importance of particular factors is greater in some domains than in others – knowledge is perhaps

relatively more important in science, technique in music, to take an example. The specific contents of these elements also vary according to the particular field or activity in question: the specific knowledge required for designing and building bridges may not be very relevant for creative research in, let us say, botany, but both require a knowledge base. Both mathematical creativity and creative writing require mastery of a set of abstract symbols for representing ideas, although the two symbol systems may be quite different. Thus, there is specificity in creativity, but a general approach is also possible.

What is the Role of Products in Studying Creativity?

The role of a physical product is particularly obvious in fine art or performing arts (where specific works or performances are judged by specialized critics as well as interested members of the public), science (where peer judgment of published discoveries is of great importance), engineering, architecture and the like (where creative work usually leads to concrete products that are sometimes the source of public and professional controversy), or in business, where a concrete product is the usual result of creativity, but the 'wrong' product may spell ruin. On the other hand, in some areas, most obviously mathematics or philosophy, immaterial products such as novel *concepts* or *symbol systems* may well be the usual result of creativity. The two kinds of product are possible in all fields of creativity, and both may be identifiable in more or less all creative achievements, concrete objects being more prominent or dominant in some situations, symbol systems in others.

Although products are of great interest to both artists and business people, engineers, scientists, designers, and architects, to give some examples (i.e., products are important in both esthetic and functional creativity), they present problems for a psychological discussion. Artistic products in particular are often the subject of great controversy, with serious differences of opinion about their degree of novelty and especially their effectiveness: criteria vary from beholder to beholder (for instance art, literature or theatre critics) and from epoch to epoch. The perceived creativity of paintings has been shown by researchers to vary according to the viewers' beliefs about the identity of the painter or the amount of time they believed was expended on completing the work. In the case of business, acceptance by the market or positive effect on the bottom line is paramount. Various writers have thus suggested that psychological discussion should concentrate on process, person and press (social environment). However, from almost the beginning of the modern era some writers emphasized the importance of products. Donald MacKinnon concluded that they are "the bedrock of all studies of creativity." Sharon Bailin labeled efforts to study creativity without reference to products as 'misleading' and 'dangerous.'

Can Creativity Occur by Chance?

There are many examples of apparently lucky combinations of events that led to acknowledged creative solutions: for instance James Austin refers to many famous creators who described chance events that led to breakthroughs. Just what is meant by chance can be divided into four sets of circumstances: blind

chance (the individual creator plays no role except that of being there at the relevant moment; serendipity (a person active in a field hits upon something novel and effective without actually looking for it); the luck of the diligent (a hardworking person eventually stumbles onto something); self-induced luck (special qualifications of a person – such as knowledge, close attention to detail, or willingness to work long hours – create the circumstances for a lucky breakthrough). Case studies suggest that genuinely creative results require a combination of all four kinds of luck, which raises the question of whether it is a matter of luck at all!

An example of the complexity of the way chance works is to be seen in the case study of the Latvian/German veterinary pathologist Eugen Semmer. In 1870, he published a paper in the German-language scientific journal, *Virchows Archiv* (which still exists today), reporting on the strange return to health of two horses that had been admitted to the clinic where he worked suffering from what we would now call 'infections.' Moved by the personal property of curiosity he carefully examined the now-recovered horses (whose corpses he had expected to be dissecting), and applied his specialized knowledge and research skills to discover that they had unintentionally been exposed to spores of the fungus *Penicillium notatum*, which happened by chance to be growing unnoticed in dark corners of the lab. In his article he explained how he had carefully cleaned out his laboratory and had succeeded in eliminating the troublesome mold: No more sick horses would be recovering by accident in his clinic! Chance had presented Semmer with the opportunity for a momentous piece of creativity – he had accidentally discovered antibiotics – but because of other factors such as his inability to re-define the problem he was working on, medicine had to wait another 70 years for Alexander Fleming to discover penicillin, also more or less by accident. Blind chance alone is not enough (see also the discussions in the next section).

What is the Role of Hard Work and Knowledge in Creativity?

Although early studies of creativity supported the view that it frequently results from bursts of sudden inspiration, apparently out of the blue, opinion is divided among contemporary researchers. In some case studies, acknowledged creators have reported that their 'inventive,' 'innovative,' or 'emergent' creativity came from nowhere. In 1881, as he was about to enter a coach for a sightseeing trip during a conference, the mathematician Henri Poincaré was not thinking about mathematics at all when the Fuchsian functions (nowadays known as 'automorphic functions') suddenly came unexpectedly into his head. The poet, A. E. Houseman, described how the lines of his poems simply appeared in his head. Wolfgang Amadeus Mozart reported that he never revised his work, but wrote down complete music that occurred to him in its final form. Such reports have encouraged the idea that hard work and knowledge are unnecessary for creativity, or even that the two are incompatible, and has led to conclusions such as that simply relaxing or letting ideas flow will lead to creativity. However, Poincaré had been working on his problem for many years, and possessed a vast amount of relevant knowledge accumulated by hard work. Houseman's descriptions of his effortless production of poetry go on to recount how after

the first free flow of six or eight lines the next one or two took hours to emerge, and Mozart's account is inconsistent with the fact that corrected early versions of his music have been found.

In fact, a number of researchers have confirmed the role of knowledge in creativity: The Canadian Intellectual Property Office reported in 2007 that no less than 90% of new patents are improvements of existing patents. In explaining his own generation of effective novelty Edwin Land, the inventor of the Polaroid camera, expressly emphasized knowledge. He argued that he had had a purpose – the invention of a camera that developed its own pictures on the spot – and that all the necessary knowledge already existed. His achievement was to become familiar with this knowledge and work his way logically through it to the almost inevitable result, the Polaroid camera. It seems appropriate to adopt a modified version of an aphorism uttered by Thomas Alva Edison, which was printed in *Harper's Monthly* in 1932: "[Creativity] ... is 1% inspiration, 99% perspiration." Apparent serendipity may, in fact, be 'quasiserendipity,' as Cora Díaz de Chumaceiro put it, that is, 'accidentally' finding something you were searching for.

Although some theorists maintain that creativity is so novel that it has nothing to do with anything that already exists, the idea that creativity draws from the wellspring of conventional knowledge was already well established prior to the modern era. For instance, studies of inventors early in the twentieth century concluded that they work with existing knowledge gained via past experience. More recent writers have concluded that novelty always arises out of what already exists. John Feldhusen and Donald Treffinger summarized this view by referring to the 'knowledge base' of creativity. In general, an apprenticeship of 10–15 years seems to be necessary for acquiring the necessary fund of knowledge and skills, even in the case of famous youthful prodigies such as Mozart, who, it is true, produced creative music in his teens, but started his interaction with music by playing at the age of four. There is evidence that scientific and technological creativity may benefit more from knowledge than artistic creativity.

It should be borne in mind, however, that knowledge is a two-edged sword. Some recent research has looked at the problem that, although working successfully in a field over a long period of time (i.e., acquiring a great deal of knowledge) can provide a knowledge base that can be manipulated to yield effective novelty, it can also produce a kind of tunnel vision that narrows thinking and restricts it to the conventional – the Semmer case study is an example. In the absence of appropriate personal properties such as openness to the spark of inspiration, flexibility, or courage to try the new, expertise can inhibit the production of novelty. Great knowledge is thus both the friend and also the foe of creativity. Colin Martindale described the relationship as curvilinear: Too little knowledge is bad for creativity, but so is too much. In order to achieve effective surprise, experts need to be thoroughly familiar with the contents of their field but capable of seeing them in a new light. Creative experts often show a freshness and openness that is more typical of beginners: This has been referred to as the 'novice effect.' I once attended a lecture by the then 58 year old Hans Selye, nominated for the Nobel Prize no fewer than ten times, who apologized for being in plaster from his toes to his hip – he had fallen out of a tree a few days before, after he

saw something that seemed odd and interesting in the tree and climbed it in order to have a better look!

What is the Relationship of Creativity to Intelligence?

Conventional intelligence is heavily dependent on recognizing, recalling, and reapplying, and requires among other things substantial knowledge of facts, effective acquisition of new facts, rapid access to the contents of memory, accuracy in finding the best answer to factual questions, and logical application of the already known. Creativity, on the other hand, requires generation of novelty: that is, departure from the facts, finding new ways, inventing answers, seeing unexpected solutions. The initial position adopted in the 1950s and 1960s by psychologists was that creativity and intelligence are thus separate, more or less competing or even mutually exclusive dimensions of intellect. However, later theory has emphasized that the two overlap or interact. Some writers have referred to this interaction as involving 'true' intellectual giftedness, with neither intelligence alone nor creativity leading to the production of effective novelty. In studies of achievement at school or university level, for instance, it has been shown that, by and large, those students are most successful who display both creativity and intelligence. Research on practical creativity showed that engineers rated as creative displayed a combination of characteristics.

Liam Hudson conceptualized creativity not as a separate ability but as a way of applying intelligence or of organizing ideas, the difference between the two being that they are *thinking styles* or *tactics*. Another approach is seen in the threshold model, according to which a minimum level of intelligence is necessary before creativity is possible. A slight extension is the idea that, as intelligence approaches this threshold (corresponding to an IQ of perhaps 130) from below, the possibility of creativity rises (i.e., creativity and IQ are positively correlated below the threshold). When intelligence lies above the threshold, increases in intelligence have no consequences for creativity (i.e., IQ and creativity are uncorrelated once intelligence is high enough).

This view has been expanded somewhat by the idea of a 'one way' relationship between creativity and intelligence. Intelligence determines the upper limits of a person's ability to obtain and store information, without actually being itself part of creativity. The degree of creativity depends upon the amount of divergence displayed in the processing of the information made available by intelligence. An approach even more clearly oriented towards information processing is the idea that intelligence involves channel capacity, while creativity arises from flexible and versatile handling of the information delivered by the channel to generate novelty, lack of creativity resulting from use of this information to yield orthodoxy.

A different way of looking at the issue is the *overlapping components* approach. For instance, Robert Sternberg identified six 'facets' of creativity: knowledge, insight, intrinsic motivation, the courage of one's convictions, special personal factors such as flexibility and willingness to take risks, and relevance. Some of these facets are shared by intelligence and creativity, with the result that the two are correlated: for instance, knowledge is indispensable for both a high IQ and also for creativity. Other facets, by contrast, may be favorable for one but not for

the other, with the result that creativity and intelligence do not correlate: although highly facilitatory for creativity, flexibility, and risk taking may even detract from performance on an intelligence test. Insight, which seems to be involved in creativity, may be favorable for intelligence without being absolutely necessary for obtaining a high IQ. Intrinsic motivation is favorable for the acquisition of knowledge, but it is possible to operate rapidly, accurately, and logically without it, whereas it is believed to be particularly helpful for creativity. To the extent that they share facets, creativity and intelligence are correlated, to the extent that they depend on different facets or give greater or lesser weight to particular facets, they are separate. Summing up, it can be said that creativity and intelligence are neither identical nor completely different.

What is the Relationship of Creativity to Problem Solving?

The term 'problem solving' has a special meaning in research and theory, especially in psychology. It is often discussed in cognitive terms or as a special form of information processing. In conventional problem solving, the person solving the problem knows that it exists and understands the nature of the problem, intends to solve it, possesses special knowledge, some or all of which is required to solve the problem, and knows, at least in a general way, what broad form the solution will take. Creativity researchers, however, distinguish between problem solving and *creative problem solving*. The latter is required when one or more of the elements just mentioned (knowledge of the problem, of the means of solution and of the nature of the solution) is missing. In other words, creativity can be involved in problem solving but is not always necessary, while not all problem solutions are creative.

One way of showing the role of creativity in problem solving is to divide problems according to: (a) their degree of definition; (b) the degree of familiarity of the means for solving them; and (c) the clarity of the criteria for recognizing solutions. Clearly-defined problems that are solvable by means of standard techniques and for which there are obvious and well-known criteria identifying the solution constitute 'routine' problems. They can often be solved without the help of creativity, although when existing knowledge is applied in settings where it has previously been treated as irrelevant, a certain 'technical' or 'inventive' creativity occurs. Nonetheless, creativity is not absolutely necessary, and is probably not usual. By contrast, some ill-defined problems require, in the first instance, becoming aware that there is a problem at all, defining it, working out techniques for solving the problem, and developing criteria for recognizing a solution. Such 'complex' or 'intractable' problems demand a high level of creativity.

It is possible to distinguish between *recognizing* problems that are already evident in the present organization of available information and are obvious to any qualified observer, *discovering* hidden problems as a result of an intensive analysis of a situation, and *inventing* problems that are only apparent after the available information has been reorganized according to novel principles. A number of researchers see the discovering or inventing of 'good' problems as the vital step in creativity. The Semmer case study (see above) is a good example: He knew the answer (penicillin cures infections), but failed to ask the 'right' question. As a pathologist, whose job was

investigating deaths, he recognized and solved the obvious problem of how to prevent dying horses from getting better; had he re-defined the problem as how to make use with other sick horses of the life-saving phenomenon he had just observed, he would probably have made the momentous discovery for which Fleming received the Nobel Prize 75 years later.

Creativity as a Social Phenomenon

The Social Rules of Creativity

Creativity requires doing things differently from the way they are usually done, or even defying the norms of society, what Robert Sternberg and Todd Lubart called 'contrarianism' (although they were writing about giftedness in general, and not specifically creativity). In a certain sense, creative people defy the rules, even those who do not call attention to themselves through antisocial behavior. Thus, creativity can be seen as involving a failure to conform to the norms of society.

In principle, all people are capable of a wide range of responses to life situations, but in the process of growing up they learn that most of these are forbidden, and usually restrict their responses to a narrow range of socially tolerated behaviors. This has the advantage that life becomes predictable, since it is known what can be expected in everyday situations, but the disadvantage is that unusual, unexpected reactions are discouraged and become rare. There are even rules about the right way of thinking and the contents of correct thought. Societies are prepared to tolerate the breaking of the rules to a certain degree, which rules can be broken or how large a deviation is accepted varying from society to society and from time to time, as well as according to the age, social position, occupation, and other characteristics of the individual doing the rule breaking. For instance, the North American society would tolerate deviations from the norms for behavior at a wedding by a 21-year-old art student that would not be tolerated from the local bank manager. In general, there are rules about breaking the rules. People publicly acclaimed as creative break these rules, but succeed in staying within acceptable limits. If they do not, and produce excessively 'radical originality' they are likely to be regarded as eccentric, immoral, mentally disturbed, or criminal rather than creative, with the possibility of being criticized, shunned, or even locked away.

Research suggests that, as a result of the issues just outlined, creative people often need the support of advocates or facilitators. Some such people may achieve this by energizing, activating, or releasing creativity in others, without necessarily producing effective novelty themselves. An important function of such people is to offer creative individuals a safe space where they can break the rules without sanctions, as well as to offer them a positive perspective on themselves, for instance the view that their ideas are not crazy but creative. This recognition can help to foster the courage to deviate from what everyone else is doing, among other things by offering an opportunity to test the limits of the acceptable without risk or feelings of guilt. Creativity facilitators can be unsung people, such as a grade school teacher. In mature workers, such as scientists, working in a team may provide contact with facilitators. The groups of which a person is a member, either intimate groups such as the

family, more public groups such as playmates or friends, or more or less formally defined groups such as experts/critics, colleagues, or employers can also foster creativity by offering a social environment marked by recognition and encouragement (or, of course, hinder or block it by withholding such positive feedback). Some researchers regard exposure to social support in a congenial environment as the crucial factor in the emergence of creativity.

Socio-Cultural Validation

To have an effect or be recognized, a creative product must not only be novel, but must also be communicated to other people and, most important in the present context, be accepted or at least tolerated by them. This acceptance involves what Mihaly Csikszentmihalyi called 'socio-cultural validation' of a product, without which it is not creative, but involves only generation of variability. According to this view, creativity is not really a property of products or processes at all, but a category of judgment in the minds of observers, often acknowledged experts or specialists. In some areas the rules for applying the label 'creative' are well established, with the result that there is a high level of agreement not only among judges, but also between experts and ordinary members of the public. In other areas, however, there is less agreement, with the result that there are often controversies, for instance over the quality of a painting or a piece of music, the creativity of a new building, or even the acceptability of a novel law-enforcement procedure. This approach not only places great emphasis on *communication*, but it also emphasizes the final step in the emergence of a creative product: the phase of *validation* by the surrounding society. Interestingly, the socio-cultural validation of products does not occur in a social vacuum. It is striking that research has shown that there is a relationship between the economic/political situation of a society and the contents of the relevant and effective novelty created in that society: After an economic depression, there may be a burst of, let us say, literary creativity, after a successful war (if any war is ever 'successful') creativity in the performing arts, after an unsuccessful war, in business and industry, and so on.

The Organizational Environment

In business and industry, the emphasis is frequently on *innovation*, rather than creativity. The difference is that innovation requires not only creating novelty, but also putting it into concrete practice in a particular setting: Thus, in a certain sense, creativity can be seen as a prerequisite for innovation or as encompassing a stage or phase of innovation. Several definitional problems are easy to solve in the framework of innovation, for instance the question for whom novelty should be surprising, relevant and effective, or the issue of chance: Innovation requires the deliberate introduction of ideas, products, production and marketing processes, and the like, that are novel for a work group or an organization into which they are introduced. Effectiveness is also, at least in theory, easy to judge: production rises, sales improve, costs sink, absenteeism or staff turnover falls, or accidents in the workplace occur less frequently, to give some concrete examples.

Innovation can also be seen as a process having two phases. In the initial *ideational phase* ideas emerge that are new for the setting in which they occur. These ideas can be novel in an absolute sense (i.e., involving 'innovative' or 'emergent' creativity), but they need not be: For instance, a manager could make suggestions based on standard practice at a former place of work, novel only in the new workplace. Applying the already known in a new setting constitutes a creative act ('inventive creativity'), but only involves minor or secondary creativity. After this ideational phase comes the *behavioral phase*, in which the novel idea is put into practice. Creativity can occur without the behavioral phase, but this phase is essential for innovation.

In the case of innovation, the context is usually referred to in the relevant research literature as the *organization*. The process of insertion seems to occur in steps or phases, described in, for instance, the five phase model involving 'agenda setting' (the problem is defined and possible solutions considered), 'matching' (the suitability of possible solutions is considered), 'redefining/restructuring' (the innovation is adapted to the specific situation of the organization or the organization adapts itself), 'clarifying' (the organization grasps what the innovation is all about), and 'routinizing' (the innovation becomes part of the daily life of the organization).

Researchers have described aspects of the organization that facilitate or block innovative behavior, and these bear a strong similarity to the properties of the 'congenial environment' described by creativity researchers. Among these factors are freedom to make decisions, support from colleagues with whom one directly works, and facilitating attitudes or other factors (e.g., leadership style) of superiors. Inhibiting factors include negative aspects of the organizational climate, negative attitudes and leadership style of superiors, and inhibiting structure of command. In the case of the individual person, innovation often demands acquisition of new skills, on the one hand, cognitive reorganization on the other (changes in thinking strategies, in the organization of knowledge, or in ways of evaluating work activities). These can lead to a conflict of values with resultant uncertainty or anxiety, and may have consequences for the self-concept. As a result, personal characteristics of the individual such as openness for the new, willingness to take risks, and flexibility interact with the characteristics of the organization to facilitate or inhibit innovation and to moderate its psychological consequences.

The Psychological Basis of Creativity

Thinking Processes

The decisive event in modern psychological analyses of creativity was the acceptance speech in 1949 of the – at that time new – President of the American Psychological Association, J. P. Guilford. In a nutshell, he complained that existing concepts of intelligence visualized it as the finding of single correct answers to circumscribed problems. By contrast, he argued that intellectual power could also be applied to the finding of substantial numbers of new, original and unexpected answers, quite possibly to loosely defined problems. He referred to this process as a special kind of thinking, which he labeled 'divergent.' Guilford's original paper had the title 'creativity,' and the

equating of creativity with divergent thinking quickly established itself, especially after the Sputnik shock already mentioned. Other researchers have also concentrated on thinking processes as the basis for creativity. A well-known popular scientific approach emphasized 'lateral' thinking. Other concepts are 'janusian' thinking (named after the Roman god Janus, who could look backwards and forwards at the same time), 'homospacial' thinking (ideas from different domains are brought together into the same space), 'biphasic' thinking (in the first phase uninhibited combinations of ideas, which are then organized and sorted out in the second phase, for instance according to social acceptability), and 'tertiary' thinking (in the psychoanalytic sense, primary process and secondary process thinking are combined).

Associational theories emphasize the process of linking ideas. The theory of 'remote associates' is based on the observation that, in the course of their experiences, people learn a number of responses to a particular stimulus. Some of the stimulus-response associations occur frequently, others seldom. As a result, people learn a hierarchy of associations. Pairings that occurred frequently in the past stand high in the hierarchy, and have a higher probability of being chosen when the stimulus occurs again than associations which occurred infrequently in the past. These less likely associations are 'remote' and the person who makes them produces unusual or unexpected ideas. A similar approach is seen in the theory of 'bisociation,' which assumes that ideas occur in 'matrices' or fields. Normally, ideas from the same field are combined in a process of association. However, some people combine ideas from separate matrices in a process of bisociation which, by virtue of the fact that the ideas are not normally found together, means that the combination is surprising.

Cognitive Processes in Creativity

Generation of effective novelty depends on special cognitive processes over and above reception, organization, storage, and recall of information which are basic to all cognition, creative or not. Special processes include branching out, generating alternatives, recognizing similarities, making remote linkages, and the like. It is possible for 'ordinary' cognition to function efficiently without these, but they are vital for creativity. In a number of relevant studies, however, actual creators have emphasized the importance of heuristics such as construction of neural networks. The processes may also be guided by, for instance, intuition, a sensing that certain approaches offer more promise than others. Quickly discerning promising lines of attack is greatly facilitated by possession of rules or guidelines for detecting such approaches or for recognizing blind alleys from the start and ruling them out. Evaluation skills that make it possible to see that a line of attack is proving inadequate or to recognize that a solution is at hand (for example, mental blueprints or patterns of what an effectively novel solution might look like and techniques for matching the present state with this blueprint) are of great help. Thus, creative thinking processes seem to be guided by knowledge about how to acquire, organize, or apply knowledge: heuristics, strategies, hunches, or 'rules of thumb' – what is commonly called 'meta-cognition.' These include monitoring progress, redefining plans or the existing line of attack where

necessary, being aware of alternative routes, recognizing opportunities, or understanding the costs and benefits associated with possible changes.

Personality

A number of writers have emphasized the importance of *personality* in creativity, some even arguing that creativity may have little to do with cognitive processes at all, and may be the result of a special personality constellation. Reviews of the relevant research typically list characteristics such as flexibility, sensitiveness, autonomy and ego strength. Recent analyses of earlier research, however, suggest that the relationship between creativity and personality is by no means simple and straightforward. It is not possible to identify a certain kind of personality profile that is typical of the creative, regardless of their field, and also distinguishes the creative from the noncreative. Some research has emphasized the importance of a 'complex' personality that combines, among others, sensitivity with toughness or high intelligence with naïveté. Striking in the discussion of this point is that the personality characteristics regarded as important for creativity sometimes seem to be contradictory: for instance, the creative personality seems to be simultaneously stereotypically 'masculine' (autonomy, self-confidence, toughness) and yet stereotypically 'feminine' (sensitive, intuitive, responsible). Creativity requires a 'paradoxical' personality characterized by polarities such as openness combined with drive to close incomplete gestalts, acceptance of fantasy combined with maintenance of a strong sense of reality, critical and destructive attitudes together with constructive problem solving, cool neutrality combined with passionate engagement, self-centeredness coexisting with altruism, self-criticism and self-doubt together with self-confidence, and tension and concentration side by side with relaxedness.

Motivation

The creation of novelty requires not only appropriate thinking and personality, but also the desire or at least the readiness to diverge, take risks, defy conventional opinion, or expose oneself to the possibility of being wrong: In other words, appropriate *motivation*. Many studies have confirmed that *motivation* plays an important role in creativity. In addition to interest or curiosity, creative individuals are also affected by *cognitive motives* which derive from their knowledge, especially from recognition of gaps in existing knowledge (incompleteness), a drive to round out recently emerging knowledge (development), and identification of contradictions in accepted knowledge (conflict/discrepancy). Albert Einstein, for instance, indicated that he experienced *all three* of these motivating forces, but at different times.

A widely accepted idea popularized by Therese Amabile is that creativity is based on *intrinsic* motivation: the wish to carry out an activity purely for the sake of the activity itself, regardless of external reward. This position can be contrasted with working for external rewards such as praise, awards, pay raises, promotion, and even avoidance of punishment (extrinsic motivation). More recently, however, researchers, including Amabile herself have accepted that extrinsic motivation is not

necessarily fatal to creativity. Some researchers report negative effects of extrinsic motivation, to be sure, but others claim positive effects, and still others report mixed effects. Kerrie Unsworth argued that the effects of external versus internal motivation depend on whether the problem is imposed from outside or is self-discovered.

According to the Edward Nečka's 'triad' model, there are five classes of creativity motive: Instrumental motives, playful motives, intrinsic motives, control motives, and expressive motives. In contrast to the emphasis on intrinsic motivation, this approach argues that creativity can be a means to an end, for example a person might write a book in the hope of making money. Motives interact or change with time. To take an example, a person might begin to write novels in order to earn money – instrumental or extrinsic motivation – but might become aware in the course of writing of the feeling of having an important message that must be expressed regardless of the consequences (expressive or intrinsic motivation). At a particular time a creative person may be dominated by extrinsic, at another by intrinsic motivation. Such 'individual structures of motivation' are capable of changing with time, so that a given person might at one point be more extrinsically motivated, at another more intrinsically. The idea of a dynamically changing structure of creativity motivation is supported by the 'evolving systems' approach of Howard Gardner, according to which a creative product emerges as the result of a long process of development of knowledge, emotions and feelings, and goals.

Feelings and Creativity

Research on creativity and mood, such as that of Geir Kaufman has shown that mood is a precursor to creativity, accompanies it, and results from it. Furthermore, despite the widespread belief that positive mood is necessary for creativity and negative mood is fatal, research indicates that there is a role in creativity for negative mood too. Thus, both 'generative' feelings such as the 'thrill of the chase' when facing a challenge, the feeling of excited anticipation when generating novelty, or the feeling of satisfaction after achieving an effectively novel product, but also 'conserving' feelings such as anxiety in the face of uncertainty, frustration when progress is impeded, or disappointment when a product is not validated play a role in creativity.

The Psychological Paradoxes of Creativity

The Phases of Creativity

The 'classical' description of the emergence of creative products is the phase model, first introduced into modern creativity research about 100 years ago. Nowadays researchers usually focus on the four-phase approach attributed to Graham Wallas (although he initially identified seven phases). In the phase of *Information* a person becomes thoroughly familiar with a content area, in the *Incubation* phase the person 'churns' through the information obtained in the previous phase until a solution appears; this marks the phase of *Illumination*. The solution may seem to the person in question suddenly to have appeared from nowhere because its emergence into consciousness may come all at once, thus creating the subjective feeling of creativity without perspiration. This could explain why some creative people overlook the hard work involved in their own creativity

(see above). Finally comes the phase of *verification*, in which the person tests the solution thrown up in the phases of incubation and illumination.

The phase of 'incubation' is the subject of disagreement among researchers. It is intuitively obvious that creativity requires processing of information. However, there is disagreement among more recent theorists and researchers about whether such processes are chaotic and more or less random, or whether they involve incremental improvement of an initial solution in a sequential series of orderly steps. The first version of incubation would involve many possible solutions popping up more or less complete out of the seething cauldron of ideas, until one was recognized as better than the others and survived through a Darwinian process of survival of the fittest. The second version would involve 'monotonic' sequential refinement (polishing) of a single preliminary solution, step by step, each step improving the result of the previous step until the final form is reached.

Resolving the Paradox of Creativity

A phase approach is helpful in sorting out the problem of the paradoxes of creativity (see above): Creative individuals seem to combine apparently contradictory or even incompatible factors including thinking processes (e.g., divergent versus convergent thinking), personal motivation (e.g., intrinsic versus extrinsic motivation), and personal feelings (e.g., thrill of the chase versus fear of failure). Martindale described this as involving moving backwards and forwards between poles, and labeled it 'oscillation.' In cricket-playing countries, people who are good at this are described in everyday language as 'all-rounders,' while in baseball terms until recently they might have been known as 'switch-hitters.' A phase approach suggests that both poles of the paradoxes really are of central importance, but *not simultaneously* – certain properties wax and wane in importance depending on what phase of the innovation process is currently active. Particular human properties may foster production of effective novelty in one phase, but inhibit it in another. For instance, the personal trait of non-conformity or the process of unfettered thinking may together foster seeing problems in a new light and getting novel ideas about what to do about them, but inhibit painstaking verification of the ideas or effective communication of them in ways that are understandable and acceptable to others.

Figure 1 shows an expanded phase model incorporating other psychological components of creativity including feelings. In each phase (see left-hand column), core psychological processes (second column) are applied to content generated in the previous phase (third column), to produce the material for the next phase. The psychological processes are made possible or at least facilitated by factors such as positive motivation, openness for the new or willingness to take risks. The total process is accompanied in its various phases by feelings such as fascination, pride, or satisfaction.

The figure shows how apparently contradictory psychological factors are of particular importance in different phases of the process of generation of creative products. For instance, convergent thinking might dominate in the phase of *Preparation*, divergent thinking in that of *Illumination*, the personal property of modesty in the phase of *Verification*, self-confidence

during *Communication*. The figure depicts a successful process of creation culminating in a socially validated product. In practice, the process can be broken off earlier, for instance when evaluation of the product to date indicates that it is a failure. The creative process can also start part way through, for instance when a person returns to an earlier novel configuration to verify it. It can also function as a kind of spiral; for example new information could make it possible to verify a novel configuration that had earlier been rejected.

The Dark Side of Creativity

The Problem of Negative Creativity

A theme underlying almost all definitions of creativity is that it is inherently good. In closing, however, it is necessary to draw attention to what Keith James called 'negative' creativity: creativity that derives from evil intentions or leads to bad ends, or of course both. Sometimes the negative results of creativity are unforeseeable; for instance the discoveries of Edward Jenner and Louis Pasteur were hugely beneficial to humankind, but laid the foundation for germ warfare. Even where an undesirable outcome is foreseeable, negative creativity is not necessarily the result of deliberate evil intention. Some people may even create evil despite generally having benevolent motives, for instance, because they are unable to, unaware of, or unwilling to anticipate the dark side of their work, deliberately or sub-consciously blinding themselves to negative consequences. This may occur, for instance because of a lack of information, their fascination with what they are doing, or because they are deceived or coerced by factors like the prospect of money and fame.

Creativity is misused, perhaps in the way just outlined, in advertising, where it is employed for instance to promote the sales of among other things unhealthy food or dangerous products, in business to evade regulators or to steal competitors' secrets, in entertainment to promote repulsive values, glorify crime, etc., in politics to promote, for instance, racial hatred, in science and technology to develop and build weapons of mass destruction, in social or work life, for instance to avoid work, curry favor, gain unfair advantage, or steal from an employer, in crime, in war, or in terrorism. Most obviously dark, however, is the deliberate application of creativity with the conscious primary intention of doing harm to others – 'malevolent' creativity. However, such intentional negative creativity may be widely applauded as positive by one side (for instance the victors in war), even though it is devastatingly negative for the other. Thus, it is necessary to avoid being carried away by a general euphoria about creativity, and to look at it in a more differentiated way.

Moral and Immoral Creativity

To define creativity in a more differentiated way, it is necessary to consider not just the presence of novelty and effectiveness in products, the degree of divergence in processes, or the existence of motivation or other personal properties of the people who generate the novelty (with the tenor that these are either inherently good or are not subject to moral judgment), but to look also at issues of 'goodness' or 'badness.' These lie in the domain of morals, and imply that not everything that is creative is

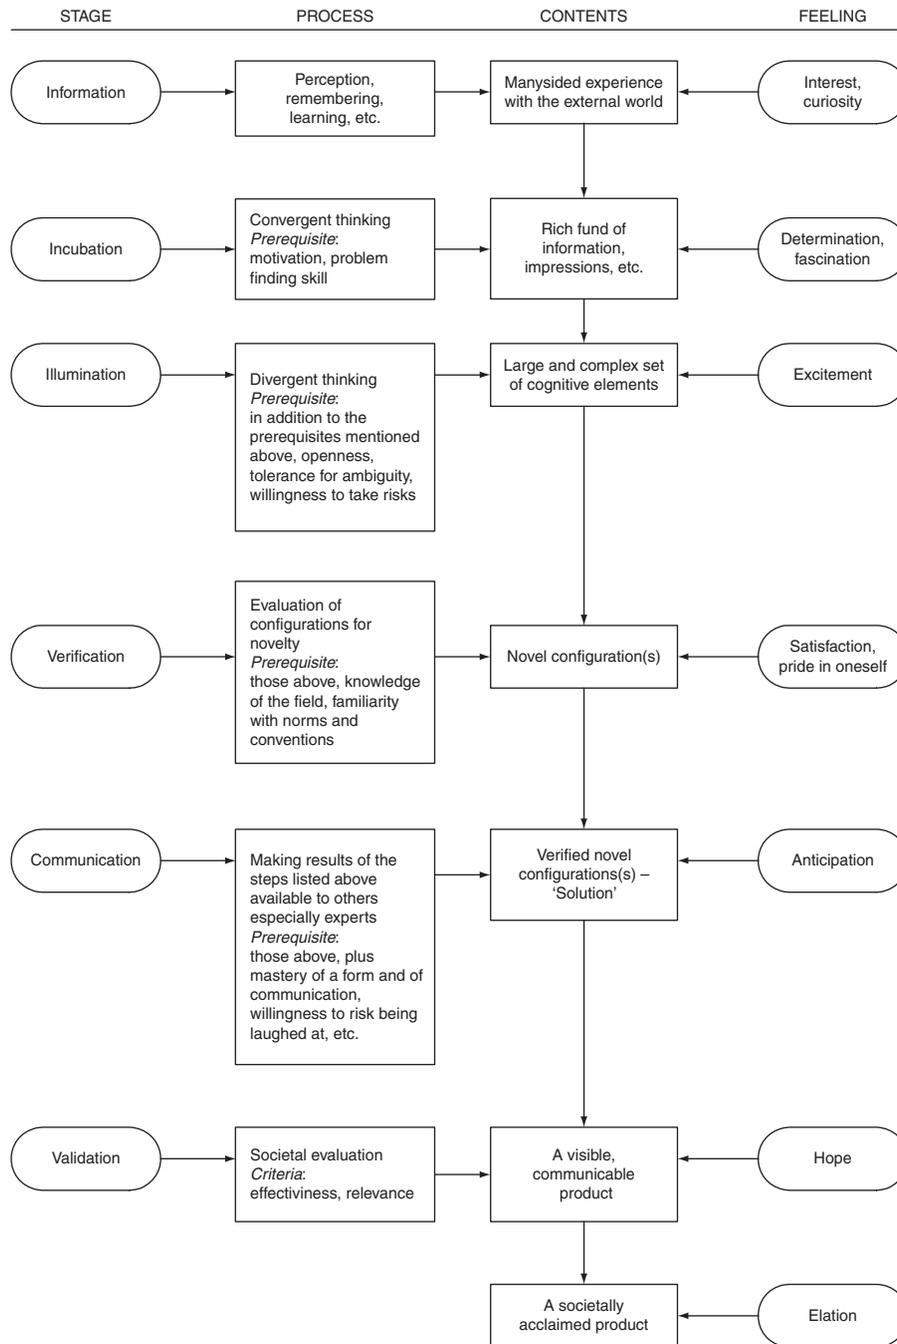

Figure 1 The psychological elements involved in achieving a creative product. Reprinted from Runco M (ed.) (1997) *Handbook of Creativity*, p. 100. Cresskill, NJ: Hampton Press.

moral, thus raising the idea of immoral creativity. Despite the subjectivity of ideas of good and evil, a common core of moral principles that transcend cultures and eras has been worked out in philosophical discussions. Broadly stated, these center on placing concern for the common good ahead of narrow self-interest; the golden rule, in fact. Sternberg called the ability to do this 'wisdom,' and argued that creativity that is tempered by wisdom is automatically moral. Although I have introduced them last, I believe that in defining creativity moral issues should come first.

Glossary

Behavior The attributes that can be derived from the structure of an artifact. Informally, behavior can be described as ‘what the artifact does.’

Design The outcome of the process of designing.

Designing The process that transforms requirements into designs. It creates new worlds by reformulating some of the requirements based on the designer’s situation. This provides opportunities for producing designs that were not possible or not obvious in the previous world.

Design world The set of expected design alternatives produced by the designer’s current situation. A design world consists of three subspaces: function subspace, behavior subspace, and structure subspace.

Emergence The process of making implicit properties of a design explicit.

Function The teleology or purpose of an artifact. Informally, function can be described as ‘what the artifact is for.’

Situated creativity (or s-creativity) A type of creativity in which novelty is defined relative to a current situation. It is the result of a change of the world of possible designs.

Situation The process that directs what concepts are produced during designing, based on the designer’s experience and interactions.

Structure The components of an artifact and their relationships. Informally, structure can be described as ‘what the artifact consists of.’

What Is Design Creativity?

Designing

Everything around us with the exception of natural things is designed, and even an increasing number of what appear to be natural things are designed. We will use the word ‘designing’ as the verb and the word ‘design’ as the noun to distinguish between the process (designing) and the outcome of designing. Designing is the process by which we posit changes to the physical and virtual worlds in which we live through intentional acts. Designed physical objects include architectural, mechanical, industrial, textile, electronic, graphical, and chemical objects, amongst the many physical objects designed. Designed virtual objects include those that exist in virtual environments (e.g., computer games) as well as plans and strategies, processes and conceptual models, representations and systems, and hypotheses and theories. Designing is not a unitary activity and as a consequence cannot be simply explained from a single perspective. The distinguishing feature of designing is that it creates new worlds within which it operates. These worlds can be thought of as new ways in which design requirements are viewed. They provide opportunities for coming up with designs that were either not possible or not obvious in the previous world. This feature of designing is most apparent when designs are required to meet conflicting constraints. For example, aircraft fuselages are designed to exhibit high strength but low weight, and digital cameras are designed to provide sufficient image resolution at affordable prices. Some of the conflicts can be resolved through simple tradeoffs that do not require new worlds to be created. However, in many cases of designing there are hard constraints (such as physical or legal constraints) that cannot or must not be violated. As an example, let us assume that an engineering design problem requires the length of a physical part to be at least 10 cm. However, during designing adjacent parts it turns out that this length must be restricted to a maximum of 5 cm.

This conflict is depicted graphically in [Figure 1](#), where x is a variable that represents length. Using this representation, it would not be possible to find a solution.

The conflict can be shifted into a different space by introducing a new design variable y that represents a new geometric dimension (e.g., width), as shown in [Figure 2](#). The constraints now become $x \leq y + 5$ and $x \geq 10 - y$, which leads to the feasible solution space as depicted.

New worlds can be created at all levels of a design. At a low level, they lead to changed elements of the same overall design. At the highest level, they lead to changed needs and actions of users of the design. As the architect Denys Lasdun put it:

our job is to give the client [...] not what he wants, but what he never dreamed he wanted; and when he gets it, he recognizes it as something he wanted all the time.

This may even require violating some of the constraints that initially appear mandatory. A famous example is the Sydney Opera House; its architect, Jorn Utzon, broke all of the original design constraints and yet won the design competition. He even broke the constraint that required the ‘building to lie wholly within the site.’ His design required a larger site than the one specified. In this case since the site had water along three of its four sides it was possible for the client (here the state government) to expand the site to fit the proposed building. The resulting building is considered to be highly creative and is one of the architectural icons of the twentieth century.

Designing involves activities that range in a continuum from selection to routine through to the nonroutine activities. Selection typically occurs at the level of individual elements. For example, materials, springs and bearings can be selected from standard design catalogues. Selected elements do not need to be assessed. Routine design activities involve the generation and testing of alternatives within existing worlds of designs.

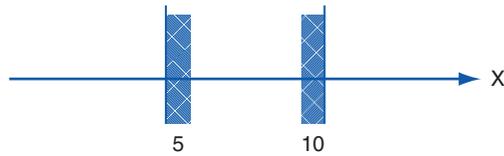

Figure 1 The constraints $x \leq 5$ and $x \geq 10$ lead to no feasible solution.

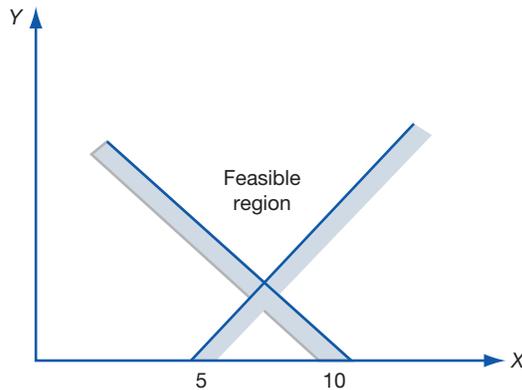

Figure 2 Introducing a new variable changes the constraints to $x \leq y + 5$ and $x \geq 10 - y$ that now lead to a feasible solution space.

They are often carried out iteratively. The criteria for testing alternatives are known and fixed, making designing resemble a process of search within an existing world of designs. Nonroutine design activities are those that create new worlds that allow searching in areas that were not available before. As a result, novel designs can be generated that are potentially creative.

Nonroutine design activities account for the common observation that designs tend to be unique even though they have been produced using the same initial requirements. This means that different designers create different worlds within which they operate. And the same designer often creates different worlds at different times during the process of designing. The notion that accounts for these changes is called the 'situation.' When designers reason about and act upon a design problem, they do so within a unique situation that directs what concepts the designer brings together based on experience and how the designer interacts with the design, the design process and other designers.

Design Creativity

For designs to be creative, three necessary conditions must be fulfilled: (1) The design needs to be novel; (2) the design needs to be useful; and (3) the design needs to be surprising. The first condition allows separating creative designs from routine designs. The second condition is often used for delineating design creativity from purely aesthetic creativity (although 'usefulness' can be understood in a broad sense that may include aesthetic value). The third condition describes the unexpectedness of creativity, providing the potential to change people's expectations.

Creativity in design draws three distinctions: the common distinction between historical creativity (or h-creativity) and psychological creativity (or p-creativity), plus a third distinction that is situated creativity (or s-creativity). h-Creativity is

the strongest form of creativity, where novelty is assessed in relation to the history of humankind. For example, the first steam engine was an h-creative design. p-Creativity implies novelty with respect to the history of an individual. An architect designing a high-rise building using, for his or her first time, reflecting glass can be viewed as producing a p-creative design. h-Creative designs must also involve p-creativity. s-Creativity is defined relative to the situation that pertains during the process of designing. A design or design feature is s-creative if it is the result of a change of the world within which designing operates. p-Creativity must involve s-creativity.

It is important to distinguish design creativity from design innovation. Design innovation turns the outcomes of design creativity into practice by realizing (implementing, manufacturing, assembling) or using them. Therefore, design innovation needs design creativity as a precursor. On the other hand, design creativity also needs design innovation, because outcomes of designing must be realized to be useful. Consequently, the study of design creativity must consider both the producers and the adopters of creative designs.

Design creativity can be located in designs, in the process of designing, in designers, and in users.

An Ontology for Locating Design Creativity

Identifying and characterizing the loci of creativity in design requires a systematic framework for describing the knowledge of the design domain in terms of all the concepts in this domain and their relationships. The notion of an ontology provides such a framework. The function-behavior-structure (FBS) ontology is a design ontology that describes all designed things, or artifacts, irrespective of the specific discipline of designing.

Structure (S) of an artifact is defined as its components and their relationships ('what the artifact consists of'). **Table 1** shows some examples of the structure of various artifacts.

Behavior (B) of an artifact is defined as the attributes that can be derived from its structure ('what the artifact does'). Behavior provides measurable performance criteria for comparing different artifacts. The examples of behavior in **Table 1** show that most instances of behavior relate to notions of quality, time, and cost.

Function (F) of an artifact is its teleology ('what the artifact is for'). It is ascribed to the artifact by establishing a connection between one's goals and the artifact's measurable effects. **Table 1** shows some examples of function.

Relationships between function, behavior and structure are formed by humans through experience and between behavior and structure through the development of causal models based on interactions with the artifact.

Locations of Design Creativity

Design creativity can be located in designs, the process of designing, designers, and users.

Creativity in Designs

There are three locations of creativity in a design: function, behavior, and structure.

Table 1 Examples of function, behavior, and structure of different artifacts

	<i>Building</i>	<i>Text editing software</i>	<i>Manufacturing process</i>	<i>Team</i>
Structure(S)	Geometrically interconnected walls, floors, roof, windows, doors, pipes, electrical systems	Computationally interconnected program components	Logically and physically interconnected operations and flows of material and information	Socially interconnected individuals
Behavior(B)	Strength, weight, heat absorption, cost	Response times, cost	Throughput, accuracy, speed, waste rate, cost	Working speed, success rate, cost
Function(F)	Provide safety, provide comfort, provide affordability	Be time efficient, provide affordability	Be safe, be time efficient, provide sustainability, provide affordability	Be time efficient, provide affordability

Creativity in function

Creativity in function is the result of ascribing novel and surprising purposes to the artifact. An example is the 'pet rock' conceived and marketed in the 1970s. Pet rocks were simple grey stones to which a new function was ascribed – 'be a low-maintenance pet,' because unlike living pets they did not require feeding. Although pet rocks seem like a bizarre idea, they were very successful in the market.

Creativity in function may or may not require changes of behavior or structure. In the pet rock example, no further behaviors needed to be added to the stones' existing ones, and no changes had to be made to their structure (although some pet rocks had 'eyes' attached). The new function was just a changed interpretation of the stone.

Other instances of creativity in function do require changes in behavior and structure. For example, changing the function of a chair from that of an artifact for sitting to a multifunctional artifact that includes both sitting and being used as a ladder would involve changing its behavior to allow for 'ladderly' behavior by having more than one step and hence changing its structure such that the chair's back could be rotated to produce an additional step or two.

Creativity in behavior

Creativity in behavior is the result of deriving novel and surprising attributes of an artifact. These attributes are often new mechanisms, techniques, or physical principles that may support existing or new functions. For example, replacing a car's existing behavior 'petrol consumption' with the new behavior 'rapeseed oil consumption' may not change the existing function 'move people from A to B' but is likely to introduce the new function 'operate ecologically responsibly.'

Creativity in behavior may or may not require changes of structure. The new behavior 'rapeseed oil consumption' of the car is likely to require changes of the structure of the engine and other parts. No structure changes are required when the new behavior can be brought about by modifying the interactions between the artifact and its environment. For example, holding a large piece of hardboard and shaking it in a lateral direction produces sounds without changing the hardboard's structure. This novel and surprising behavior was used by the Australian musician Rolf Harris to create a new musical instrument, known as the 'wobble board.'

Creativity in structure

Creativity in structure is the result of introducing novel and surprising components or relationships between components

in an artifact that may support existing or new behaviors. Studies of designers indicate that this is the most common form of design creativity. For example, the first suspension bridges introduced novel components, component configurations, and materials with respect to the earlier arch bridges. Suspension bridges have left most behaviors unchanged, except for replacing compression strength with tensile strength.

It is more common to replace some element or relationship in the structure than to replace an entire structure by another. For example, replacing a large petrol engine with an electric motor and a smaller petrol engine, along with the elements needed to capture energy in the battery that runs the electric motor, produced the novel, useful, and unexpected design of the hybrid system in many cars today. The rest of the car remains unchanged.

Some creative designs involve a subtractive change in structure followed by the addition of a new structure element. An archetypal example of this is the design of the Sony Walkman. Prior to the Walkman all portable electronic music players had speakers and as a consequence were large and heavy. They were difficult to carry around. The Walkman eliminated the speakers and shrank the player dramatically so it could fit into a pocket. The speakers were replaced by earpieces. Earpieces themselves had never been used with music players previously. This change in structure resulted in a change in behaviors of the design (sound from earpieces) and a change in the function of the design. Previously, music listening via portable players was a group, social experience (hence their nickname 'ghetto blaster'), however, the Walkman changed listening to music from a public to a private experience. This social dislocation was an emergent function (see 'emergence' later in this entry). It took the recent introduction of the design of digital file sharing applied to music to turn music listening into a social experience again, albeit a new kind of social experience.

Creativity in Designing

Creativity in designing is located in the activities that produce new worlds in which new designs can be found. A world can be thought of as a set of possible design alternatives based on expectations produced by the designer's current situation. Design worlds are partitioned into three subspaces: function subspace, behavior subspace, and structure subspace, as shown conceptually in Figure 3. The subspaces are interconnected through the designer's knowledge of qualitative and quantitative relationships between function, behavior, and structure.

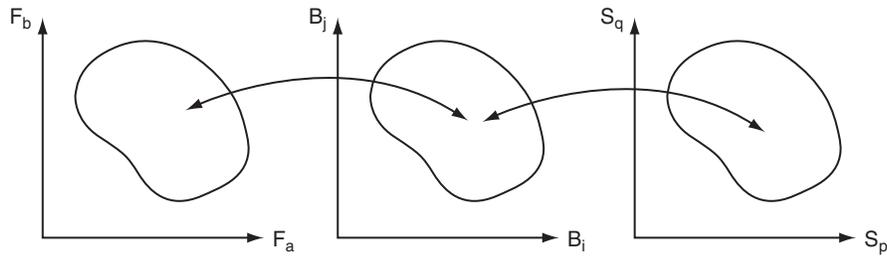

Figure 3 Function, behavior, and structure subspaces, and their interconnections.

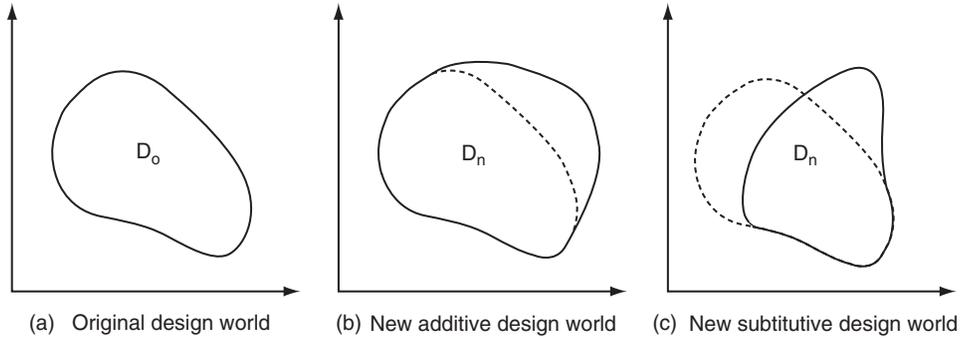

Figure 4 Possible changes of a design world. (a) The original design world, (b) additive change, (c) substitutive change.

The notion of a design world allows distinguishing two fundamental classes of design activities:

- Activities that use a situation to create new design worlds: They are described as shifts of an existing design world through changes in the designer’s interpretations and expectations. The changes may be additive or substitutive, as depicted in Figure 4. The example shown in Figure 2 is of an additive change produced by introducing a new design variable. Figure 5 illustrates a substitutive change where one set of variables (the two squares) is replaced by a different set of variables (the two L-shapes and the smaller square). It is in these activities where creativity in designing is located.
- Activities that operate within a design world produced by a situation: They are described as moves through an existing design world to search for the most appropriate design alternative. Most commonly, the moves occur within the structure subspace and involve mapping their effects on behavior, as depicted in Figure 6. A good example is design optimization that searches for the ‘best’ design by generating and then testing variants of the same type of structure. Figure 7 shows different variants of the same cross-section of a beam and their effects on two behaviors: section modulus (related to the strength of the beam), and moment of inertia (related to the stiffness of the beam). As the moves do not cross the boundaries of the design world, no creativity is involved. All creativity in designing is in the activities that operate on, rather than operate within, the design world.

Creativity methods for designers are concerned with changing existing design worlds or producing novel design worlds within which the designer then continues to operate until they change that world. Some creativity methods are formal and others informal, in the sense that they are used unconsciously. Typical

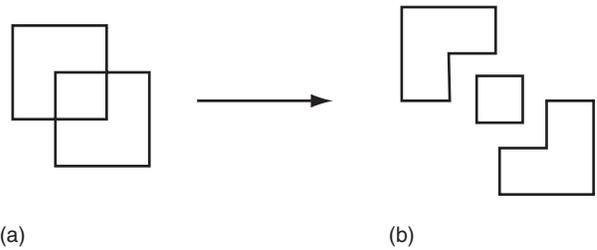

Figure 5 Example of a substitutive change: two overlapping squares (a) are replaced by two L-shapes and a smaller square (b).

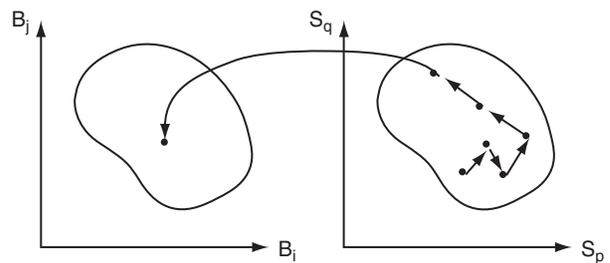

Figure 6 Search within a design world.

creativity methods employed by designers include: brainstorming, morphological analysis, synectics, back to first principles, analogy, mutation, inversion, and TRIZ (the acronym for a formalized method, developed in Russia, for invoking physical principles that can be used to produce creative solutions). All these methods are concerned with introducing new variables and hence changing the design world within which the designer is designing.

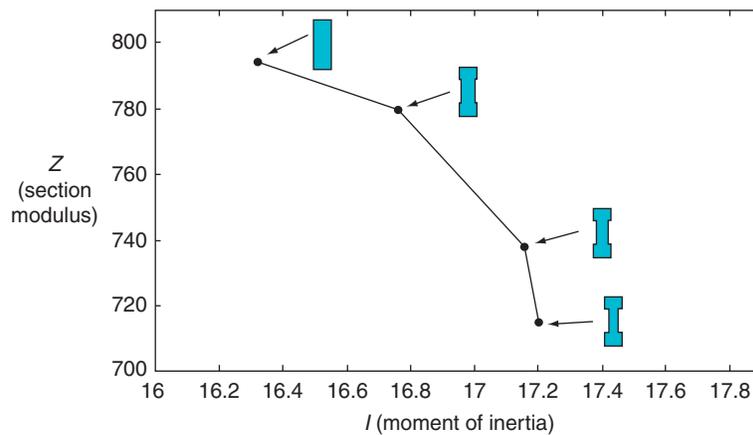

Figure 7 Example of search within a design world: optimizing the cross-section of a beam.

Creativity in Designers

Creativity can be located in individual designers or teams of designers, whose creative designs have led to innovations that have been exceptionally successful. In many cases, these designs spawn new classes of artifacts. For example, the first ballpoint pen spawned a whole new class of ballpoint pens that vary in form but use the same underlying design concepts. The creativity in this design certainly reflects back onto its original designer, Laszlo Biro. In fact, his surname has been used in many countries as a generic term for all ballpoint pens.

Once designers have gained a reputation of being creative, any subsequent design from the same designers is likely to be seen as creative even though its degree of novelty is relatively low. This is because the designers' names suffice to produce expectations of creativity without the need for objective assessment. Many examples can be found in the world of fashion design, where expectations of designers' creativity are based more on the designers' (or brands') names than on the actual designs. These names can be thought of as representative for certain styles of design creativity.

The close connection between a designer's reputation and successful design innovation is one of the reasons why most designers strive to be creative all the time. It also underpins the widely held view that designers belong to the 'creative professions.'

Creativity in Users

Creativity can be located in individual users or groups of users that discover new ways of using existing artifacts for new purposes. There are often adoption effects among users with similar needs and goals, leading to wider spread of the new use of a design. The pioneers of this process may then gain a reputation of being creative, depending on their visibility among peers. The 'wobble board' mentioned earlier in this article is an example of a new way of using an existing design, and many people would agree that its inventor, a popular musician, was creative.

Similar to the creativity in designers, the reputation of being a creative user often lasts for a long time, even when no more creative use is demonstrated by that user. However, these users are often accepted as opinion leaders for assessing creativity or

adopting creative designs, as their own choices of using designs influences their peers' choices.

Many creative users may never gain such a widespread reputation. For example, the skateboard was reportedly invented by children that experimented with different uses of a scooter whose handles had fallen off. This is a form of serendipitous design creativity.

Interactions in Design Creativity

There are three primary interactions in design creativity; they are in the sociotechnical environment of designers, designs, and users, as shown in [Figure 8](#):

1. Interactions between designers and their designs
2. Interactions between users and designs
3. Interactions between designers and users.

Interactions Between Designers and Their Designs

Designing is an activity during which designers perform actions to change their current designs. By observing and interpreting the results of their actions, they then decide on new actions to be executed on the design. The designers' situations may change according to what they are 'seeing,' which itself is a function of what they have done. The design researcher Donald Schön has coined the phrase 'interaction of making and seeing' to describe this phenomenon. The interaction between designers and their designs is one of the fundamental acts that can lead to creativity because it can lead to the generation of new design worlds. Because of this interaction design creativity is not predictable.

One of the processes that result from this interaction is emergence, a process that makes implicit properties of a design explicit. Implicit properties are those that are not intentional. An example of this process is shown in [Figure 5](#). Emergent properties often include visual forms and their potential consequences. They are based on the fact that producing designs, by means of sketching or modeling, necessarily imposes organization and detail on the design, not all of which are specifically intended by the designer. For example, sketching components of a design on a piece of paper produces a set of lines that compose shapes with intended spatial relations.

Other spatial relations emerge when the designer inspects the sketch at a later point in time.

Take the layout of a set of buildings produced by an urban designer, shown in Figure 9(a). At the initial time of drawing the layout, the designer attends to the four buildings individually. Upon inspection of the layout, the designer becomes aware of a horizontal axis and an urban space between two buildings, as shown in Figure 9(b). These features are spatial relations that were implicit in the initial design but are now made explicit. Figure 9(c) shows how the designer subsequently changes the design of an individual building to more directly produce an urban space.

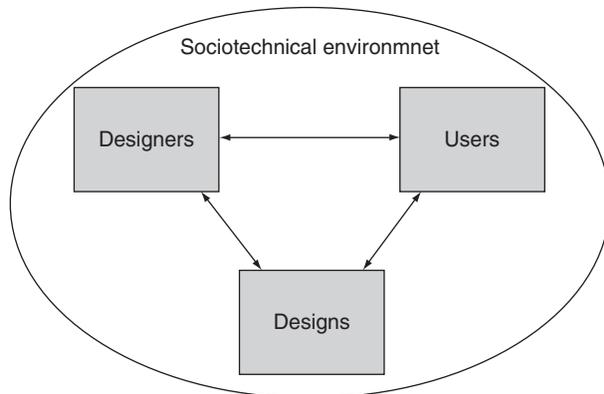

Figure 8 Interactions in the sociotechnical environment formed by designers, designs, and users.

Emergence is well known in the art world, as is its role of driving creativity. For example, in his description of Leonardo da Vinci’s creative process, the art historian Ernst Gombrich stated that “in searching for a new solution Leonardo projected new meanings into the forms he saw in his old discarded sketches.”

Interactions Between Users and Designs

Users interact with designs in various ways based on their current situation. These interactions are visible mostly as the users’ actions aimed at using the design. Similar to designers’ interaction with their designs, users observe and interpret the results of their actions, to decide on subsequent actions. This changes their situation that can affect their view of the design and consequently any further interactions. A creative use can be the result of these changes.

Most creativity driven by the interaction between users and designs is related to function and behavior.

New function can arise as a result of changes in a user’s goals and needs. Some of these goals and needs arise dynamically from the unique circumstances of an individual user. For example, using a screwdriver as a weapon introduces the new function ‘injure someone.’ This function may arise from a user’s sudden need for self defense.

New behaviors can arise as a result of changes of the artifact’s environment that were either accidental or intended for different purposes. For example, a user may accidentally drop a timber slab into water. By observing it floating on the water’s surface, the user realizes a new behavior, ‘buoyancy.’ The user

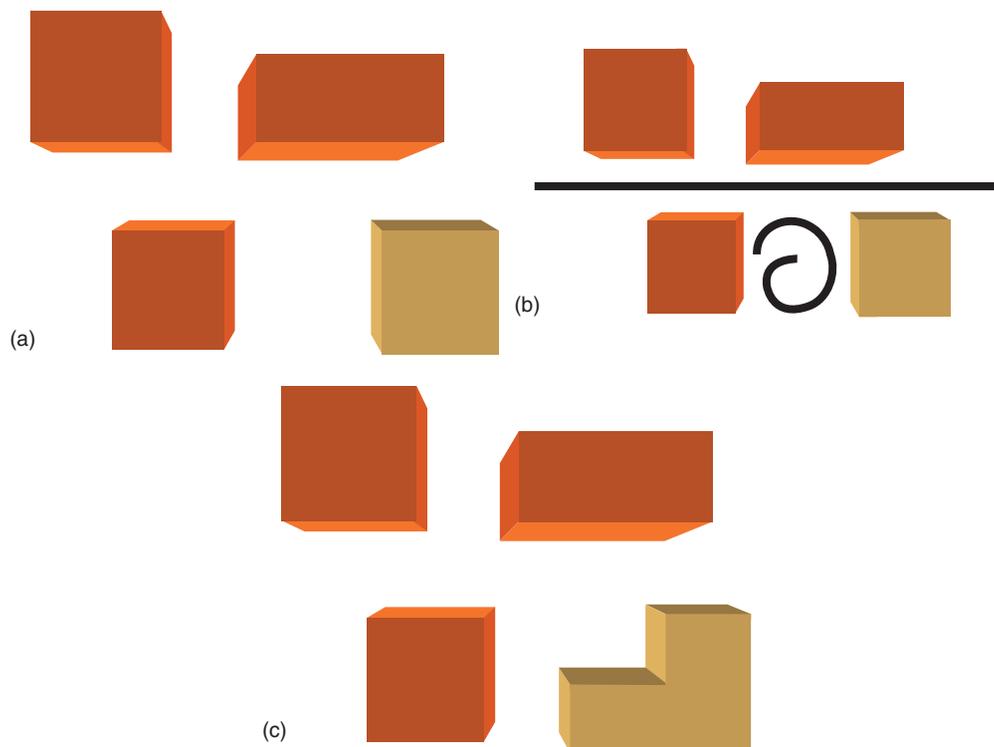

Figure 9 A sequence of sketches of a town layout: (a) the initial layout, (b) the same layout highlighting an emergent urban space and horizontal axis, and (c) subsequent change of the design as a consequence of the emergent urban space.

may explore further possible behaviors by grasping, pushing, or pulling it. This produces a new 'floating' behavior, which the user may find useful for activities such as transporting objects.

New structure can arise as a result of changes of the artifact itself, occurring either accidentally or for different purposes. The skateboard mentioned earlier was an instance of an accidental change of structure. The children found this changed structure useful after they explored new ways of interacting with it.

Interactions Between Designers and Users

Designers and users interact in two ways: directly, and indirectly via the market.

- Direct interaction includes all forms of design-related communication between designers and users. The communication from designers to users includes the designs, instructions of use, and marketing campaigns. The communication from users to designers is via studies of focus groups and general customer feedback.
- Indirect interaction via the market includes all other forms of communication and the interpretation and analysis of market data. The most common form of indirect interaction is the influence of indicators of market success on both designers and users. These indicators may be market share, sales figures or other metrics. Creative designs that are successful on the market will affect expectations of what future creative designs are produced by designers and adopted by users.

Both direct and indirect interactions between designers and users generate new situations that can lead to novel designs. Situations can change in designers and users. Their interconnection allows propagating changes from one individual to another.

Conclusions

Just as designing is multifaceted, so too design creativity has multiple facets. The creativity can be in the design or artifact, in the designer or in the user. Equally it can be in the interactions of the designer with their developing design, in the interaction of the user with the design or with the user with the designer. Most commonly it is in the interactions between the designer

and the developing design. It is here where most design creativity support tools are targeted.

The examples in this entry have been mainly about physical artifacts, however, virtual artifacts are no different and much of design creativity is increasingly focused on them as designing is applied to manufacturing processes, business processes, government processes, and research processes.

Creative designs can be thought of as Lamarckian evolution rather than Darwinian evolution in that the attributes of a creative design change all the designs that follow it. It matches Schumpeter's notion of 'creative destruction' as a descriptor of innovation.

Creative designs change our expectations of future designs by changing our perceptions through changing our value systems.

Glossary

Assimilation The process by which information is altered to fit into existing cognitive structures. In behavioral terms it reflects the construction of personal interpretations of experience.

Conventionality Tendency to go along with norms, expectations, rules, and conventions.

Fourth Grade Slump The drop in original thinking and behavior that occurs for many children at about age 9.

Problem Finding Occurs before a problem can be solved. Operationally, it may involve the identification of a problem or the definition of an ambiguous situation into a workable problem.

Strategic Creativity Actions or processes used intentionally to increase the likelihood of original insight or creative behavior.

Development as Experience

Continuity theories of development assume that the more experience an individual has, the more mature and capable he or she will be. Experience supplies knowledge, or information, and once obtained that information can be put to use. Since experience is obtained in a gradual fashion, a little bit each day, so too is the increase in one's maturity gradually developed. This increased experience may directly influence creative potential. This is, after all, the crux of 'expertise,' and famous creative works are often produced by experts.

There is, however, also a possibility that experience may lead an individual to make certain assumptions which in turn preclude original thinking. Experience may lead individuals to think that one method is best, and they can easily come to rely on that method, thus becoming inflexible and rigid in their thinking because of their expertise. In this light children's lack of experience may keep them from performing creatively (if they lack important information), but it may also keep them from making unoriginal assumptions. They may be more open-minded than someone who has more experience. In discontinuity theories experience contributes to development, but developmental progress is constrained, at least within stages. Thus if a child is in what is called the 'conventional stage,' he or she is sensitive to conventions, norms, and peer pressure. New information and experience may be useful to the child, but it cannot take him or her to a new stage of development until the child in question is of an age where he or she is ready to make the move. The four most commonly recognized stages of cognitive development are 'sensorimotor,' 'preoperational,' 'concrete operational,' and 'formal operational.' An alternative conception better applies to moral reasoning, artwork, language, and originality in children and adolescents. This alternative describes 'preconventional,' 'conventional,' and 'postconventional' stages. Children in the middle stage are likely to be very literal in their use of language (and thus avoid creative metaphors and the like); they are likely to prefer realistic, perhaps representational, art (and thus stop making art that is wild and unconstrained); and they are unlikely to

give truly original ideas (perhaps falling into the quite common 'fourth grade slump').

The four more common stages are suggestive of the kinds of information the individual may be capable of accommodating. The sensorimotor child, for example, only grasps information from immediate sensory or motoric experience. The preoperational child develops the ability to deal with symbolic information, but he or she is not yet very logical in the conventional sense until the stage of concrete operations. At that point the individual has the potential to be very logical, although he or she is still limited in the kind of information that can be used. As the name of the stage implies, at this point the individual is only capable of dealing logically with concrete information. Only in formal operations can the individual deal logically with hypothetical and highly abstract information.

A fifth stage of development – the postformal stage – has also been proposed, but it has received much less attention and confirmation than the other four. It would be an important stage because one manifestation of it is a kind of 'problem finding' whereby the individual recognizes that problems can be redefined to be workable. This kind of activity is an important part of many creative achievements. What is most important here is that the stages are qualitatively different, and the differences are manifested in what information individuals can use in their thinking. Clearly there are implications from this for parents and educators. Simply put, children in different stages require different kinds of experiences. They require experiences that communicate different kinds of information, information that is appropriate to their stage and cognitive tendencies.

Stages are also implied by the various descriptions of developmental trends in creativity. The fourth grade slump implies that development can be characterized by a U-shaped function. Other functions, including a J and an inverted J, have also been reported. The ages of the slumps and peaks vary, depending on the measures used to estimate creativity. Slumps and peaks have also been found throughout adulthood. In certain areas (e.g., mathematics), the peak is in the 20s. In other domains (especially those dependent on large knowledge

bases), peaks are much later. In some of the arts there are even peaks in the 80s and 90s, especially if the artist initiates the 'old age style.'

Given the variety of measures used and the lack of replication used in research in this area, most trends are at this point merely suggestive, or at best descriptive, of certain groups. The evidence for individual differences suggests that slumps in creativity are not inevitable. Creative performances no doubt reflect both nature and nurture. While certain abilities or aptitudes may be expressions of the degree that biological potentials are fulfilled, similarly, slumps may occur as an individual's reaction to his or her environment and experience.

Developmental Differences in Cognitive Processes

Importantly, the cognitive mechanisms used when processing information may not change all that much in the various stages of development. These mechanisms are thought to involve a kind of assimilation of information and a kind of accommodation of that information. As noted above, the information that can be accommodated differs at different ages, but this is because experience is always interpreted in the light of the individual's existing cognitive structures – his or her current understanding of the world – and not because the mechanism or processes differ.

Children may seem to be uncreative because they have particular responses to their experiences. Indeed, one reason children are occasionally described as uncreative is because they may not express their insights. Even if they create some new insight, it may be a personal accomplishment and not one that they express. They are not, in this sense, productive. The expressive and productive components of creativity can be separated from the creative components, however, which means that children can in fact be creative even if they do not have anything to show for it. This may be clearest in their pretending and imaginary play, and in their tendency to lose themselves in the play, even if there is no end objective of that play activity. It is also apparent in children's new understandings of their experiences. Those new understandings are probably useful (at least for the child him- or herself) and original (again, at least for the child him- or herself), and that means they are creative. Creativity is typically defined in terms of originality and usefulness. Each of these may be defined in relative terms; what is original to a child may not be original to an adult. Yet the process used by the child to find or construct that new insight is probably the same process that is used by a mature expert. The difference is in the expression and in the product. Children can then think creatively even if they are not productive.

Another difference between the creativity of children and adults involves intentions. Children's creativity may be unintentional, at least some of the time. Their originality may appear to be accidental, as is the case when a child says something that seems insightful or funny to adults but was simply an effort on the child's part to find the words to capture an idea. In this view children may often do something creative just because they do not know any better. Because they do not know the conventional way to say something ('children say the darndest things') or the conventional way to react to something, they may make up their own description or reaction.

Does this lack of intentions imply that the result is any less original and appealing? Is it uncreative because it was not planned? This question has been debated a great deal lately, but it is clear that if accidental insights are deemed uncreative, many serendipitous discoveries (e.g., penicillin) will also need to be reevaluated.

Once again this same issue can be turned to the advantage of children. Perhaps children are unintentionally creative in part because they are so spontaneous. That spontaneity has many benefits. It precludes the rigidity and inflexibility mentioned above, for example, and it probably ensures a kind of mindful awareness of one's experience. Improvisation of all kinds is creative and necessarily spontaneous.

Strategies, Flexibility, and Assumptions

Children can be strategically creative. The empirical research for this shows how well they react to 'explicit instructions' designed to communicate strategies. Most children, gifted and nongifted alike, respond well and use the strategies to find original ideas. This of course has clear implications for education. It also implies that children's creativity can be intentional, for strategies are by definition intentionally used.

The position that children can be *more* creative than adults was suggested when inflexibility was tied to expertise. Children lack expertise (and may even lack certain basic kinds of information) and this may ensure that they are *not* inflexible. Children also avoid making assumptions that adults often make. Assumptions, like conventions, are often very useful, but they can lead to routine and uncreative behavior. Because they lack experiences children have not yet developed those assumptions. They may try to fly and only conclude that they cannot leave the ground after they try again and again, running up and down a sidewalk, flapping their arms like wings. Adults will not even try to fly; they assume it cannot be done. Of course in this instance they are correct – humans need airplanes and jets – but the point is that assumptions can keep an adult from even considering certain options.

Assumptions can be tied to the information children lack because they are constructed as the individual learns more and more about the world. Many things come to be taken for granted. This can be beneficial because it makes information processing more efficient. We do not always need to examine all details of every experience but instead can focus on novelty and make assumptions about (and not even bother with or devote cognitive resources to) things we have experienced again and again. There is a cost, however, because assumptions lead to routine behavior, and that is never original. Children do not have the experience to develop the same assumptions, and they thus avoid these routines. In this way they may find original ideas more easily than adults, at least some of the time. The same tendency can give a novice in a field an advantage. The insights of Piaget, Freud, and Darwin have been attributed to their abilities to take a new perspective within one field, and that may have resulted from their studying one field and then moving into a new one. Some contemporary scientists explicitly recommend this kind of movement, from topic to topic or even field to field, as a means for maintaining the novice's original perspective.

Potential Versus Actual Performance

Consider also the idea that individuals sometimes have the potential to be creative but do not take advantage of it because they are constrained by cultural convention and taboo. This is yet another way of saying that experience can inhibit original thought by narrowing the options considered. Surely conventions must be learned, and many of them contribute to the smooth flow of social interaction. But it is difficult, if not impossible, to be original in a conventional way. This is the point of many creativity techniques which focus on the 'conceptual blocks' that keep a person from seeing a problem, tack, or solution clearly. Those blocks, be they cultural, social, intellectual, or perceptual, may depend on experience. Once again, if the child lacks that experience, he or she will not have the same blocks.

There is a time to be conventional and a time to be unconventional. Truly creative work occurs when unconventional thinking and behavior is appropriate – when it is only disruptive in a manner that gets people to reevaluate their experience. The point is that originality alone is sufficient for creative work. Creative contributions are original, but they are also timely. They fit in; they solve a problem. Creativity requires a kind of discretion. Surely we do not want children who are original all of the time. Instead, parents and educators need to ensure that children do not lose their capacity to be spontaneous and flexible. Many children do seem to lose this

capacity; many experience a 'fourth grade slump' at about age 9. At that age they are very sensitive to conventions: They react to peer pressure more than any other time; their art becomes highly representational and realistic; and they stick to the rules in their games rather than making them up as they go along.

The trick is to encourage children's originality while allowing them to learn important conventions. In that way they will use their discretion and know when to exercise their originality and when not to. They will be strategically creative.

Glossary

Contrarianism Behavior that is intentionally different or opposite from what others are doing.

Deviance Different from what is typical; differing from the norm.

Eccentricism Tendency toward unusual and sometimes outlandish behavior that may contribute to original thinking or may result from it.

Open-mindedness Tendency to consider all options and tolerate or even appreciate different perspectives.

Psychosis Disorder characterized by a loss of contact with reality. Historically, it has also been called madness, insanity, or lunacy.

Tolerance Seeing the value in behaviors or ideas even though they are deviant.

The word *deviance* may elicit various negative images. Indeed, whether from a sociological or psychological perspective, a deviant is often thought of as someone who is suffering mental illness, or someone who poses a threat both to individuals and to society in general. When viewed statistically, deviance is seen as a departure from the mean or some other measure of central tendency. Most dictionary definitions of deviance involve the departure from what people normally consider to be acceptable. Taken collectively, these implicit theories and formal definitions imply that deviance entails a departure or a difference from prevailing cultural, political, physical, behavioral, emotional, and psychological norms. Deviants are rule-breakers or offenders against social conventions. Someone who dresses in black on a hot sunny day, someone who scores very high or very low on a test relative to his or her peers, or someone who eats everything through a straw are all examples of behavior or persons who would be considered deviant. Deviance is necessary for societal and cultural evolution. In the Darwinian model of natural selection, deviance provides the variation from which adaptive ideas and behaviors are selected. Conversely, research in social psychology suggests that a lack of deviance within a group usually results in poor decision making and problem solving.

Relevant Aspects of Creativity

Research on the personality correlates of creativity behavior imply a profile of creators that is in many ways similar to the above-mentioned deviance definition: displays unconventional behavior, avoids entrenched ways of thinking, is dissatisfied with the status quo, sets own rules, takes risks, rejects limits imposed by others, is willing to try new things, is open to new experiences and growth, and is receptive to new ideas. Creative individuals seem to have less time to be courteous, often refuse to respect other people's opinions, and tend to be critical of others.

Some characteristics of creativity are found to be closely associated with deviance. For example, originality, the most

widely acknowledged aspect of creativity, assumes unusualness, uniqueness, or novelty. An original or new idea requires some sort of deviance. When we say something or someone is unusual in comparison to something or someone else, this typically means that the thing or person is different from a collection or group rather than a single instance. That group represents the norm. You cannot be like the norm and yet unusual, unless you are unusual in one particular way but fit the norm in all others. Deviance is, then, characterized by unusualness, uniqueness, originality, and novelty – and at least one of these is required for creativity, although it may be a necessary but not sufficient condition.

The Scales for Rating the Behavioral Characteristics of Superior Students are often used by teachers to identify students' creativity. This instrument includes the following descriptions of students' behavior: often offers unusual responses, is uninhibited in expressions of opinion, is sometimes radical in disagreement, is more open to the irrational in him- or herself, is nonconforming, accepts disorder, and does not fear being different. These behaviors are deviant from conventional classroom practices and the traditional values of our social norms.

Although people generally value creativity, both research on implicit theories of creativity and conventional wisdom suggest that creative individuals and the creative process test norms, question authority, and push limits. Creative persons explore and often seek out deviance, suggesting that the distinction between creativity and deviance is often blurred and difficult to identify. Given the common connotations of the concept of deviance, it might be worthwhile to recognize the value of deviance. Popular use of the adjective 'creative' in phrases such as 'creative accounting' and 'creative financing' quite frequently implies unethical and negative behavior. Creative work can be deviant – and yet not unethical.

Issues and Implications

Given both the negative connotations of deviance and the possible importance of deviance to creativity, an analysis of

the comorbidity of creativity with different types of deviance is necessary. In this section, the relationships between creativity and open-mindedness, psychosis, contrarianism, eccentricity, crime, and drug use and abuse are explored.

Open-Mindedness

Creativity is often defined as a complex construct or a syndrome, the idea being that more than one trait and ability is involved. This is pertinent in that autonomy, nonconformity, or even deviance may interact with a person's open-mindedness, a fairly common personality trait of creative individuals. Perhaps creative people, because of their open-mindedness (willingness to consider other ideas and concepts), are more accepting of the deviance of other individuals.

There is very probably a functional connection between open-mindedness and deviance within the individual: individuals may entertain unconventional and even deviant thoughts and behaviors because of their open-mindedness. This is a critical notion in several ways. Not only does it help explain the relationship between deviance and creativity; it also suggests that open-mindedness by one person may ensure that he or she will be tolerant and perhaps even appreciative of the creativity and apparent deviance of other persons.

Because open individuals may be more accepting of other deviant individuals, we might expect a kind of Matthew effect, found in other areas of creativity research, where those with something (in this case the right combination of open-mindedness and originality) will obtain and generate even more of it. Perhaps parents who have creative traits will model and value them, and thereby raise children who also have them. The tolerance supplied by the traits may subsequently generate increased creativity in others who are raised in the same environment.

This may also lead to an increased distance between creative and uncreative persons. This may explain why there are certain expectations for creative persons, such as the stereotypes commonly held about artists and other unambiguously creative individuals and their eccentricities.

Psychosis

Many distinguished artists, musicians, and writers were diagnosed with some kinds of mental illnesses, Adolf Wolfli, Lord Byron, Virginia Woolf, Edvard Munch, Victor Hugo, and Jackson Pollock, to name but a very few. Robert Schumann, who is one of the most productive Romantic composers of the nineteenth century, ended his life in an insane asylum. The world-renowned impressionist artist, Vincent Willem van Gogh, suffered recurrent bouts of mental illness during the final two years of his life, which at last led to his suicide. This link also holds for the average population. For a group of children with manic-depressive illness, researchers found an unusually high proportion of special ability among them.

Many explanations for the relationship between creativity and psychosis are offered. One is from Eysenck who suggested that both the capacity for creativity and the tendency toward mental disorder result from the same 'overinclusive thinking.' This occurs when something that does not belong in a category or concept is nonetheless included in it. At the extreme, this

leads directly to psychotic ideation. The psychotic individual is viewed as out of touch with reality – a deviant, at least in thinking, and often in manifest actions. At other times overinclusive thinking can allow the individual to find unusual but useful connections among ideas. In this way it can lead to creative thinking.

Another alternative explanation posits an 'inverted-U' shaped relationship between creativity and psychopathology, that is, moderate psychosis results in an increase in creativity while a severe situation may lead to a decrease. When individuals have moderate manic illnesses, the psychopathological symptoms lead to high arousal in brain activity, which may stimulate people with millions of novel ideas. On the other hand, creativity is seen as a channel to relieve psychological conflicts and emotional distress. Sometimes working on creative products serves as self-therapy.

The evolutionary hypothesis or Darwinian theory of creativity argued that the link between psychoses and creativity is a consequence of genetic selection. The genes that are liable to suffer from mental illness become adaptive and are retained in human evolution when they show the positive aspect of creativity. Here creativity is taken as one type of 'compensatory advantage' yielded by psychoses in the gene pools.

However, modern researchers are still struggling with questions such as what kinds of mental illness are associated with what types of creativity, and what kinds of creative people tend to experience psychoses. Kaufman used the term 'the Sylvia Plath effect' when he found that female poets were more likely to suffer from mental illness than other types of writers.

Contrarianism

Creative individuals often choose between working within the old prototype or pursuing a novel but probably unacceptable framework. When they think creatively, they are often more intentional than the section above might imply. Sometimes this is the result of tactics or strategies. One tactic is the contrarian one. Here the individual ensures that his or her actions are original by intentionally doing what others are not doing. The economic metaphor is 'buy low and sell high.' This tactic suggests that creative individuals often seek ideas which may be out of fashion but still have potential to gain favor. They do not back down from their unpopular view in the face of resistance, and later find an opportunity to sell those ideas high. This strategy works well because it does indeed ensure originality, the most commonly recognized facet of the creativity complex. There is, however, the caveat that contrarianism can be used in a manner that is contrary to creative achievement, and contrarian behavior is not necessarily creative. It will probably look like deviance, and for the same reason it ensures originality. A contrarian tries to find the boundary, tries to be an outlier, and is therefore trying to be in some sense a deviant.

Eccentricity

People's antagonism to conventional values and entrenched ways of thinking assumes many forms. Eccentricity is one form. In everyday life, eccentricity is shown explicitly either

by absent-mindedness or weird behaviors, especially in trivial matters. This may suggest that eccentrics are more engaged with their own work but pay scant attention to things other than the domain they are devoted to.

Eccentricity is a type of deviance that is often mistakenly associated with psychosis. While schizophrenia and other mental disorders usually lead to dysfunction, eccentrics tend to function well (albeit in ways that appear strange to most people). In both cases, the concept of freedom – to think and behave as one wishes – is present, but the exercise of personal freedom is less dysfunctional in the eccentric.

Studies of eccentrics tend to report that highly gifted individuals exhibit signs of eccentricity, and eccentrics are often creative. The relationship between eccentricity and creativity is hypothesized to hinge on the fact that individuals exhibiting both tendencies are individualistic and apt to go against established norms of behavior. Perhaps the most notable example of eccentric creativity is Albert Einstein, whose behavior was often described as erratic or eccentric (e.g., wearing slippers or pajamas to formal events).

Eccentricity has been found to be a predominantly Western phenomenon. This follows from the emphasis on rugged individualism and privacy rights in the Western world. But the evidence in support of the hypothesized link between eccentricity and creativity is very thin, with some research suggesting that eccentrics are not eminently creative, and creative individuals are not necessarily eccentric.

Crime

Throughout history, many creative individuals have spent time in jail. This is not surprising, because creativity is often perceived as a form of deviant behavior which can frighten people and threaten established societal norms. The jail lives of many famous persons are good evidence of the conflict between creativity and conformity. At the extreme, creative persons are willing to take risks and be nonconforming, and their novel ideas are not in line with traditional, societal norms. It may be that some of these individuals do not fear change and are deviant in thought, allowing them to produce creative works, but also leading them to break society's laws. A subtle distinction can be made between creators who were jailed because their creative activities were perceived to be threatening (e.g., Socrates, Thomas More, Galileo) and those who saw a stint in jail as furthering their creative endeavors (e.g., Thoreau, Gandhi, and Martin Luther King, Jr).

On the other hand, the difference between creativity and crime is hard to identify without referring to the product and press (e.g., the social context) in the four Ps, which also include person and process. Products that are socially useful can be considered truly creative, otherwise they are regarded as criminal. This is similar to Sternberg's opinion that creativity and intelligence need to be tempered by wisdom. In addition, researchers distinguish 'negative creativity' from 'malevolent creativity' due to the different intentions of the behaviors. Both kinds are seen as deviants in creativity research and may lead to criminal acts, but the former may not indicate evil-intentioned creativity or may suggest some potential benefit for society. One example is a man who found a novel way to enter and change the database of the bank where he was

working. He did it not because he wanted to destroy the database or steal the information from the bank but because he was curious. 'Malevolent creativity' makes use of creative ideas to inflict deliberate harm on other people or the society as a whole. It is frequently seen in warfare, and a striking example is the introduction of poisonous gas into Nazi concentration camps during World War II.

Convicted Criminals

Over the past decade, the empirical evidence has linked creative individuals and prisoners. Some studies found that like most criminals, creative people tend to be antisocial, while both are more likely to ignore authority and do things in their own ways. Other research showed that creative people tend to consider themselves impulsive, and impulsivity is a common characteristic shared by creative individuals and prisoners. Russell Eisenman has, however, investigated the creativity of prisoners and found little evidence that convicted criminals are more creative than noncriminals. On the contrary, Eisenman believes that prisoners are generally less creative than nonprisoners, although creative prisoners do exist. Much remains to be discovered about the relationship between creativity and crime.

Drug Use and Abuse

An indirect link between creativity and psychosis would be that the conflicts created by creativity might result in maladaptive coping strategies such as drug use.

At first glance, considerable evidence linking drug use and creativity appears to exist. Many eminently creative individuals, including Ernest Hemingway, Edgar Allan Poe, Tennessee Williams, Jackson Pollock, John Belushi, and Eric Clapton, abuse or abused alcohol or other drugs. Potential explanations for the apparent relationship include creative individuals' penchant for risk-taking, the disinhibitive effect of alcohol and other drugs on creativity, and the role of drugs in easing the stresses of the creative life.

But a deeper look at the issue raises serious questions about the relationship between drugs and creativity. First, while the deviancy necessary for drug use and creativity is often mentioned as a reason for suspecting the existence of a relationship, it is worth noting that the use of many drugs, especially nicotine and alcohol, is quite common and thus not dramatically deviant. Second, much of the evidence supporting the presence of a positive effect of drug use on creativity is anecdotal in nature; indeed, empirical research generally does not support a strong, positive, causal relationship between creativity and drug use. On the contrary, long-term use of alcohol, marijuana, and other drugs appears to have a negative effect on creativity. Even in studies which partially confirm disinhibiting effects, other factors appear to hinder the degree to which individuals capitalize on the production of disinhibited ideas.

However, this is not to say that creativity does not lead to drug use. Creative success often leads to the amassing of financial resources that increase the ability to obtain drugs, and people may turn to drugs to alleviate the many stresses

associated with creative activity. A relatively new hypothesis is that people who consider themselves creative may experience pressures to conform to societal expectations of creative individuals' behavior. For example, a writer may react to stereotypical depictions of the 'alcoholic writer' – stereotypes held by society and the other writers in his or her peer group – by using alcohol more frequently.

Conclusion

Consider the anecdotes surrounding the lives of creative individuals such as Einstein, Poe, Kafka, Martha Graham, and others mentioned in this article. Their deviant behavior was frequently considered outlandish or dangerous and threatened to overshadow their creativity. Their deviance was often such that only the most sympathetic friends and family members could tolerate it. Steven Spielberg's mother has observed that if she had known the typical means for dealing with her son's frequently bizarre behavior, the arts would have lost a major creative talent. Instead, she simply tolerated her son's deviant behavior and encouraged his creativity.

We each need to accept the role of deviance for both creative work or individuals and for societal progress. It should be accepted because we need to tolerate it – or we will lose it, and thereby lose an opportunity to enhance creative work and societal progress. Indeed, regardless of the ambiguity of research on creativity and deviance, most researchers voice the same basic conclusion: tolerance for creative ability.

More specifically, what is needed is (a) increased tolerance for seemingly deviant behaviors and (b) discretion about when to be deviant and tolerant and when not to be. Clearly, both can be taken to inappropriate extremes.

This article is a revision of the previous edition article by Bernice Yan and Patricia Arlin, volume 1, pp. 547–552, © 1999, Elsevier Inc.

Glossary

Creativity A multifaceted term often including concepts of novelty, innovation, and effectiveness.

Dialectic In philosophy, the term has been used to refer to different concepts including form of reasoning, logic dealing, with contradictory aspects of knowledge, and a related family of worldviews.

Dialectical thinking A specific form of postformal reasoning that involves the coordination or integration of contradictory views or frames of reference.

Equilibrium A fundamental principle of development described in Piaget's theory of cognitive development through which qualitative change potentially takes place.

Nonabsolute/Relativistic (N/R) thinking A form of higher-order thinking that is operationally defined as multiple-frame operations on ill-defined problems and is associated with a nonabsolute worldview. It is considered a commonality underlying some of the most representative models of post-formal reasoning.

Postformal reasoning A form of higher-order thinking that employs a kind of logic that is different from that of formal (abstract logical) reasoning.

Problem finding A specific form of postformal reasoning that involves the raising of generic questions from ill-defined problem situations. It is also a concept used to designate the fifth or postformal stage in cognitive development.

Meanings of Dialectic

The dialectic has been studied from a cultural-historical perspective across the ages. Its philosophic roots can be traced back to the ancient Greek philosopher Zeno of Elea. The term dialectic (Dialektikos in Greek) means dialogue or conversation within one's self or between the self and others. As such, it is used as a method of inquiry for the purpose of generating knowledge or seeking truth through reasoning. The dialectic when used as a method of inquiry can be linked to certain forms of creative thinking.

Modern conceptions of the dialectic particularly in psychology emerged in the late nineteenth century. These conceptions were based largely on the works of Hegel (1910/1967) particularly his conception of dialectic idealism. According to Hegel, the essence of dialectic is contradiction which is inherent in everything and which is the source of change. Change and contradiction are terms that appear consistently in developmental psychology research on adult cognition. Dialectical thinking is a form of reasoning associated with the logic of dialectic: dialectical thinking is regarded as a form of higher order thinking or reasoning, specifically postformal reasoning, for which creativity is necessary. Dialectical thinking, however, is only one of several proposed factors that can be described as 'post formal.'

Dialectical thinking has been variously characterized as a process, a cognitive style/attitude, a type of thinking associated with advanced cognitive development, or a philosophic or political system. In 1980, Basseches describes dialectical thinking as involving "orienting toward, change, forms, or relationships or in integrating these three orientations" (p. 407). Building on Basseches' work in 1983, Kramer proposed three themes running through post formal thinking: "awareness of the relativistic nature of knowledge; (b) acceptance of contradiction; and (c) integration of contradiction into the dialectical

whole." Dialectic thinking is seen as core to the conception of adult cognition.

Recently Paletz and Peng described the nature of dialectical thinking as "involving the acceptance of contradiction or necessitating the resolution of tension" (2009: 139). Peng's earlier description (Peng and Nesbett, 1999: 714) emphasized the process associated with dialectic thinking as a "cognitive tendency toward acceptance of contradiction broadly defined." Similarly Ruisel describes dialectical thinking as referring to "knowledge of processes, comparing or synthesizing facts, standpoints and opposite viewpoints" (2006: 81). In effect, this is a restatement of the thesis–antithesis–synthesis process. Despite these various characterizations, dialectical thinking for the purpose of this discussion is one of several cognitive forms of reasoning that contributes to creative thought and is an essential feature of postformal thinking.

Thesis–Antithesis–Synthesis Process of Dialectic Thinking

The thesis–antithesis–synthesis cycle represents the form or structure of reasoning associated with dialectical thinking. In a dialectic analysis, the thesis refers to the statement and the antithesis refers to the counterstatement. Both constitute the contradictory aspect of an argument. The synthesis refers to the resolution that is achieved through the coordination or integration of the contradictory parts into a dialectical whole. A synthesis in turn becomes a new thesis thus renewing the cycle of change resulting in on-going development and greater construction, deconstruction, and reconstruction of knowledge at newer, more comprehensive levels.

Consider the following thesis–antithesis–synthesis example. Nuclear waste can have a half-life of 10000 or more years depending on the type of material. Scientists therefore

search for ways to protect the public from the effects of the radiation. One common solution is to put it in massive concrete blocks and sink it to the bottom of the ocean or bury it deep in the earth at a remote location until it is no longer active.

Antithetical thinking leads to the rejection that half-life necessarily has to run its temporal course. The question becomes "How can half-life be sped up so that storage is no longer necessary for public safety?" This leads to the proposal that nuclear waste can be rendered harmless and therefore would not require storage. This dialectic thinking is highly creative in the act of bringing about resolution. Dialectical thinking does not necessarily bring an immediate problem solution but it frames well the question.

The thesis-antithesis-synthesis dynamic also underpins both Piaget's and Vygotsky's views of how cognitive development occurs. For Piaget development occurs when the stability or equilibrium of the organism is disturbed and a type of disequilibrium occurs. Equilibrium is restored when the organism is able to coordinate and integrate the source of disturbance or contradiction into the overall system. For the organism, stability is its normal state and it seeks this integration. Vygotsky, by contrast, holds that cognitive development is a product of the dialectical interaction between the self (internal) and the environment (external). He introduces the essential role of cultural context into this internal/external interaction.

Dialectical Thinking and Postformal Thinking

Riegel (1973) also emphasized the role of disequilibrium (contradiction and change) in the course of cognitive development. He argued that 'primitive' dialectic is used by people at different developmental stages, but that it is the conscious and systematic use of the dialectic that marks the final stage of cognitive development. A similar cultural argument is made by Paletz and Peng (2009: 140) with respect to a 'naïve dialecticism' which is defined in the earlier work of 1999 by Peng and Nesbitt as having three main components: (1) the theory of change; (2) the theory of contradiction; and (3) the theory of holism, that derived from ancient Asian and religious traditions.

While Piaget considers that the stage of formal operations to be the final stage, a 'fifth' stage or post formal stage of cognitive development that includes dialectical thinking as one of its forms of reasoning was proposed by Arlin in 1975.

Basseches (1980) defined dialectical thinking as a group of specific moves of thought and he provides evidence that dialectical thinking is an instance of higher order cognitive development. Basseches categorized the most mature forms of dialectical thinking as "meta-formal schemata." Features of this type of dialectical thinking include:

1. location of contradictions or sources of disequilibrium;
2. resolution of contradiction;
3. operation on open self-transforming systems;
4. comparison and contrast among systems; and
5. coordination of multiple systems.

If one takes these features and reanalyzes the 'half-life' problem the parallel to the thesis-antithesis-synthesis process is quite apparent and what appeared to be a contradiction is not.

These complimentary views of what constitutes dialectical thinking reflect early work on post formal thinking. Post formal thinking can be characterized as reasoning that is meta-systematic, reflective, and dialectic. The logic of post formal reasoning is relativistic and dialectic. It involves simultaneous expansions and contradictions of thought, a fundamentally dialectic construction. Apostle used these terms in 1979 to propose to the Piagetians a model consistent with their framework to explain development beyond formal operational thinking:

something has to happen after formal stage has been reached is the combination of different spaces of possibilities. . . . This involves two simultaneous moves . . . contractions and expansions. [Both] consist in the comparison of different types of universal logical possibilities.

The act of this type of comparison is fundamentally dialectic in nature. In 1973, Riegel used the term dialectic operations as "those directed at the creation and tolerant coexistence of inconsistency rather than its removal."

The construct of post formal thinking thus emerged out of discussions of a 'stage beyond' Piaget's stage of formal operations. To understand postformal reasoning, one needs to understand the fundamental relationship between postformal thinking and formal operational thinking and the role that dialectic thinking plays.

Formal Reasoning and Postformal Reasoning

In the latter half of the twentieth century, the dominant theory of cognitive development was that of Piaget's. Conceived first as a progressive set of age range specific stages and later as more fluid levels of increasing complexity and generality of thought, formal operational thinking (hypothetical-deductive reasoning) was considered the final stage in cognitive development in Piaget's four-stage model. In later years, Piaget himself hinted at the possibility of stages or adult forms of thinking beyond formal reasoning.

Formal operations referred to a particular logical grouping of operations, the INRC group (Identity, Negation, Reciprocal, and Correlative) and all possible combinations of these operations. Through the application of these operations eight formal operational schemes developed. These formal operational schemes were by definition "concepts which the subject potentially can organize from the beginning of the formal level when faced with certain kinds of data, but which are not manifest outside these conditions" (Inhelder and Piaget, 1958: 308). What is remarkable is that the individuals begin to think about their own thinking and to reflect on it. Formal thinkers consider not only "what is," but also "what is possible." The concept of the possible opens up new forms of creative thinking as well as well as creative problem solving.

Kuhn (2008: 50) makes the point that Piaget "raises the possibility that new, more specialized structures will be identified that are specific to particular domains" or alternatively that formal operations develop late in adolescence but only in particular domains in which they have experience, this latter view very close to Inhelder and Piaget's original definition of the eight formal schemes (1958: 308).

Postformal Reasoning and Problem Finding

One of the eight formal operational schemes or concepts is the "coordination of two or more frames of reference." This concept implies a type of relativity of thought and is one of the later developing formal concepts. Careful analysis of the tasks used by Inhelder and Piaget in 1958 and the eight formal concepts suggest that each of these tasks presents a well-defined problem to be solved through logic and the problem itself, even if very complex, has one and only one correct solution. Only the one concept of the coordination of two or more frames of reference opens up the new possibility that, depending on one's frame of reference or point-of-view, contradictory views can both be 'right.' This type of thinking marks a real advance in cognition.

The coordination of two or more frames of reference is a concept that supports the physical knowledge of relativity – which introduces relativism into one thinking. Yan and Arlin suggested in 1998 that the transition from formal to postformal reasoning involved a shift from closed to open system thinking. Open system thinking they described as nonabsolute/relativistic thinking which they proposed underlies most models of postformal thought. Recently, Wu and Chiou found that "dialectical and relativistic thinking were positively correlated with creative performance, whereas formal thinking was negatively correlated." Their finding supports the view of formal operational thinking as logical convergent problem solving and problem finding, dialectic thinking and relativistic thinking as postformal and closely related to creativity. Wu and Chiou also found that postformal thinkers scored higher than formal thinkers in all dimensions of creativity. Recently Wu and Cheng concluded that "formal operational analysis does not appear to describe adequately the creative aspects of evolving thought, that is, of theory creation rather than theory testing." In fact, they see formal thinking as in opposition to creativity and novelty.

The outcomes between problem solving and problem finding also differ. Successful problem solving is "the discovery of one specific acceptable answer to one well-defined problem" while success in problem finding is "the discovery of many general questions from many ill-defined problems" (Mackworth, 1965: 57). Mackworth further observes that:

basically it is a rather exacting requirement to have to work back from an unknown point – or to have to simplify the mismatch between present position and an unknown destination. [In effect one is] ... searching for the unexpected. (Mackworth, p. 60)

In his 1965 work on originality, Mackworth distinguished problem solving from problem finding. According to Mackworth, these are essentially different processes: "Problem solving is the selection and use of an existing program from an existing set of programs" while problem finding is defined as the "the detection of the need for a new program by comparing existing and expected future programs." Ruisel (2006: 81) describes dialectical thinking as referring to "knowledge of processes comparing or synthesizing facts, standpoint and opposite viewpoints" which brings it more in line with Mackworth's sense of problem finding rather than problem solving. Savina (2000: 77) puts it more succinctly describing dialectical thinking as 'mediation of oppositions.'

What emerged from the research on formal operations and problem finding is the suggestion of a 'fifth' stage, the problem finding stage by Arlin in 1975, as a "stage beyond formal reasoning," (Riegel, 1973), that incorporates dialectical reasoning and living with contradiction, or simply a "stage beyond" (Niemark, 1975) that account for some forms of adult cognition not accounted for by Inhelder and Piaget's (1958) formal operations.

"Awareness of and reflection on one's own mental processes showed a similar developmental pattern to relativistic/dialectical thinking" (Verkman, 2005: 211). In her work Verkman described a variable developmental pattern with a low relationship in adolescence; an increase in early adulthood, peaking in mature adulthood and a slight downward trend in older adulthood with respect to relativistic/dialectical thinking. This is a line of inquiry consistent with the earlier cited work of Yan and Arlin in 1998.

Fifth Stage and Postformal Thinking

The recognition that the formal operational stage is about problem solving of well-structured problems that yields one agreed-upon solution led to the question of how to account for ill-structured problems for which there are no known solutions and no criteria by which proposed solutions might be judged. A proposed new stage, the fifth or postformal stage emerged. This fifth stage is the problem finding stage since the stage of formal operations is best characterized as the problem solving stage.

This new stage accounts for the formulation of and grappling with ill-structured problems, the solution of which is "the discovery of many general questions from many ill-defined problems" (Mackworth, 1965: 57). Mackworth quotes Bartlett (1958) that "the most important feature of original thinking was the discovery of overlap and agreement where formerly only isolation and difference was recognized" (p. 63). These early emphases appear to link originality and creativity to dialectical thinking, relativistic thinking, and problem finding or, in other words, the "searching for the unexpected." "Searching for the unexpected" is an apt description of the creative process.

Researchers from a variety of perspectives intensified their studies of different forms of uniquely adult cognition and in the process transformed the search for a fifth stage within the Piagetian framework to studies "beyond formal operations" and ultimately to studies of postformal reasoning which were in large measure "stage free" and represented competing philosophical and psychological stances about adult cognition.

Dialectical Thinking and Creative Thinking

Schon described in 1966, the process of invention as involving the displacement of concepts. Displacement takes place through analogy that he defined as the shift of old concepts to new situations. The old concept is taken as a symbol or metaphor for the new situation in the process of shifting

concepts. In face of conflicts, a process Schon calls 'frame-restructuring' takes place that involves the "coordination and reconciliation of conflicting descriptions of particular situations." The product of this coordination and reconciliation is a "new integrated image of the situation." 'Frame restructuring' seems to involve not only relativistic thinking but also a type of dialectical thinking that opens the door to a new way of thinking about the relationship between dialectic thinking and creative thinking.

New measures and assessments of postformal and dialectical thinking have contributed to the progress made in the study of advanced forms of adult thinking. There is no parallel development of ways to assess mature creative thinking. Even the most recent assessments rely heavily on Guilford's "structure of the intellect" model of 1967 and Torrance's translation of a subset of these factors into a set of divergent thinking tasks. What is needed to propel this research forward are well developed postformal measures of creativity. Paletz and Peng have recently taken a step in this direction.

In effect, it appears that the core of dialectical thinking is fundamentally creative in nature. Invention, discovery, originality, the use of metaphor as a process of thought, frame-restructuring are all ways researchers have sought to describe the creative process and creative thinking.

New work suggests that the relationship between dialectical thinking and creative thinking may be culturally moderated as well as moderated by task and process. Nonetheless, Paletz and Peng argue that dialectic thinking conceived as "an understanding of reality, thought, and the interrelation of systems supports creativity and is post formal" (2009: 141). Succinctly Peng in earlier work (Peng and Nesbett, 1999: 714) suggests that dialectical thinking is broadly defined as the "cognitive tendency toward acceptance of contradiction." What other factors there are that moderate the relationship between dialectical thinking and creative thinking for the most part remain to be discovered.

ISAK DINESEN was a Danish writer who married Baron Bror von Blixen, moved to Africa and established a coffee farm in Kenya from 1914 to 1931. Her experiences with the African people enabled her to write Out of Africa, required reading for U.S. Peace Corps members working in Africa. It was the loss of her coffee farm that led to her writing when she returned to Denmark. She wrote in English; her first book, Seven Gothic Tales, became an immediate success in the United States. She worked in the genre of the tale and in nonfiction narrative. Internationally admired by other authors and poets, she was a literary force both in the United States and in Denmark. When Ernest Hemingway accepted the Nobel Prize for literature, he cited Isak Dinesen as a writer who also deserved it.

Isak Dinesen. (Copyright Rungstedlund Foundation.)

Background

Isak Dinesen, Karen von Blixen, was born in Denmark on April 17, 1885, as Karen Christentze Dinesen (Tanne). Her parents were Wilhelm Dinesen (1845–1895) and Ingeborg Westerholz (1856–1939). There were four other Dinesen children: Inger (Ea), born in 1883; Ellen (Elle), born in 1886; Thomas, born in 1892; and Anders, born in 1894.

In Denmark, Dinesen and her sisters were privately educated, which meant that they were expected to marry and were not prepared to earn a living. Later they attended the Ecole Benet, where Dinesen showed a talent for drawing. Dinesen's family history formulates a basis for her creativity and the subsequent relationships in her life. Karen Dinesen was the second-born child. The firstborn daughter, Inger, was

smothered by the Westerholz females, and the father, Wilhelm, had been excluded. Overwhelmed by this enormous female presence, Wilhelm promised himself that the next child would be his. Karen Dinesen was the only one of the five siblings who became extremely close to her father. Wilhelm told her stories of his life. He had gone to America as a young man; it was a romantic pilgrimage from Quebec to Chicago to the wilderness around Oshkosh, Wisconsin, where he bought a cabin and renamed it Frydenlund. He lived there alone for months, during which time he hunted and he baked his own bread. He loved the Indians and saw them as romantic figures, powerful and wise.

Dinesen spoke of her father's total acceptance of and love for her as a small child. She adored him and did not want to share her intimacy with him with anyone. She took pride in being her father's girl, not "theirs," her term for the Westerholz women. Wilhelm confided in her, treated her like an adult, and shared confidences with her, especially when he was troubled. That is why she was devastated at the age of 10 when her father committed suicide in 1895.

In Wilhelm's suicide note to his wife, Ingeborg, he wrote that the two other girls would fend for themselves, "but my heart aches for little Tanne." He did not mention his two sons, Thomas (age 3) and Anders (age 1). Karen (Tanne) Dinesen felt an enormous guilt that somehow she was powerless to dissuade Wilhelm from his ultimate fate: He hanged himself from the rafters of his apartment. Thomas believed that his father had been suffering from syphilis. Ironically, when he shared this revelation with Karen Dinesen, years later, she herself was suffering from syphilis. "My father's destiny," she said, "has, curiously enough, to a great extent, been repeated in my own."

Dinesen grieved for her father, even into adolescence. She thought "constantly" about her father and felt his absence from her life as an intolerable tragedy. At the age of 15, in the following letter, she makes a passionate plea to him:

My dear and beloved friend, my wise and gentle brother: If you had been on earth still, I should have come to you and you would have taught me to love and to approach thine [sic] light, but you are gone away to high worlds, I know not where you dwell, spirit that I love. But do not leave me alone, if your spirit dwells still sometimes on earth, where you loved and suffered, let it dwell within me, who love you. And give me only once a token that you live and are the same, and that my spirit could reach thine, and if you give it me, I shall follow your footsteps and be your disciple, today and always. Perhaps I shall be it in all cases, but you know, my brother, how hard it is to be alone, be with me, and give me your bless [sic] dear beloved brother, my master, and teacher, my dearest friend.

It is significant that this letter was written in English, a foreign language to Dinesen, but a foreign language can provide distance and thus protect one's emotions. It can also ensure privacy.

This letter is also a remarkable example of Dinesen's romantic ideation of her father. She literally attempts to merge her identity with Wilhelm, to become him in order to possess his characteristics. His wisdom, his power shall be hers. She will not feel so vulnerable; she will not be alone. Her choice of words to address Wilhelm reveals her feelings toward him: "dear beloved brother, my master and teacher, dearest friend, wise and gentle brother." Theirs was a relationship that transcended father and daughter in an intimate and interdependent way, for Dinesen becomes both *personas*.

That sense of union extended into her later life. When her marriage and her farm were both foundering, she wrote to her mother: If I can make something of myself again, and can look at life calmly and clearly one day—then it is Father who has done it for me. It is his blood and his mind that will bring me through it. Often I get the feeling that he is beside me, helping me, many times by saying: "Don't give a damn about it."

Dinesen's idealization of her father and her subsequent romantic ideation of him pervaded her life. It was the first link to a series of romantic ideations and losses that also led to her creativity as a writer.

The second significant male in Dinesen's life was Bror von Blixen (1886–1946). Though he became Dinesen's husband, it was his twin brother, Hans, with whom she fell madly in love at age 24. Hans, who raced horses and airplanes, rejected her, and Bror was not interested in her either until he realized that she was passionately in love with Hans. Then he assiduously courted her. Hans's rejection was very difficult for Dinesen. Her maxim was that the final word as to what one is worth lies with the opposite sex. So it was Bror whom Dinesen accepted as her husband after his third proposal.

Her family fought the engagement; her friends questioned her integrity in marrying the twin of the man whom she really loved. All of this made her more tenacious in her decision to marry Bror, to leave Denmark, and to begin their coffee farm in 1914. It was Bror von Blixen who taught her how to shoot. He took her on safari with him, and she loved it—even the skinning of the lion down to his "elegant bones." It was von Blixen who gave her syphilis, a fact long hidden in her earlier biographies. Dinesen returned to Denmark for medical treatment in 1915, and by 1916 the disease was under control and she was noninfectious. Von Blixen never hid the fact that he slept with native women, and syphilis was almost epidemic among the Masai women.

In Africa it was Bror, not Hans, who became a romantic legend, immortalized as Robert Wilson in Hemingway's "The Short Happy Life of Francis Macomber," and worshiped for his enormous courage and spirit by Beryl Markham in *West with the Night*. He became the standard by which hunters were measured. Dinesen loved this aspect of von Blixen, and she loved being the "Baroness."

Though Dinesen tolerated von Blixen's affairs and entertained a few of her own, she did not want the divorce. Von Blixen left the house in 1919 and divorced her in 1922. It was in 1918 that Dinesen met Denys Finch-Hatton. Finch-Hatton, too, was a superb hunter who frequently went on safari with

von Blixen (von Blixen would laughingly introduce Finch-Hatton as "my friend and my wife's lover"). A year after the divorce, Finch-Hatton moved his things to the farm.

Denys Finch-Hatton (1887–1931) was the great romance of Dinesen's life. Adored by everyone at Eton, enormously successful at Oxford, worshiped in Africa, his charm, wit, and intellect were tremendously admired. Like Wilhelm and like Bror, Finch-Hatton came and went frequently; he, too, was restless. In 8 years of living on the same farm, he and Dinesen actually spent only 2 years and 2 months together. The constant separation heightened their passion: a blatant definition of romantic love. They never dealt with reality, and Dinesen catered to his every wish. He enriched her life with music and poetry; he gave her a new perspective of Africa from his small plane. Good food, fine wines, stimulating conversation—these were the things they shared.

Isak Dinesen (Karen Blixen) at 30 years of age taken outside of Karen House in Kenya. (Copyright Rungstedlund Foundation.)

Midway in their relationship, Dinesen (age 41) thought she was pregnant. She cabled Finch-Hatton, using the code name Daniel for the child. Finch-Hatton replied, "Strongly urge you to cancel Daniel's visit." A second cable read, "Do as you like about Daniel as I should welcome him if I could offer partnership but this is impossible." Given her age and medical history, Dinesen probably had a miscarriage: Daniel was never born. This was a reality she could not ignore. Nor was the loss of her farm in 1931. Never economically viable, the coffee farm finally folded. Again, Finch-Hatton refused to help her. There was no offer of marriage, no arrangement for her economic security. She returned to Denmark, to her mother's house at Rungstedlund. The couple later quarreled, and he took back his ring. It was Beryl Markham whom Finch-Hatton invited to accompany him to Voi, his final and fatal flight in his gypsy moth. At first she accepted, then refused because her flight instructor, Tom Black, had a "bad feeling" about her going. It was a fatal crash that claimed Finch-Hatton's life in 1931.

Ironically, it was only in Finch-Hatton's death that Dinesen finally possessed him. She picked his gravesite which they had once chosen, and presided at his funeral; she acted as the significant woman in his life, changing the stories of their last moments together. But this romantic ideation was not enough. Dinesen attempted suicide, slashing her wrists in a friend's house before she left Africa. She also left a suicide note,

which has since vanished from the von Blixen archives. Though she lost a lot of blood, her attempt served as a catharsis from her excruciating pain. It is not insignificant that Dinesen attempted to replicate her father's demise. Wilhelm was the idealized male model whom Dinesen repeatedly sought. Her choices of von Blixen and Finch-Hatton reflected her narcissistic needs. She projected onto these men what she felt she wanted, needed, to be complete. What she desired from both men was an intimacy, a commitment that even her father had not given her. Had she transcended her narcissistic needs, she might have observed that neither of the two men possessed nor desired a capacity for intimacy or commitment. They had much in common: their physical prowess as hunters, their courage, their independence from convention, their need for adventure and solitude, and their reluctance for commitment in relationships.

The two men were blatant in their words and actions. Dinesen saw and responded to what she wished to see. Von Blixen was uncultivated and rough beside Finch-Hatton, but she fought the divorce because she felt vulnerable, abandoned. With Finch-Hatton, the scenario was repeated. Things went well until she needed him. The possession, the control that she desperately sought, always evaded her—until later in Denmark where she met Thorkild Bjørnvig. Dinesen returned to Denmark to live with her mother at Rungstedlund and began writing *Seven Gothic Tales*. Published in 1934, it was a huge success both in the United States and in England. In 1938 *Out of Africa*, an account of her life on her coffee farm in Kenya and her experiences with the native Africans, marked Isak Dinesen as a modern classical writer. She explained why she chose Isak Dinesen as her pen name. Dinesen was her family name and a connection with her father, Wilhelm. Isak means "laughter" in Hebrew, and like the biblical Sarah, who miraculously bore Isaac past her prime, Dinesen now bore her literary creations past her own prime. She had found laughter, she said, and she continued writing: *Winter's Tales* was published in 1942 and *The Angelic Avengers* followed in 1946.

In 1949, Thorkild Bjørnvig, a young Danish poet, entered Dinesen's life when she was 64 years old, living in Denmark, and experiencing "a period of great starkness in her life." The more a "productive dimension" eluded her in her own writing, the more she considered turning Bjørnvig into a poet. "Imperfect and incomplete alone, together they would be a unity." Once more Dinesen was engaged in romantic ideation, searching for the male to bring her to perfection. They formed a pact, a mystical union, a vow of eternal love. Bjørnvig would justify her efforts by becoming a firstclass poet by bringing glory to them both.

Dinesen began by trying to make Bjørnvig "a man of the world"—like her father, Wilhelm, or Finch-Hatton. This relationship lasted for 4 years (until 1953). Though Bjørnvig had a wife and son, Dinesen repeatedly claimed him: he lived in her house for months at a time. She dominated him, played God with his life, caressed and bullied him simultaneously, and spoke of leaving Rungstedlund (her family estate) to him if he would live with her. When Bjørnvig fell in love with a young woman, Dinesen felt betrayed, both as a woman and as his "god." When the affair ended, Bjørnvig returned to his wife and attempted to break the pact with Dinesen. The following is an excerpt from the pact:

You shall belong to no one and to nothing, to no party, to no majority, to no minority, to no society except in that it serves me at my altar. You shall not belong to your parents, nor to your wife nor children, nor to your brothers and sisters, nor to them who speak your language, nor those who speak any other—and best of all to thine own self. You shall belong only to me in this world.

Dinesen signed this document and gave it to Thorkild Bjørnvig. It took time. In one of their last meetings, on a walk, they encountered a snake lying in the sun. It did not move as they approached it. How each construed the snake as a symbol defines their relationship. Dinesen saw it as a good omen, something to protect them both from good and evil. Bjørnvig saw it as an indication of Dinesen's satanic power over him. He wrote his final good-bye to her, and she accepted it. But she did not completely relinquish her control over him. She used him in her fiction.

Like most writers, Dinesen exploited her experiences and transformed them into her tales. In "The Dreamers" from *Seven Gothic Tales* she creates Pellegrina Leoni, a great opera diva who allegedly died in a theater fire in Milan 13 years before the story begins. Though she recovered from the burns, Pellegrina lost her voice and would never sing again. She insisted on a burial service, and the world believed her to be buried in a little cemetery in Milan. She had attempted suicide and now felt that Pellegrina was indeed dead. "I will not be one person again . . . I will be always many persons from now. Never again will I have my heart and my whole life bound up with one woman, to suffer so much."

Pellegrina admonished her Jewish friend, Marcus, "Be many people." And she does precisely that: She becomes Ollala who inhabits an Italian brothel; she is also Madame Lola, a milliner by day and a revolutionist by night; she is also a religious martyr named Madame Rosalba. Three men fall in love with each female character whom they have met, and when they tell each other their stories, they all define "their woman" as the possessor of a deep, white scar from her left ear to her collarbone who is followed by a very wealthy, elderly Jew. When each man tries to possess her, or force her into a fixed identity, she disappears.

Pellegrina's rejection of self, of identity, evolves from her excruciating pain: the loss of the beautiful voice that defined her. Knowing who she is and who she was, she consciously assumes a myriad of identities. In becoming all of these women, she is none of them. She has traded the myth of Pellegrina for a series of mythic women, none of whom really exists; she is spiritually dead. When Pellegrina is discovered by her three former lovers, she throws herself from a precipice and loses consciousness. When she awakens, she is Pellegrina, the opera diva, and she attempts to finish the aria of *Don Giovanni* that she was singing the night of the fire. She has returned to herself.

Dinesen admitted that Pellegrina represented herself; that the loss of the diva's voice by fire symbolized the loss of her farm. It is likely that this loss extended to Finch-Hatton, to her broken marriage, and even to Wilhelm. Her loss was inextricably bound to these men to whom she looked for her own identity. The romantic ideation in her life evolved into her fiction. It became a powerful source for her creativity.

Later, Pellegrina Leoni becomes the focal point for Dinesen's relationship with Thorkild Bjørnvig, the young Danish poet.

Dinesen admitted that his violent rejection of her possessiveness formed the basis of her story “Echoes” in *Last Tales*. The theme again deals with romantic ideation, with the possession of the qualities of the idealized romantic figure. Pellegrina no longer has a voice, but she has a young pupil, Emanuele, who sings like an angel. Pellegrina wants total control of and adulation from him. When she first hears him sing, she is convinced it is the voice of the young Pellegrina Leoni. She felt her own lungs drawing breath in his body and his tongue in her own mouth . . . she made him talk and made his eyes meet hers, and she sensed, as she had often done before, the power of her beauty and her mind over a young male being, her heart cried out in triumph: “I have got my talons in him. He will not escape me.” And later, “In three years we two will be one, and you will be my lover, Emanuele.” Pellegrina’s possession will be complete when she also sexually rules Emanuele. He will become *her* voice, the manifestation of her talent, her creativity, her genius. But Emanuele finally fights for his freedom, his identity. When Pellegrina pricks his finger with a needle, takes three drops of blood on her handkerchief, and sucks them, he believes she is a witch or a vampire and he flees. When she pursues him, he hits her with a large stone, drawing blood from her head. It is only his violent action that enables him to free himself from her possession. Pellegrina needs Emanuele to be whole, to be vital. First, she idealizes him, and then she needs to possess him. There is also an inherent narcissism here, because Pellegrina does not think or care about Emanuele as a person, but as an extension of herself.

Thus the theme of romantic ideation permeates the life as well as the writing of Karen von Blixen, whom the literary

world knew as Isak Dinesen. Although the men in her life whom she wished to possess finally eluded her—her father, Wilhelm; her husband, Bror von Blixen; her lover, Denys Finch-Hatton, and the young poet, Thorkild Bjørnvig—she possessed a portion of all of them in her writing as she sought out the idealized male figure as a way to make herself complete. In 1955, Dinesen’s spinal nerves were severed in surgery; 6 months later she experienced extensive surgery for a stomach ulcer. As a result she was virtually an invalid and never regained her health, but she continued to write: *Last Tales*, 1957; *Anecdotes of Destiny*, 1958; *Shadows on the Grass*, 1960 (a return to Africa and the native Africans). She was appointed an honorary member of the American Academy and was one of the founders of the Danish Academy. *Letters from Africa (1914–1931)* was published posthumously in 1978. On September 7, 1962, Dinesen died peacefully in her sleep at Rungstedlund; she was 77. She was buried at the foot of Ewald’s Hill (named for a poet) on her family estate.

Glossary

Aesthetics The set of criteria used to decide what is worth investigating and to compare the relative values of discoveries and inventions.

Anomaly An observation that is reproducible but that challenges current theory by refusing to fit within its explanatory framework.

Hypothesis A provisional explanation of phenomena devised with the intention of testing its adequacy.

Illumination A sudden insight following a long period of fruitless problem-solving effort, resulting in a previously unimagined solution to a puzzle.

Invention The creation of something novel by intention (as opposed to serendipity – see below).

Serendipity Searching for one thing and finding another as a result of error, unexpected observation, or unpredicted results.

Theory A broadly explanatory, integrative, mature hypothesis that has repeatedly been challenged by skeptical testing, the predictions of which continue to be validated without yielding contradictory results of significant anomalies.

Definitions of Discovery

Scholars have offered many definitions of discovery, each of which captures a different facet of the subject. For Noble laureate Albert Szent-Gyorgyi, "Discovery is seeing what everyone else has seen and thinking what no one else has thought." Even in the discovery of new phenomena, there is always a concomitant intellectual or theoretical leap. At least a dozen people saw the fogging of photographic plates by radioactive materials before William Röntgen recognized that it was not a problem with the manufacture of the plates, but of something in the laboratory causing the fogging. The result was the first systematic search for what might cause fogging and the discovery of X-rays. More than two dozen bacteriologists saw antagonisms between microbes before Alexander Fleming brought to his observations the problem of how to cure pathogenic infections and perceived the antagonisms as evidence of antibiotic properties. The result was penicillin. Even the discovery of a new species of plant compound or star is only interesting or important within the context of broader issues of chemical engineering, pharmacology, taxonomy, evolution, or cosmology. Martin Harwit argues that, "the distinction between mere detection and actual recognition of a new phenomenon is therefore crucial. We may now be detecting many phenomena that we do not recognize."

To discover something requires giving it meaning within a broader context of human knowledge. The more profound the discovery, the more data or phenomena it connects, the broader its applications, and the more diverse its implications and meanings. Nothing has been discovered if its meaning is not understood. In consequence, there is often a delay between the first time a new object or phenomenon is described and when it is discovered.

Discoveries also link observations, ideas, or theories in new, previously unexpected ways. Albert Rothenberg suggested that discovery can be almost Janus-like: the melding of two

opposing faces or concepts into one body. For example, during the 1920s most scientists believed that Darwinian evolution and Mendelian genetics were contradictory because Mendel's laws assumed that genetic traits were conserved and unvarying, whereas evolution required constant sources of genetic novelty. Either one or the other was wrong. The apparent contradiction was resolved during the 1930s when T. H. Morgan and H. J. Muller discovered mechanisms of genetic mutation. Genetic traits are both invariant and new ones can also occasionally arise by mutation. *Either-or* became *both-and*. Rothenberg's Janus-like view of discovery also captures how discoveries link apparently unconnected concepts. J. C. Maxwell connected electricity, magnetism, and motion. Charles Darwin integrated comparative anatomy, paleontology, geology, geography, animal breeding, anthropology, and economics. Prior to the work of these scientists, these fields had developed largely without regard for each other. Afterwards, they were integrally linked.

An equally broadly applicable analogy for the process of discovery has been provided by Arthur Koestler who suggested that discoveries have the same basic structure as jokes. Jokes often employ structures in which the listener is led to expect one outcome and is surprised to find that the punch line provides an unexpected resolution. Indeed, many scientists have commented that the greatest discoveries are met with the same sort of surprised laughter elicited by a good joke. Sometimes the laughter is born of surprise, sometimes of disbelief, sometimes of ridicule.

One critical issue on which debate persists is whether discovery is a process or an act. Is the discovery, as Koestler would have it, made at the exact time one has the surprising insight, or is the preparation that precedes it also an integral part of the process, as Henri Poincaré argued? Is discovery synonymous with inspiration (the sudden illumination that has given rise to the popular image of a light bulb going off in one's head) or the 99% perspiration that Thomas Edison insisted was

necessary to make the inspiration pay off? This article assumes that discovery is a process in which inspiration plays only a small role.

The basic model of the process of discovery has a series of interlinked steps. Generally a problem is recognized by some inconsistency between accepted observations and theory; the nature of the mismatch between observation and theory defines the kinds of hypotheses that are possible to explain the problem; possible solutions to the mismatch are elaborated and ways to test the solutions proposed; techniques or methods are acquired or invented to test the possible solutions; more often than not, the cycle is repeated as the tests yield unexpected results that disprove or simply do not fit the proposed set of solutions; and thus, new problems are posed. Sometimes, however, the predictions made by one of the hypotheses appear to match the outcome of the tests. Then the investigator must verify the insight by repeating it and showing that other obvious explanations for it are untenable, communicate the results, convince skeptical colleagues of the legitimacy of the result, and demonstrate that the discovery proffers new things to be investigated or solves outstanding problems in novel and useful ways.

As Thomas Kuhn argued, one of the most critical aspects of any discovery is that it changes the way scientist think about and do their science. The change can be in theory, experiment, method, or even institutional organization. More and more investigators are recognizing that part of this process involves social forces that determine the latest fads in funding and hiring, and that aesthetic considerations, such as how the discovery fits into current scientific fashions, may speed or delay acceptance and recognition of a discovery.

In sum, the process of discovery is complex, involving philosophical, empirical, theoretical, aesthetic, and social elements, as well as the psychological ones that determine how the discoverer creates or stumbles upon his or her novelty. The surprise of insight that some investigators identify with discovery is but one temporally distinct phase within this complex process.

Who Discovers

Every discovery to date has been made by a person. In the age of computers, this is not a trivial statement. So far, several computer programs have generated novel proofs of previous conjectures made by human beings, but no computer has yet generated a new and useful problem, hypothesis, or conjecture, let alone observation. As Poincaré once said, logic proves, it does not invent. Thus far, his statement has proven to be true. Whether computers will be able to be programmed to have 'imagination' in the future will stand as one of the greatest challenges of artificial intelligence.

Given that people have made all known discoveries up to the present time, one must ask what characterizes discoverers. It is clear that the ability to make discoveries is just as asymmetrically distributed in the general population as is, say, musical or artistic talent. While nearly everyone can learn to do an experiment or play an instrument, very few have the talent of an Einstein or a Mozart. The difficulty is that recognizing this talent is not a trivial problem. Einstein's potential was

certainly overlooked well into his adult years. A few eminent scientists have, however, displayed the same sort of precocity as Mozart. William Bragg, who won the Nobel Prize at the age of 22 is one example. Notably, studies of precocity among scientists, as determined by high standing in Science Talent Search competitions for high school students, shows that precocious teenagers have no higher probability of staying in science as a career than do other students planning science careers. While some national winners have gone on to win Nobel prizes, the majority have not even remained within science. Intelligence tests, standardized tests such as Achievement tests, tests of divergent thinking, and psychological profiles have also failed to identify any significant predictors of who will succeed in science. A significant number of eminent scientists have moved into science careers only during or after college, in fact, so that their talents were late blooming.

The factors that do seem to correlate significantly with the ability to make discoveries are of quite unexpected sorts. One is training with a previously successful discoverer. Nearly all Nobel prize winners have studied with a previous laureate at some time during their schooling or early careers. Whether such training conveys certain tricks of the trade or creates personal networks of power that help to facilitate the acceptance of discoveries, or both, is not clear from current studies. In any event, there are clearly established student-teacher lineages of eminent scientists that can be traced for many generations.

Another personal correlate for success as a discoverer is hobbies, or intensive leisure time activities. Those scientists whose work is recognized as being the most important for their science (as measured by honors, total citations to their papers, or the number of individual high-impact papers they publish) tend to engage intensively in hobbies such as painting, music, writing poetry, sculpture, professional-level chess, or other endeavors that require significant time and energy to master. These discoverers are often highly talented in their avocations, so that a significant proportion of Nobel laureates report that they have faced difficult career decisions between science, one of the arts, and sometimes the law or business as well. A few, such as Desmond Morris, who is a professional painter as well as ethologist, and Aleksandr Borodin, whose musical compositions are better known than his chemistry, have even managed to carry on joint careers.

Mitchell Wilson, a physicist, inventor, novelist, and historian of technology, notes that the reason hobbies may correlate with scientific success is that the discoverer needs not only expert knowledge, but a poet's affinity for words and their meanings, the artist's ability to observe and think graphically and dynamically, and the musician's appreciation for complex patterns and the finesse of playing instruments – in this case, scientific ones as well as musical ones. A breadth of skills therefore hones the scientist's talents for discovering.

Non-scientific talents may also hone the discoverer's thinking skills. A direct correlation has been found between the ability of eminent scientists to think in three dimensions and their participation in the arts. Musical ability also seems to improve visualization as well as kinesthetic sensibility. Similarly, verbal skills are highly associated with verbal hobbies such as poetry. The ability to think in three-dimensions, dynamically, to use kinesthetic thinking skills, and to utilize an

unusually broad range of nonverbal forms of thinking, is in turn highly correlated with the importance and number of discoveries a scientist makes. As Max Planck, who received a Nobel Prize in Physics, once commented, “the creative scientist needs an *artistic* imagination.”

Age is also certainly related to the probability of making discoveries. Young scientists are more likely to make discoveries than older ones and the earlier that a scientist has the opportunity to do independent research, and the earlier they publish, the greater the probability of long-term recognition. The probability distribution of making a discovery varies by specific discipline, however. The probability peaks at around 25 years of age for mathematicians, 30 for physicists, 35 for chemists, and in the early forties for biologists. As with all statistical distributions, there are, in this case many important, exceptions. Some mathematicians have made their first major discovery in their sixties, and some biologists have done their best work in their early twenties.

What is perhaps more interesting about age and the probability of discovery is that there are two very different groups among discoverers themselves. The dominant group consists of people who make a single important discovery during their lifetimes – a Jonas Salk with his polio vaccine or Watson with the structure of deoxyribo nucleic acid (DNA). These people tend to stay within the field of their expertise. The minority group consists of individuals who make multiple, major discoveries often spanning their entire careers. These people tend to change fields often and are characterized by having made three or more major discoveries by their mid-forties. Such people tend to state explicitly that they use field changing, or what has been called the ‘novice effect,’ purposefully to stimulate new ideas. Linus Pauling, who worked on chemical bonding, protein structure, DNA structure, hemophilia, vitamin C, and many other scientific problems, is typical. Such field-changers state that they are invigorated by having to grapple with new problems and mastering new scientific tools, while they also bring to the new field their experience and knowledge of the ones they have explored previously. Insights, they say, often result from this melding of previously separate knowledge and practices.

While the most successful discoverers tend to be productive, productivity cannot be used as a measure of either discovery or potential to discover. There is no correlation between productivity and discovery at all. Gregor Mendel produced a mere seven papers and revolutionized science by inventing the basic principles of genetics. Banting gave the world insulin and a lifetime total of less than three dozen papers and earned himself a Nobel Prize. James Watson’s total scientific output consists of less than 50 scientific papers, and yet he, too, revolutionized science with his discovery of the structure of DNA, the molecule containing the genetic code.

Some discoverers are, on the other hand, prolific. Pauling produced many hundreds of papers, as have most of his Nobel-winning colleagues and Thomas Edison produced 1093 patents, still a record for an individual inventor. Edison, however, never discovered any new principles or devised any theorems that contributed to science, whereas another great inventor, Michael Faraday, not only invented electrical motors and generators, but also provided the intellectual basis for the science of electromagnetism. He, in other words, not only

created new things, but explored and explicated their meaning. He thereby raised his work from mere invention to the plane of real discovery. Thus, simply being prolific does not necessarily lead to discoveries. Indeed, some of the most prolific scientists are also the most obscure. John Edward Gray, an nineteenth-century botanist whose work is largely forgotten, produced 883 papers. Similarly, the most prolific author in current computer sciences, with more than a thousand papers, has not, according to his colleagues, ever written one worth reading and most of his papers have never been cited by anyone in the computer literature, including himself. Clearly, the quality of the discoveries or inventions made by an individual is, in the long run, of much greater consequence than the quantity.

It is also worth noting that a significant number of discoveries have been made by amateurs (see also the later section ‘Discovery Outside of the Sciences’). Amateur astronomers have been responsible for the first sightings of the planet Pluto and of many of the comets that have been named. Amateur geologists are a constant source of new finds for paleontologists and are responsible for the discoveries of some of the most outstanding dinosaur remains found in recent years. Dedicated investigators such as farmer Wilson Bentley, known to posterity as ‘the snowflake man,’ have provided some of the best data and many of the key concepts in meteorology. And it is worth remembering that Charles Darwin, Jane Goodall, Dian Fossey, and many other eminent biologists have also been amateurs. What makes a discoverer is not necessarily formal training, but the acquisition of expertise by dint of hard work and hard thinking.

Indeed, it is worth remembering that in the fields of ignorance, there are no experts; for if the experts had the answers, then persistent unsolved problems would not exist. Discoverers, no matter what their educational background, are therefore always pioneers.

How Discoveries Are Made

Discoveries come about in as many ways as there are discoverers. There are, however, some general strategies that seem to work more often than others. Peter Medawar, a Nobel laureate in Biology, has admonished students that if they want to make an important discovery, they must choose a big, important problem. G. P. Thomson, a Nobelist in Physics, notes that there is no correlation between difficulty and importance of a problem. The big ones can be just as easy (or difficult) to solve as the little ones. Neils Bohr, another Physics laureate suggested that the best problems can be found by focusing on paradoxes – the places where theories and observations are non-congruent or contradictory, and thus of the sort Rothenberg describes. Physicist and historian of science, Thomas Kuhn notes that revolutions in science always follow the recognition of outstanding anomalies to the assumptions underlying a field. Pauling argued that the key to success is to, “have lots of ideas and throw away the bad ones.” And almost everyone agrees that the greatest discoverers have great courage when it comes to speculating and inventing. Thus, the greatest discoverers are also universally characterized as having made some of the biggest scientific blunders on record. Einstein, for example, announced at least three times in his life that he had

invented a unified field theory to explain all of physics. He was demonstrably wrong each time. The lesson is that to succeed in science, you must dare; and to dare, you must be willing fail.

Error itself is a frequent source of discoveries. "Man errs, so long as he is striving," said Goethe. Indeed, every discoverer of note has made errors from Newton and Vesalius to Einstein, Crick and Watson. What distinguishes the discoverer from the forgotten scientist is that the discoverer recognizes in his own errors the seeds of new possibilities. As Magendie, the founder of modern physiology, often said when an experiment gave a result different from that he predicted: "I was mistaken, but it is much more interesting than if I had succeeded. . . . A new phenomenon, so much the more important as it is so little expected." Similarly, J. J. Thomson was found of saying that "though a theory might be Bohemian, it might be the parent of very respectable facts." What counts in science is the dialectical process of self-correction that constantly pits theory and experiment against one another. In fact, if one follows Sir Karl Popper's philosophy of science, then error is the only true method of science, since Popper maintains that theories can only be disproven, but never verified. The best scientists are therefore often those who actually search for errors, comparing and contrasting existing theories.

Error is, of course, only one of many strategies employed by successful discoverers. Some discoveries have resulted from scientists taking infinite pains with the minute details of systems they are studying. The discovery of the element argon resulted from the observation by Lord Rayleigh that nitrogen prepared from the air is heavier volume for volume than that prepared from chemical compounds. This observation suggested that something must be contaminating the aerial nitrogen. This contaminant turned out to be argon.

Another common strategy is to extrapolate. As soon as Rayleigh announced the discovery of argon, William Ramsay predicted that an entire column of previously unsuspected inert gases must be present in the period table of elements, and he proceeded to isolate them. Rayleigh and Ramsay both won Nobel Prizes for their work.

Other scientists have played mental games with current scientific dogmas, turning them on their heads, contradicting basic premises, or simply wondering 'what if' some principle that everyone considered to be unquestionable were not. Curare, which kills by paralysis, for example, has been turned into a useful drug by harnessing its paralytic effects for surgical procedures in which complete cessation of movement is necessary on the part of the patient. A deadly poison thus gives life. Analogies, metaphors, and even the recreation of ancient historical experiments have all been touted as additional aids to discovery.

In conjunction with various strategies of research, many scientists and inventors have also discussed the mental 'tools' that they have used to make their discoveries. Their descriptions are generally similar and quite surprising. To begin with, very few scientists use either mathematics or verbal languages to do their thinking. Einstein, in fact, stated explicitly (in what may amount to an overstatement) that, "No scientist thinks in equations." He then went on to explain that in his case, he did his problem solving by using "certain signs and more or less clear images which can be 'voluntarily' reproduced and combined . . . as well as muscular feelings. . . ." Einstein also noted

that the use of words and equations came only when the images and feelings had become well enough developed that they needed to be formally tested and communicated. Cyril Stanley Smith, a metallurgist, also noted that "The stage of discovery was entirely sensual and mathematics was only necessary to be able to communicate with other people." Notably, both the use of visual images, kinesthetic feelings, and other non-verbal forms of thinking, as well as the secondary nature of words and mathematics have also been reported by a very large number of other eminent scientists and inventors including Richard Feynman, Nichola Tesla, Charles Kettering, Stanislaw Ulam, Santiago Ramon y Cajal, Joshua Lederberg, Jonas Salk, and Barbara McClintock.

McClintock, whose work in genetics earned her a Nobel Prize, is also remembered for explicitly speaking about her 'feeling for the organism.' Far from attempting to be objective about her work, she studied each individual plant until she knew it so intimately that she empathized completely with it. She even found that she could do this with chromosomal preparations, imagining herself down among the genes. "The important thing," she said, "was that you forget yourself." Indeed, Jonas Salk reported that his best ideas about how to fight polio came from "imagining myself to be a virus." Physicists have reported 'becoming' photons, electrons, black holes. Ethologists such as Jane Goodall, Dian Fossey, and Desmond Morris, who study animal behavior, say that their best ideas have come from empathizing so completely with the animals that they can imagine being one themselves. Thus, Joshua Lederberg, another Nobel laureate proclaimed that every scientist, "needs the ability to strip to the essential attributes some actor in a process, the ability to imagine oneself *inside* a biological situation; I literally had to be able to think, for example, 'What would it be like if I were one of the chemical pieces of a bacterial chromosome?'"

This nonverbal, nonmathematical nature of creative thought creates some interesting conundrums for understanding the nature of discovery. What is Stan Ulam talking about when he claims to "calculate, not by numbers and symbols, but by almost tactile feelings combined with reasoning"? To what was Richard Feynman referring when he talked about solving quantum physics problems using "acoustical images"? How do objective and verifiable results come from a process of thinking that has been described as entirely sensual, empathic, and subjective? Here, physicist-novelist C. P. Snow may hold the key. "If," he writes, "we could follow the process of scientific thought through many minds, as it actually happens and not as it is conventionally expressed after the event, we should see every conceivable variety of mental texture. . . . There are exactly as many ways of approaching the scientific world as there are individuals in science. It is only because the results are expressed in the same language, are subject to the same control, that science seems more uniform, than, say, original literature. In effect, in the end, it is more uniform." Unless we recognize the idiosyncratic and nonlogical nature of thinking itself, and the immense constraints that logical systems of communication place on how we express our insights, we cannot make progress on this thorny problem. There is clearly a process of translation between individual and the scientific collective that is as essential to success as having the insight itself.

When Discoveries Are Made

The temporal patterns of discovery, and especially when individuals are most likely to have their insights, are perhaps the least-studied aspect of the discovery process, but some interesting phenomena have been noted. The influence of age and changing fields has been noted above. People tend to make discoveries within five to ten years of entering a field, and they tend to have only one major insight per field they enter. Thus changing fields tends to restart the discovery clock, as it were.

Equally important to understanding discovery is that insights seem to occur more often when scientists are *not* directly working on a problem than when they are. Thus, several studies have shown that only about a third of scientific problems are solved by a direct, brute force approach. An equal number are solved when scientists give upon on the original problem and begin working on a related problem. The remaining third of the problems get solved during leisure-time activities, which range from going on vacation to taking a shower to dreaming the answer in one's sleep. Some investigators, such as Linus Pauling have even gone so far as to claim to be able to 'program' their minds to make use of this leisure time. Pauling said that when he worked on a problem that he could not solve directly, he would turn to something else during his work hours, and think very hard about the unsolved problem every night before he went to sleep. After a few weeks, he would forget to think about the problem before he slept, and then, within a few days, almost inevitably, he would wake with a plausible answer. Other scientists, such as Poincaré and August Kekulé, the discoverer of the structure of benzene, have reported using similar techniques of purposeful meditation or relaxation to stimulate ideas.

This phenomenon of nonconscious problem solving raises interesting questions for understanding the nature of discovery. As Poincaré noted, it is almost as if the conscious mind, employing the rules of logic, can prevent insights from occurring. In fact, the nature of many discoveries is such that they do break the rules of logic as they are understood at the time, or posit the existence of phenomena that are unknown and so beyond the knowledge of reason.

One can also look at the concept of temporal patterns of discovery from an historical perspective. Discoveries as a whole tend to occur during times of economic growth and cultural mixing. The Scientific Revolution, for example, occurred during a period of prosperity associated with the Renaissance and this historical period is also characterized by many voyages of discovery that led to trade – both economic and intellectual – between cultures as diverse as the Europeans, Arabs, Chinese, and native Americans. Other major periods of innovation in the sciences, such as the Industrial Revolution and the post-Sputnik era, are also associated with such economic and cultural prosperity.

What Is Discovered

Much of the literature on discovery assumes that what is discovered is a solution to a problem. Thus, one popular book about discovery is actually entitled *The Search for Solutions*. In fact, discovery is better characterized as a quest for questions.

The problem must be discovered before the search for its solution begins. Indeed, as noted above, one of the most fruitful strategies for discovering is to find anomalies and paradoxes that reveal the limitations of current theory and practice.

The greatest scientists have often excelled at discovering new problems. As Camille Jordan wrote in praise of fellow mathematician Henri Poincaré, "He solved problems which before him nobody would have even dared to pose." Indeed, it is a truism in science that properly defining a problem gets an investigator more than halfway to its solution. Thus, Einstein once wrote that "The formulation of a problem is often more essential than its solution, which may be merely a matter of mathematical or experimental skill. To raise new questions, new possibilities, to regard old problems from a new angle, requires creative imagination and works real advance in science." Being able to perceive problems where no one else sees them is therefore one of the most important skills a discoverer can cultivate.

Different types of problems lead to different types of discoveries. If we ask "what is energy or velocity, or what species is this," the problem involves one of definition, and will require invention of a concept or taxonomy. If we ask what governs the manner in which weights fall or why species are distributed as they are through space and time, then we are dealing with problems of explanation, and these require the development of a theory. To test the adequacy of a theory or definition, one will need data, and one therefore has a problem of experimentation or observation. In some cases, the experiment or observation cannot be made using existing techniques. Human eyes cannot see ultraviolet light or objects smaller than a cell. Such problems require the invention of new techniques or instruments for observation and analysis. This conjunction between problem type and the nature of what is discovered or invented may seem obvious, but experience shows that many theoreticians act as if they believe that all problems are ones that can be solved by inventing or enlarging a theory, while many experimentalists approach every problem as one that can be solved by gathering more data. Much time is wasted in science as a result.

Problems, of course, are only one of many things that can be discovered and one need not invent a problem to solve it. Outstanding problems are often as widely disseminated and discussed by scientists as are great experiments and theories. James Watson and Francis Crick, for example, tackled the well-defined problem of how genetic information is encoded and transmitted by living organisms. They neither discovered the problem nor the fact that DNA carries genetic information. They did, however, make the very remarkable discovery of how the structure of DNA itself carries information and is adapted to replicating itself. This structure was quite unexpected.

Watson and Crick's discovery was, in turn, made possible by other types of discoveries. W. H. and W. L. Bragg had previously invented the technique of X-ray crystallography by which the structure of DNA was analyzed; Linus Pauling had developed sophisticated physicochemical modeling methods that Watson and Crick could apply to DNA; and so forth. In addition, Watson and Crick's discovery led to other discoveries. All of modern genetic engineering is based on the manipulation of DNA sequences and the enzymes that a control DNA

in cells – not one wit of which was foreseen even at the time of Watson and Crick's work (*ca.* 1950). Thus, it is correct to say that every discovery builds upon other discoveries and makes new ones possible. This is what Isaac Newton meant when he said that, "If I have seen further than other men it is because I have stood on the shoulders of giants." The structure of discovery is a very complex and tightly woven tapestry of ideas, observations, techniques, explanations, inventions, and their histories.

Mention of invention raises the important issue of distinguishing between it and discovery. In general, scientists usually argue that inventions are made with intention, while discoveries occur serendipitously. Had Galileo known that there were mountains on the moon, he could not have discovered them. Had Columbus known of the Americas, he could not have discovered them. On the other hand, Galileo could not have discovered the telescope. That required intention. Morse could not have discovered the telegraph nor Fulton the steam-driven boat nor the Wright brothers powered flight by accident. These had to be planned. This is not to say that in carrying out plans to build an invention, one will not stumble across unforeseen principles or phenomena of nature, and thereby make a discovery. Nor is it to say that discoverers are not also inventors. More often than not, a discovery can only be made because of a technological invention, or can be interpreted only in light of a theory that is invented in response to what is discovered. Thus, invention and discovery are integrally entwined and both can be the results of the investigative process.

Where Discoveries Are Made

Interestingly, there appears to be a geography of discovery and its form is full of surprises. One might expect discoveries to cluster in the major centers of science at any given historical period since these centers are where the most prominent scientists are to be found. For various reasons indicated above, including the inverse correlation between age and discovery and the generally conservative tendencies of most major institutions, the most interesting science is usually done in peripheral institutions.

Before proceeding further with this point, it is first important to distinguish between what Thomas Kuhn has characterized as 'normal' and 'revolutionary' science. Kuhn defined normal science as having a well-articulated paradigm, or set of problem-solving techniques, that can be described in textbooks and classrooms and implemented in laboratories. In essence, normal science focuses on areas of science in which a major advance has opened up a well-defined set of problems that can be addressed with a fair assurance of success. Revolutionary science, on the other hand, is science that overtly challenges the assumptions of existing problem solving modes. It undermines textbooks, makes standard classes irrelevant or outmoded, and creates new methods of working and training.

In addition to Kuhn's normal and revolutionary science, historians of science have generally begun to recognize yet a third category of science as well: new sciences. There was, for example, no science of physical chemistry until the late nineteenth century when a number of scientists began to realize

that the techniques of physics could be applied to chemistry, thereby revealing many new phenomena that were unpredicted and unprecedented. Physiology, immunology, molecular biology, biophysics, astrophysics, and ethology are other examples of new sciences that emerged during the last century, carving out new scientific territories without attacking existing sets of theories, practitioners, institutions, or textbooks.

Each of these three types of science has its own geographical distribution. Normal science does indeed cluster in established centers of science. These centers have the resources and funding to attract recognized discoverers. Funding, in turn, is dependent upon granting agencies or patrons being able to identify fields in which progress is most likely. Such fields are those in which the major discoveries have already been made. The major scientific institutions at any given historical time are usually engaged in what might be characterized as being developmental, rather than breakthrough, science. Thus, if one looks at where Nobel laureates end their careers, they often end up at Harvard, Stanford, MIT, Cambridge, Oxford, Paris, Berlin, etc.

Breakthrough or revolutionary science tends towards the geographical peripheries of the scientific collective at any given time. Innovators tend to be people who go their own way rather than follow the crowd. They pay the price of having to work in third rate conditions with inadequate funding and resources. But as one scientist said, one makes a choice between the "shackles of the palace or the freedom of the shack." Thus, if one looks at where Nobel laureates train as undergraduates and obtain their first employment, it is most often at institutions that have no particular claim to prestige. In some cases, experts at major institutions actually force innovators out. William Shockley, one of the inventors of the transistor, for example, refused to allow the group of men who invented the integrated circuit, or 'chip,' to stay in his laboratory, considering their work irrelevant and unlikely to succeed. They were forced to create a small company to continue their work. Many small computer innovators and biotechnology companies have begun under similarly discouraging circumstances, when large companies have refused to sanction work that ran counter to their established research directions.

New sciences also tend to emerge on the geographical peripheries of science. This phenomenon is related to the doing breakthrough or revolutionary science – except that no field exists previously to revolutionize. Notably, only two sets of institutions tend to take up new scientific fields: major institutions that purposefully restructure existing departments to create a new one to embody the new science and its discoveries; and, more frequently, new institutions. Discoveries, in other words, tend to flourish where new opportunities for personal and institutional growth are available.

Why Discoveries Are Made

What motivates scientists to make discoveries? The basic drives seem to be control, curiosity, necessity, serendipity, and aesthetics. Often several of these drives are at work simultaneously.

Einstein commented that one of the primary reasons he became a scientist was to avoid the daily hassles of life. Many studies of the psychology of scientists and engineers suggest

that they have a need for control. Creating theories or performing experiments provides that control. Control, in turn, yields power, since understanding nature allows human beings to manipulate nature's laws. Thus, discovery provides a means for individuals to obtain power over nature and their own circumstances.

Necessity can also be a motive for discovery. 'Necessity is the mother of invention' is a well-known saying, no less true for its triteness. It is certain that many scientists, such as Louis Pasteur and Jonas Salk, have tackled questions of the cause of diseases precisely because of the threat these diseases posed to human beings.

At least half of all discoveries occur serendipitously, however. A careful distinction must be made here between serendipity and chance or accident. Chance and accident denote total lack of control of the process leading to discovery. No discovery has ever been made by chance or accident, despite many articles and books on these topics. When the laboratory notebooks detailing discoveries are examined, they inevitably reveal that all discoveries begin with some goal in mind. Those discoveries that are often said to have occurred by chance or accident, in every case, turn out to have been made while looking for something else. Finding one thing while searching for something else is the definition of serendipity. The term originated in a story by Horace Walpole called the 'Princes of Serendip,' which concerned the adventures of the Princes as they went in search of various treasures and were continuously, and fruitfully, sidetracked by more interesting adventures. Thus, Fleming, for example, discovered the antibiotic enzyme lysozyme in his mucus and tears when trying to isolate a virus that causes colds. Intention set up the experiments; serendipity yielded the surprising discovery.

Perhaps the most unexpected and yet common motivation for discovery is aesthetic. A very large number of scientists are drawn to science in the first place by the beauty of the experimental preparations they examine in the microscope or the sublimity of the intellectual constructs that we call theories. Santiago Ramon y Cajal, who won a Nobel prize for his work in neuroanatomy often waxed eloquently over the magnificent scenes that the architecture of the brain afforded, while Max Planck said forthrightly that he was drawn to physics by the beauty of the laws of thermodynamics. In some cases, the desire to recreate literal physical beauty has even led to discoveries. For example, C. T. R. Wilson became so enamored of the coronas and glories that he observed when climbing in the Scottish hills that he decided to recreate them in his physics laboratory. His success inventing cloud chambers not only allowed him to make these beautiful optical phenomena at will, they also allowed subatomic particles to be observed for the first time, and earned Wilson a Nobel prize. Similarly, it appears that Fleming's habit of making 'paintings' in Petri dishes using a 'palette' of colored microorganisms provided the basic techniques and observations that led to his discovery of penicillin.

Multiple or Simultaneous Discoveries

While most discoveries, such as Fleming's discovery of penicillin and Röntgen's discovery of X-rays, are unique, a significant

portion are made simultaneously by two or as many as a dozen other people or groups of people. Discoveries that are made independently by more than one individual or groups of individuals are termed 'multiple' or 'simultaneous' discoveries. The probability of simultaneous discovery is, in fact, hinted at by the fact that many other scientists saw what Fleming and Röntgen saw without thinking it. Sometimes, if a problem is well enough defined and the techniques for investigating it are available to enough people, several will converge on the same general answer at the same time. The simultaneous discovery phenomenon brings into contrast the extent to which discovery is dependent on unique forms of individual creativity and the degree to which there is a logic to discovery that is independent of individual psychology. The existence of simultaneous discoveries is also a necessary prerequisite for understanding the controversies over priority that frequently occur in science.

The phenomenon of multiple discovery has been well documented in several cases. One is the invention of calculus by Newton and Leibniz at the end of the seventeenth century. Similarly, in the 1840s, Robert Julius von Mayer, James Prescott Joule, Ludwig A. Colding, William Robert Grove, and Hermann von Helmholtz (among others), all published versions of what would eventually become known as the first law of thermodynamics (energy is conserved), and numerous priority disputes broke out among the claimants. The co-publication of the theory of evolution by natural selection by Charles Darwin and Alfred Russell Wallace in 1858 is one of the few cases in which a simultaneous discovery did not result in friction between the codiscoverers, mainly because Darwin gave Wallace credit for his contribution, but clearly had a far more articulated theory to present in his *Origin of Species* the following year.

Each of the examples described above showcase the differences that always exist in the formulations of discoveries. Newton and Leibniz utilized very different, largely incommensurable notations that required mathematicians to choose one of their formulations or the other, and in the event, Newton's applications of his invention were deeper, wider, and more insightful than those of Leibniz. Darwin's formulation of natural selection was far more developed and encompassed a much wider range of phenomena than did Wallace's, including copious examples from animal husbandry, plant breeding, animal behavior, and paleontology, which were fields that Wallace had never investigated. Thus, Darwin's formulation was much more far-reaching and integrated far more material than did Wallace's – one of the reasons that we refer to 'Darwin's theory of evolution' rather than 'Wallace's' today. Similarly, Kuhn has shown that each of the formulations of the first law of thermodynamics has many more differences than it has similarities, and that it is only in retrospect, and largely due to the work of Helmholtz, that one can recognize that all are partial statements of the same basic principle.

Simultaneous discovery does not, therefore, necessarily, or even frequently, denote *identity* of discovery. Every investigator has a unique style of research that is manifested in how they pose problems, what tools they use to solve them, and how they present their findings. Nowhere is this clearer than when several scientists claim to solve the same problem at the same time since part of the subsequent squabble over priority in

such cases is really about which formulation of the solution will become canonical. A classic case is that of Richard Feynman, Julian Schwinger and Sin-Itiro Tomonaga, who eventually shared the Nobel Prize in Physics in 1965. Each man addressed the problem of quantum electrodynamics using a different set of very abstruse mathematical techniques. When each claimed to have solved the problem, the formulations were so dramatically different, and the equations so difficult, that it was not clear to any one which, if any, of the solutions was correct. It took a fourth physicist, Freeman Dyson, to resolve the problem by demonstrating that all three formulations of quantum electrodynamics were essentially interchangeable. Dyson also translated the results of all three men into mathematics that was far more accessible to other physicists than were any of the original formulations. Dyson's work, along with 'lost' discoveries such as Gregor Mendel's on genetics, reminds us that it is not enough to discover something new; it is also necessary to convince one's peers that what has been discovered is meaningful and useful.

So what studies of simultaneous discovery tell us is that science-in-the-making is actually much more similar to art-in-the-making than might first appear. Style matters. Even when the logic of the field suggests to several individuals that an important discovery is in the offing, how each individual attacks the shared problem, the techniques they use to address it, how broadly they link it to other problems, and how they choose to convey their discovery to their colleagues all affect the reception of their work. Even when several scientists or groups of scientists make a common discovery, they imprint their unique personal and psychological factors onto that discovery so that no formulation is exactly like any other.

The existence of multiple or simultaneous discoveries therefore argues that while there very likely *is* a logic to discovery that permits many scientists to perceive the same possible solutions to similar problems at the same time, individual differences in experience, knowledge, and psychology affect the precise way in which different versions of the resulting discovery are manifested. This conclusion must cause us to rethink the common saw that a major difference between sciences and arts is that ten scientists given the same problem will arrive at the same solution whereas ten artists given the same scene to paint will paint ten different pictures. In fact, ten scientists working on an unsolved problem will very likely arrive at ten different solutions that will share only some features in common. Equally, ten artists all using the same style to paint the same scene will produce ten recognizably similar pictures (as Expressionist and Neo-Expressionist painters often did!).

Discovery Outside of the Sciences

The notion that scientific discovery may be more like artistic creativity than is at first apparent raises the more profound issue of whether discovery is possible outside of the scientific disciplines. The answer depends largely upon whether one looks primarily at the *products* of the discovery process or at the *process* itself. The literature comparing science with the humanities and arts is clearly split as to whether nonsciences make discoveries or progress in ways similar to the sciences.

It is generally accurate to say that all those authors who compare the products of the sciences with those of other disciplines find that science alone makes progressive discoveries, while those who compare the processes by which people in different disciplines work claim that people in all fields make discoveries.

Similarities may also hide differences, however. Even within science itself, there are very different ways of making discoveries. Geology and paleontology present cases of sciences in which it is rarely possible to make what most scientists would characterize as predictions. In general, predictions are defined as constituting the description of events or phenomena before they have happened. Geology and paleontology, however, deal largely with things that have already happened. Thus, philosophers characterize the description of as yet undiscovered artifacts or physical objects by those in historical fields as properly being called *postdictions* or *retrodictions*. Each discipline, in other words, may require a different set of logical and physical tools in order to make discoveries, and the nature of these discoveries may differ quite markedly even when proceeding from the same basic process of investigation.

The distinction between prediction and retrodiction is critical for analyzing whether fields such as history and philosophy can make discoveries. It must be obvious that they cannot discover new things that have never existed before. But it must be equally obvious that they have the same ability as geology to unearth things that have previously existed and been forgotten, and to provide general understanding of the processes that guided the past and permit us a glimpse of the future.

Artists and musicians can also be said to make discoveries and inventions comparable to scientists. Artists, for example, have discovered perspective, anamorphosis (the process of mapping an image onto a nonflat surface), optical illusions, the techniques necessary for casting sculptures (which usually anticipated existing engineering capabilities), techniques for displaying motion (including motion pictures), mobiles (kinetic sculptures), and even the process of pixelization that underlies all modern computer and CD-ROM visual technologies. Musicians have similarly invented harmony, counterpoint, 12-tone and other 'natural' scales, aural illusions, and many other aural phenomena we take for granted. There is no reason, as artist-inventor-neurobiologist Todd Siler has commented, that these sorts of discoveries should be valued any less than those within the realm of science. Each is an intellectual addition to the panoply of human understanding.

In addition, artists, musicians, and other creative people often arrive at their insights simultaneously, resulting in the same kinds of multiple discoveries and consequent priority disputes that characterize many scientific discoveries. Igor Stravinsky and Arnold Schoenberg spent most of the first half of the twentieth century squabbling over which of them had invented twelve-tone musical composition. Claimants to the invention of electronic music include Lejaren Hiller, Jr., J. R. Pierce, Claude Shannon, and Max Matthews, Raymond Scott, Iannis Xenakis, and many others who had musical training and access to the first computers during the 1950s. Georges Braque and Pablo Picasso never agreed on which of them invented cubist painting. Kinetic sculptures were invented almost simultaneously in Italy by Giacomo Balla and Fortunato Depero, in Russia by Naum Gabo around 1915, and mobile sculptures simultaneously by Alexander Calder

and George Rickey in the United States and Jean Tinguely in France, during the 1940s. Buckminster Fuller and Kenneth Snelson never agreed on which one invented the sculptural principle of tensegrity after World War II.

Equally to the point is the undeniable fact that a large number of *scientific* discoveries has been made by professionals in the fine arts, most of whom had little or no formal scientific or engineering training. Here are a few examples. The concept of camouflage both as a biological principle explaining animal adaptation and as a military technology was discovered by portrait painter Abbott Thayer at the end of the nineteenth century. The principle of geodesy was discovered by architect-inventor Buckminster Fuller and applied to making geodesic domes long before it was applied by scientists to understanding the structures of spherical viruses or for synthesizing C60 carbon compounds now known as 'fullerenes.' The equally basic physical principle of tensegrity was worked out by Fuller and fellow artist Kenneth Snelson who used it to make sculptures. Tensegrity is now thought to underlie the structures of cells and is being applied to the building of stable platforms for use in space. And musician-inventor George Antheil collaborated with actress Hedy Lamarr to invent the concept of frequency hopping, in which a message is encoded in constantly varying frequencies in order to protect it from detection or interference from enemy sources. Frequency hopping is the basis for protecting a great deal of military communications at present.

These examples demonstrate that there is no fundamental difference between the creative thinking of the scientist, the artist, the composer, and the writer, and no reason to believe that discovery is the preserve of sciences or engineering alone. Unfortunately, too little research has yet been done comparing the thought processes of scientists, artists, writers, and others. Such comparisons would undoubtedly bear interesting fruit. For example, historian of technology Thomas Hughes has noted that "the invention of machines, devices and processes by metaphorical thinking is similar to verbal creation, but the fascinating possibilities have not been much discussed, probably because persons interested in language are rarely interested in technology." Similarly, some recent studies, most notably by James McAllister, are beginning to find that the use of aesthetic criteria in the sciences, engineering, and the arts are all virtually identical, and that the notion of beauty in science may be as essential as a motivation for discovery and as a criterion for evaluating novel ideas as it is in the arts. Thus, there is, at present, no reason to believe that the process of discovery in the sciences differs in any substantial way from the process of discovery in other disciplines despite obvious differences in the types of discoveries achieved.

An Evolutionary Theory of Discovery

Evolutionary theory provides a unifying concept for understanding the process of discovery in all its manifestations. Kuhn, for example, has argued that an evolutionary model could be applied to science in his classic *Structure of Scientific Revolutions* and the argument has been elaborated since by Donald Campbell, David Hull, and the author among others.

In order to apply evolutionary theory to discovery, one must make analogies between species and ideas. Standard

Darwinian evolution requires three key elements: (1) a source of diversity among species or ideas; (2) a way for individuals to inherit differences; and (3) a nonrandom means of selecting between differences. The source of diversity is provided in part by nature, which generates the phenomena for scientists to observe, and in part by scientists themselves, who invent techniques for exploring nature and explaining it. Here it is important to remember that the vast majority of ideas and observations that scientists make are incorrect or only partially correct. There is as much waste in the intellectual realm as when species produce many more offspring than can survive.

The inheritance of variations occurs by means of learning and teaching in cultural evolution. Thus, ideas and information take the place of genes. Evolution, in consequence, is more Lamarckian than Darwinian. Lamarck maintained that species evolve by willing themselves to change, and went on to argue that alterations during their lifetimes could be transmitted genetically. Lamarck's mechanism has been completely dismissed as a means of biological evolution, but may still apply to cultural evolution since people can, in fact, change their minds and transmit their altered ideas to the next generation of scientists.

Finally, evolution requires a non-random means of selecting between competing ideas. Here a combination of natural and artificial processes come into play. The touchstone of all science is nature itself. One compares observations and theories by means of tests with nature. Often, however, several explanations may account for existing observations equally well. In this case, other criteria, such as the compatibility of the various explanations with other scientific principles, the range of phenomena explained, its simplicity and usefulness, and aesthetic criteria come into play. The point is that selection does occur and, in fact, competition amongst scientists, their observations, and theories is very rigorous.

Evolutionary theory accurately describes several other elements of the discovery process. One is the literal growth of each new development in science from previous discoveries. Every discovery builds on previous discoveries. If necessity is the mother of invention, then existing discoveries are the fathers.

An evolutionary model also describes accurately the increasingly specialized nature of discoveries in science. If one looks at science since the seventeenth century, it has developed in almost perfect imitation of a taxonomic tree. As of 1670, there was one journal of science, and all of science as generally categorized under the heading 'natural history.' Over the next century, the number of practitioners grew exponentially, as Derek de Solla Price has so well documented, creating a need for new and more specialized journals. The specific sciences of astronomy, physics, chemistry, and biology were all recognized by the end of the eighteenth century. During the nineteenth century, exponential growth in the number of chairs of science, journals, practitioners, and papers all continued resulting in further specialization. Chemistry split into physical, organic, inorganic and biochemistry, for example. At present, the discipline recognizes over a hundred specialties in which doctorates can be obtained and papers published. Every scientific field has branched into similarly diverse specialties. Thus, from the trunk of natural philosophy have emerged the general branches of the basic sciences, followed inexorably by the twigs that have produced the current crop of

thousands of leaves that represent the crown of science as it exists today. Scientists diverge and specialize just as do species.

Many aspects of the evolutionary theory of discovery remain unresolved, however. For example, standard evolutionary theory places primary emphasis on the random generation of extremely large numbers of variants from which the best adapted can be selected. The implications of this approach for discovering are that an investigator should try as many random ideas or processes as possible in order to optimize his or her chances of making a discovery. Philosopher Paul Feyerabend (*Against Method*) provides the most lucid support for this strategy in his writings. Physicist Henri Poincaré places the greatest emphasis on the selection process. Anyone can, he argues, find two ideas, theorems, facts, or techniques that have not been synthesized before and do so. Most of the results will be useless or trivial. Poincaré therefore argues that what is most important is having an aesthetic sensibility that allows the discoverer to sort the wheat from the chaff: "To invent is to choose." Indeed, if we admit that discovery is a process and not an act, then choosing the best ideas to investigate can be critical, for every idea of any value needs a great deal of nurturing. The greatest discoverers have been those who saw the oak in the acorn or the giant in the baby and put in the 99% perspiration that Edison said is always needed to make the germ of an idea grow.

Another equally important difference between standard models of biological evolution and that characterizing cultures such as science concerns integration. Standard Darwinian evolution is portrayed as a tree that constantly branches. The most adapted new variants are the ones that survive through time. But much of scientific progress is characterized by the integration of previously separate lines of investigation. Many of the greatest breakthroughs in science are syntheses and scientists are all after their field's equivalent of a 'unified field theory.' Thus, the trees that represent scientific discoveries not only branch, but they also meld back together, forming a dense network of interactions. Symbiosis or synthesis in science is, in other words, as important as speciation or specialization.

The constant interplay between the need for ever-greater specialization and the drive to unify existing knowledge creates the tension so essential to continued discovery. Those who are most likely to create the most important discoveries are therefore likely to be both analytical and synthetic. They are likely to be just as interested in how this dynamic process of discovery itself works as they are in the special knowledge in their particular area. For discovering, as we have seen, requires more than merely finding something new – it also requires knowing how to interpret its meaning within the broadest context of science and society possible.

Glossary

Matthew effect The phenomenon where the 'rich get richer, and the poor get poorer'.

Normal distribution A symmetrical distribution of data around the mean, usually represented by a bell-shaped curve.

Performance Behavior ranked with respect to quality, quantity, or both.

Positive skew distribution A case of mass mediocrity and rare exceptional quality.

Zipf distribution Distribution of data maximized at the lowest level.

Statistical Distributions

Of course, many physical objects and phenomena show normal distributions. **Figure 1(a)** shows, the most common or modal behavior is the average as well as the median, because half the cases are below and half above it. A plot of adult US heights, for example, might show an average and many instances around 5 ft 7 in. The largest number of cases are likely to be within 5 in. of the average, and very few would be less than, say, 3 ft or greater than 8 feet tall. As **Figure 1(a)** shows, the distribution is likely to be roughly symmetrical on either side of the average. Intelligence, educational achievement, and personality test scores often show normal distributions like **Figure 1(a)** but mainly because they are intentionally constructed to exhibit this distribution. It is mistaken to think that most psychological behavior follows the normal curve. As illustrated in **Figure 1(b)**, many human and social phenomena exhibit positive or right skew. This means that most people are mediocre to slightly above average, but a few are exceptional, and very few are very exceptional. Income and wealth show this distribution: In 1977 Sloan noted that the top 1% of the US population owns a third of the nation's wealth, the next 9% owns another third, and the other 90% owns the last third.

The Zipf distribution in **Figure 1(c)** forms a still more extreme curve in which nonperformance or the lowest level of performance is most common. The number of people in the world, for example, who speak a given number of words in English, Navajo, and Swahili would show this distribution; indeed, most people in the world could not speak a single word of any one of these or hundreds of other common and rare languages. The same appears true of performance in playing sports, running computers, and exhibiting expertise and creativity in many fields. Positive-skew distributions characterize many phenomena in education, linguistics, psychology, sociology, and the production of knowledge.

Causes of Positive Skew

The positive skew distributions of expertise, creativity, and other learned accomplishments often result from the Matthew effect of the rich getting richer (named by Merton in 1968 after a passage in the Gospel of Matthew in the Bible). Merton

described the stages in which distinguished scientific careers arise: initial talent advantages, study at distinguished universities, close work with eminent professors, early and frequent publication, job placement at famous laboratories, and citation and other recognition. These events and conditions multiply one another's effects to produce highly skewed scientific creativity. As few as a tenth of the scientists may account for nearly all the significant scientific work in a given field. Though a few mavericks are exceptions, Nobel laureates and similarly distinguished scientists usually follow the Matthew pattern, which resembles wealth creation in that small initial advantages multiply over decades. In modern times, the very wealthy have often gained from initial wealth, expert knowledge, and social contacts that multiply and cumulate over time. In science and other creative fields, however, the driving incentive may not be wealth but prestige, excitement, competition, the pleasure of pursuing difficult goals, and the possible contribution of research to improving human conditions. In any case, creative accomplishments are strongly determined by talent and long, intense, and specialized experience. An advantaged start and long investment of hard work often lead to later opportunities.

Motivation and Creative Performance

Why should anyone work so hard over such a long period to reach the top levels of creativity or other kind of performance? As **Figure 2** shows, more and more effort results in higher levels of performance but at diminishing rates. Because we can measure and think about physical performance more easily, consider runners: As shown on the performance curve, with more practice, those training for a marathon run at increasingly faster rates, especially those who have practiced little. Up to a point, however, each extra hour of practice per day in sports and other endeavors, other things being equal, yields a smaller rate increase. The time differences among the top few marathoners may be measured in seconds.

In most fields, much of the fame, honor, and possibly gratification goes to the winners, especially those who come in first, as shown by the value curve of **Figure 2**. Society tends to prize top performers and ignore others. Those at the top are

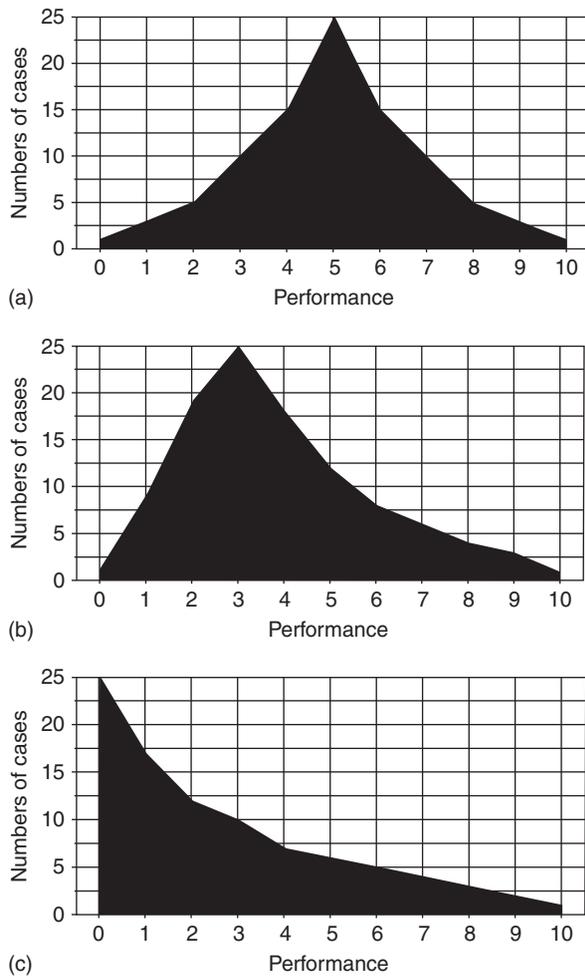

Figure 1 (a) Normal distribution; (b) positive skew distribution; and (c) Zipf distribution.

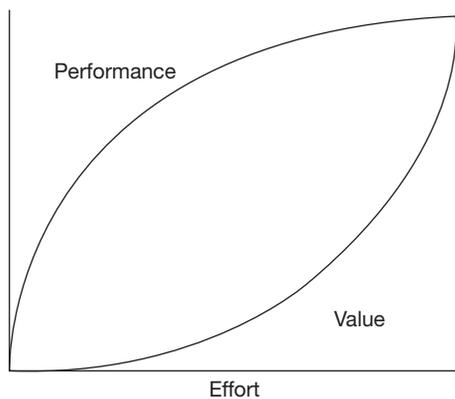

Figure 2 Effort, performance, and value.

often well compensated; those a few ranks down, though hardly different in performance, may be largely unknown except to aficionados.

Of the thousands of good painters and physicists of the last century, only a few are familiar names. Perhaps fewer than one in a thousand of all piano players have made a good living at it.

Multiplicative Theories of Creativity

Parallel to wealth accumulation and the development of scientific and other creative careers, Loehle suggested in 1994 that individual scientific discoveries are multiplicative products of cumulative events. For example, suppose a scientific discovery requires 20 necessary steps such as asking the right question, setting forth a researchable hypothesis, gaining financial support for the research, developing a detailed research plan, hiring capable assistants, supervising them, collecting data, analyzing it, drawing graphs, drafting a paper, submitting it to a scientific journal, and so on. Even if each step has an easy 90% probability of success, the multiplicative product ($.9 \times .9 \times .9 \dots$) or probability of project completion is only 12%. This poor overall success rate explains why many scientists rarely or never publish articles.

This cumulative, multiplicative theory draws together old and new ideas from several academic fields, and it apparently applies widely to behavior, education, and other fields. It is analogous, for example, to Darwinian evolutionary theory, which holds that plants and animals well adapted to their environments prosper, multiply, and ‘crowd out’ poorly adapted organisms. Mutations (random genetic variations), moreover, that are further adaptive prosper still further. Old and new cognitive theories extend such evolutionary theory to inventive thought. Campbell, in particular, pointed out that two years before Darwin’s publication of the theory of natural selection, Alexander Bain, in 1855, used the term *trial and error* in analyzing creative thought. In this evolutionary insight, psychology preceded biology. Campbell held that:

blind-variation-and-selection-retention is fundamental to all inductive achievements, to all genuine increases in knowledge, to all increases in fit of the system to environment. (p. 380)

In his view, therefore, three conditions are necessary for new ideas:

a mechanism for introducing variation, a consistent selection process, and a mechanism for preserving and reproducing the selected variations.

The efficacy of rare new ideas depends on whether they can solve problems at hand. Those ideas that are useful, often those that succinctly express important phenomena or synthesize many particular instances, grow in their frequency of expression and consumption. Such successful ideas can be routinized and widely shared. They become increasingly frequent – even dominant.

Diffusion of Creative Ideas

Once a creative idea proves successful, it can be widely adopted without endlessly recreating or even understanding it. We hardly need think about electrons when turning on lights nor internal combustion when driving cars. In a humanitarian vein, Alfred North Whitehead (1864–1947) declared:

Civilization advances by extending the number of important operations which we can perform without thinking about them. (quoted in De Wolf, 1980: 281)

Psychological theories of B. F. Skinner and other behaviorists may be similarly construed. Like successful genetic mutations, rare random behaviors, when rewarded, become more frequent, even automated. They may become widespread when transmitted from one person to another through imitation and learning. Much of human life depends on such vicarious experience and socially transmitted abstract ideas; children, for example, need not figure all things out from raw experience.

Learning, Expertise, and Creativity

Creativity, however, usually requires expertise, which is itself rare and positively skewed. In intensive case studies of experts in various fields, Ericsson and Charness, in 1994, showed that expertise is a function of (a) careful planning or goal setting, (b) daily hard work over long periods, and (c) continuous monitoring of progress – in short, self mastery. Such conditions may outweigh initial ability; missing any single one results in less than expert performance.

As many researchers have noted, studies on children's learning, creativity, and exceptional accomplishments suggest similar conditions are necessary, although parents, teachers, and coaches may initially foster such propensities. In many fields, moreover, children's acquisition of exceptionality may proceed in stages. In 1985 Bloom, for example, emphasized early talent recognition, parental encouragement, and further encouragement from first teachers (though with limited deliberate practice), followed by elite teachers with increasingly demanding standards. Ericsson and Charness, in 1994, pointed to the crucial role of exposure to tough peer-group standards. From biographies of world leaders, Gardner,

in 1995, identified general recurrent patterns of childhood experiences. Talent, opportunity, hard work, luck, and other conditions for creativity may each be common. Combining and focusing these, however, for a decade or more is rare. Although many are called, few are chosen.

Divergent Thinking

M A Runco, University of Georgia, Athens, GA, USA

This article is a revision of the previous edition article by Mark A Runco, volume 1, pp. 577–583, © 1999, Elsevier Inc.

Glossary

Criterion problem There is no widely accepted criterion of creativity. If there were such a criterion, there might be no need for any other test or indicator of creativity.

Experiential bias Some divergent thinking tasks may allow respondents to draw from memory of experience rather than testing cognitive capacity to generate ideas.

Ideational flexibility The number of themes or categories within an examinee's or respondent's ideation.

Ideational fluency The total number of ideas given on any one divergent thinking exercise.

Ideational originality The unusualness or uniqueness of an examinee's or respondent's ideas.

Ideational pools These are constructed for each examinee or respondent and contain each of that individual's ideas. Judges can evaluate the pools rather than individual ideas.

Structure of intellect J. P. Guilford's model, with 180 different kinds of intellectual processes and skills.

Background

J. P. Guilford is typically credited with distinguishing between divergent thinking and convergent thinking. (The latter is involved whenever the individual focuses on one correct or conventional idea solution. Convergent thinking is emphasized in most academic examinations and IQ tests.) He also argued cogently for creativity being a natural resource and is credited with initiating the empirical research on the topic in the 1950s and 1960s. Certainly he was the first to be explicit about the value of divergent thinking, and he did most of the early research on the topic, as part of his structure-of-intellect (SOI) model. (This model contained 180 cells, many of which represented divergent production, which was Guilford's own term for divergent thinking.) Several others before Guilford did, however, recognize the importance of divergent thinking, even if they did not call it that. Alfred Binet, for example, had several open-ended questions that required his examinees to think divergently on his early tests of mental abilities. These tests were later adopted by Louis Terman of Stanford University and refined as the first IQ tests (i.e., the Stanford–Binet). Binet was working on his tests in the late 1800s.

Guilford's work represents the most comprehensive model of divergent thinking. Several other theories are, however, largely supportive of divergent thinking as an estimate of the potential for creative thought. In 1962, Sarnoff Mednick published his 'Associative Basis of the Creative Process,' and although he developed his own test, the Remote Associates Test (RAT), the associative theory presented by Mednick also supported and encouraged the use of divergent thinking tests. This was especially the case because the RAT may be verbally biased. Individuals who do well on tests of verbal ability often do well on the RAT, and persons who do poorly on tests of verbal ability tend to do poorly on the RAT. In associative terms people respond to problems by generating ideas. Often one idea leads to another idea, which leads to another. Mednick discussed various ways that one idea could be associated with another idea, including acoustic similarity or functionality.

Very importantly, he predicted that ideas found later in an associative chain are more likely to be original than those found early in that chain. This prediction has been supported a number of times, often with divergent thinking tests. This prediction from Mednick about 'remote associates' is very important in a practical sense because it suggests that individuals taking a divergent thinking test or working on a problem that will benefit from creative insight should make certain that they invest some time into the task. Otherwise remote and original ideas might not be found.

In addition to the verbal bias mentioned above, tests of divergent thinking may be unduly influenced by experience. After all, if an examinee is asked to "list things that move on wheels," and he or she grew up in an extremely isolated area where vehicles are uncommon or are all pretty much the same, he or she will not have much information in long term memory. Another person, growing up in an area where most households own several vehicles may have a huge advantage. Yet that person may rely on long term memory and only think of things with which he or she had direct experience. This would indicate that the test is assessing experience and memory more than cognitive skill. The test would be *experientially biased*. At least one empirical study confirms this kind of bias, though it does seem to vary from test to test and from task to task. This takes us to a review of the different kinds of divergent thinking tests.

Tests and Example Questions

Guilford developed a large number of tests. Again, he was interested in the structure of the intellect and in distinguishing among 180 different kinds of thinking. (Most criticisms of Guilford's work are directed at his statistical methods, used to separate the different kinds of thinking. He often used factor analyses, for example, which required that subjective judgments be made by the psychometrician.) The three most commonly used by Guilford were probably Plot Titles, Consequences, and Alternative Uses. Plot Titles required the examinee to think of a title for a story that was presented by Guilford. Consequences

test questions asked examinees to list the consequences of some hypothetical situation (e.g., the world suddenly covered with water). Alternative uses required the examinee to generate uses of some common object (e.g., a coat hanger or brick).

E. Paul Torrance developed the Minnesota Tests of Creative Thinking in the late 1950s (published in 1966). They contained a wide variety of tasks. They were revised in 1974 as the Torrance Tests of Creative Thinking. Examples include Just Suppose, Product Improvement, Ask and Guess, Unusual Uses, Thinking Creatively with Words, and Thinking Creatively with Pictures. Torrance's work was extended in various directions. C. Woodruff Starkweather, for example, published materials describing the assessment of original ideation in preschool children. (The divergent thinking of young children can be assessed, though not with paper-and-pencil tests. Instead three-dimensional forms are given to them and they are asked to talk about all the things the form could be.)

Various other batteries are available, in addition to those of Guilford and Torrance, including Roberta Milgram's *Tel Aviv Creativity Test*, the Williams Creativity Assessment Package, and a set of tests used in several seminal investigations by Michael Wallach, including the one mentioned above. Wallach's battery has three verbal tests (Uses, Similarities, and Instances) and two Visual (or Figural) tests.

Divergent Thinking Indexes

Divergent thinking tests are scored in different ways, although most of the time a Fluency score and an Originality score are calculated. These are surely the most common indices of divergent thinking. Fluency represents the number of ideas given. Originality is scored in different ways. An objective score for originality might be calculated after determining the statistical infrequency of each idea. Highly infrequent ideas (e.g., those given by 5% of a particular sample) might be labeled original, each contributing to the Originality score. Unique ideas are sometimes viewed as original. Subjective scores have also been used, with judges rating the originality of ideas.

The next most common score is probably Flexibility. This is a very important score because (a) high flexibility precludes rigidity in problem solving and (b) it guards against an artificially inflated originality score. Without a Flexibility score, one examinee could give a large number of unique ideas, all within the same category, and each would earn an Originality point even though they are not original compared to one another. If the examinee does this but Flexibility is scored, the Originality score will be high but the low Flexibility score will indicate that it is an inflated Originality score.

In 2004 Allan Snyder and associates developed and demonstrated a new index of divergent thinking, which they called the creativity quotient. It assumes that ideas produced may not be equally indicative of creative potential. Those in disparate semantic categories are therefore weighted heavily and contribute more than semantically similar ideas to the CQ. In some ways the CQ takes both fluency and flexibility into account at the same time.

The various indices of divergent thinking are usually highly intercorrelated. This has led some psychometricians to conclude that only one score is necessary. Unfortunately, when

one score is used, Fluency is usually the one. It would make the most sense to use Originality since it is more closely associated with creativity in theory. Actually, it is probably best to use several scores because sophisticated statistical techniques (e.g., partialing unique variance and examination of interactions in canonical prediction equations) suggest that the different indices may each contribute.

The scoring of the Torrance divergent thinking tasks involves Fluency, Originality, and Flexibility, defined in a way that is comparable to the definitions given above. Torrance also recommended an Elaboration index for some of the tasks. This is based on the examinee's ideation within a category or theme. A streamlined scoring system was developed for the Torrance tests in 1980. It uses a composite of the various indexes.

Not long ago Mark Runco developed a scoring system that uses *ideational pools*. These pools are constructed for each examinee or respondent and contain each of that individual's ideas. They represent his or her entire ideational output. Judges then evaluate the pools rather than individual ideas. There are at least two advantages of this system. First is the amount of information available to judges. Second is the relatively low demand placed on their time. Judges have more information because they see everything any one examinee or respondent did, not just a small portion of it (i.e., one idea). The judges give one rating or judgment to each pool, rather than to each idea, so they need to invest much less time in the evaluations. This may preclude fatigue and allow them to concentrate better, and certainly it requires less of their time.

Task Differences and Additional Tests

The various tests differ in significant ways. The Similarities test, for example, is relatively constrained and not quite as open-ended as some of the other tasks. The Instances test seems to be wide open. The degree of openness is important in the sense that it can influence the order of test administration. If examinees have difficulty with divergent thinking, for example, which they might if they are in the midst of the 'fourth grade slump' or simply have had little or no practice at generating a large number of ideas, it might be best to start with Similarities. Because of its structure and relative constraint, it might be the most familiar to these unpracticed examinees. After working on Similarities, they might be presented with a slightly less constrained task, such as Uses, and then eventually a completely unconstrained task, such as Instances.

If divergent thinking tasks are being used in a practical setting, as exercises, it is probably desirable that the skills or strategies students learn for divergent thinking generalize to the natural environment. For this reason realistic divergent thinking tasks might be given. These ask examinees to solve problems that might occur in the natural environment, but problems that are open-ended and allow fluency, originality, and flexibility. Mark Runco has developed a number of realistic tasks, such as these tasks for students.

Example Problem 1

Your favorite TV show was on last night. You had so much fun watching it that you forgot to do your homework. You are about to

go to school this morning when you realize that your homework is due in your first class. Uh-oh . . . what are you going to do?

For this problem, you could answer, "Tell the professor that you forgot to do your homework; try to do your homework in the car or bus on the way to school; ask your roommate, boyfriend, girlfriend, or classmate to help you finish your homework; do your homework tonight and turn it in the next time the class meets; or finish your homework first then show up late for class." There are many more answers to this problem, and all of them are legitimate.

Now turn the page, take your time, have fun, and remember to give as many ideas as possible.

Example Problem 2

Your friend Pat sits next to you in class. Pat really likes to talk to you and often bothers you while you are doing your work. Sometimes he distracts you and you miss an important part of the lecture, and many times you don't finish your work because he is bothering you.

What should you do? How would you solve this problem? Remember to list as many ideas and solutions as you can.

Example Problem 3

It's a great day for sailing, and your buddy, Kelly, comes to your work and asks you if you want to go sailing. Unfortunately, you have a big project due tomorrow, and it requires a full day to complete. You would rather be sailing. What are you going to do? Think of as many ideas as you can!

There may be a trade-off with realistic tasks. They may motivate some examinees because they are realistic. Some examinees may not be all that interested in listing uses for a brick; but they might be more interested in listing excuses for not having completed homework! The trade-off arises because realistic tasks might be more constrained than the standard tasks, such as Instances or Uses. If this is the case the order of administration might be manipulated such that generalization to the natural environment is more likely. The order might begin with standard tasks, which are wide open, and then move to realistic tasks, which suggest that divergent thinking can be applied to problems found in the natural environment.

Runco has also developed divergent thinking tasks that reflect an examinee's ability to generate problems (rather than solutions). These are, then, problem discovery tasks rather than presented problems. This kind of task was developed because creative work often requires that the individual identify and define a problem before solving it. Problem generation tasks are open ended and can be scored for Fluency, Originality, and Flexibility. They can be used in conjunction with standard divergent thinking tasks to obtain a more general profile of an individual's ideational skills. Problem generation divergent thinking tasks are theoretically justified by the fact that creativity requires more than problem solving. Sometimes solving the problem is not the difficult aspect of the problem; defining it might be more difficult. And there are other important aspects of creative problem solving. Solution evaluation may be very important. Some persons seem to know an original idea when they have one, while others do not. The problem generation scores derived from divergent thinking tests may be important for certain clinical predictions. For example, the

interaction between problem generation and problem finding has been found to be highly related to suicide ideation. In particular, suicide ideation was related to the interaction between (high) Fluency scores on problem generation tasks and (low) Flexibility scores on the problem solving task. This interaction was expected because it indicates that the individual is aware of many problems (as seen in his or her Fluency) but not aware of many different solutions (as seen in the low Flexibility). Significantly, this interaction between problem generation and problem solving was more strongly related to suicide ideation than depression measures, which are typically quite respectable predictors of suicide ideation.

Psychometric Issues

The most critical psychometric issue is discriminant validity. This relates to the distinctiveness of divergent thinking. Is it distinctive or does it overlap with other forms of ability? Is it related to IQ? Can we predict divergent thinking ability from those measures of traditional intelligence?

Answers to these questions varied in the 1960s. In one seminal investigation Michael Wallach and Nathan Kogan administered divergent thinking tests under conditions that were dramatically different from the conditions typical of testing. Indeed, they told the examinees – school children – that the divergent thinking tests were games, and they avoided referring to tasks as tests. They allowed a great deal of time and were explicit about the need to generate a number of responses (rather than one correct response). Under these conditions the divergent thinking tests did display more than adequate discriminant validity.

The issue of discriminant validity is important in a practical sense because it indicates that divergent thinking tests provide information that would otherwise be unavailable. In behavioral terms it means that if we rely on tests of traditional ability we will overlook children who have outstanding divergent thinking abilities (but only moderate or even low IQs and academic aptitude).

The relationship of divergent thinking with IQ and traditional intelligence seems to vary at different levels of ability. There may even be a threshold of intelligence that is necessary for creative ideation. This would make sense because some basic information processing capacity is necessary for associative and divergent thinking. Additionally, many tests of divergent thinking require that the examinee has some basic knowledge, and that too suggests a modicum of traditional intelligence.

The 'threshold theory' suggests that some traditional ability is necessary for effective divergent thinking. The early estimates were an IQ of approximately 120, but this figure is probably just about meaningless, given that the average IQ in the population is on the rise, and given questions about the validity of the IQ. Still, the concept of a threshold does make good sense, even if we cannot pinpoint a specific IQ.

The threshold may be viewed graphically, as would be the case if divergent thinking scores were graphed as a function of IQ levels. When this is done a triangle of data points appears in the bivariate scatterplot. The top of the triangle is pointed at the origin of the graph, with the scatter of data spreading as IQ

levels increase. If that same scatterplot is bisected perpendicularly to the X axis (and at the hypothetical threshold) and once perpendicularly to the Y axis, four quadrants are formed. Empirical studies find some persons in the first quadrant, with low divergent thinking and low IQ. There are also persons with high IQs and low divergent thinking. There are a few persons with high divergent thinking and high IQ, but no one with low IQ and high divergent thinking. This is because of the minimum threshold of IQ which is necessary but not sufficient for divergent thinking.

There are persons with high IQs and low divergent thinking, which again supports the discriminant validity of the divergent thinking tests. It also suggests that individuals who are extremely good at the convergent thinking and memorization required for exceptional IQs may be at a serious disadvantage for divergent thinking and creative thinking.

A second critical issue is that of the predictive validity of divergent thinking tests. Here again, results have been quite varied. This is not much of a surprise, however, given that creativity can be expressed in so many different domains (some of which may not depend very heavily, if at all, on the kind of divergent thinking that is tapped by tests of divergent thinking). Moreover, divergent thinking tests do not guarantee actual performance any more than any other controlled assessment. As noted above, divergent thinking tests are estimates of the potential for creative thought. The biggest obstacle is the *criterion problem*. There is no widely accepted and universally applicable criterion of creative performance with which to give divergent thinking tests (or any other test of creativity) a fair evaluation. Divergent thinking tests have demonstrated only moderate, and sometimes disappointing, predictive validity. When fluency, originality, and flexibility are all taken into account, predictive validity coefficients have reached 0.55.

Divergent Thinking and Idea Evaluation

Divergent thinking tests assess how well people generate ideas. The generation of ideas is, however, only one part of creative thinking. It is very important to be able to judge ideas, as well as generate them. Further, for creative thinking it is also necessary to judge ideas specifically for originality. Some kind of critical thinking may allow an individual to recognize whether or not an idea will solve a solution, but this is a very different thing from recognizing originality. There is, then, a difference between valuation (seeing the originality of an idea) and evaluation (seeing the effectiveness of an idea). A series of studies suggests that both of these are correlated with, but far from identical with, traditional divergent thinking indices.

Hence someone can do one but perhaps not the other. Someone can generate ideas but not judge them accurately, or vice versa. There is also a difference between inter- and intrapersonal judgmental accuracy, but disappointingly, in both cases the accuracy is below 50%. In other words, original ideas are recognized as such less than half of the time! These findings of only moderate judgmental accuracy have been used to support the theory that creative thinking is more blind (or random, to use the Darwinian label) than guided.

Conclusions

Divergent thinking tests are grounded in sound theory. In particular, both associative theory and Guilford's own SOI model support their use. Divergent thinking tests have generated many interesting research findings. Divergent thinking has been used in studies of the fourth grade slump, for example, and in investigations of the relationship of creativity with suicide ideation. Much of this research is reviewed in other articles in this encyclopedia. The corpus of research is advantageous in the sense that the strengths and weaknesses of these tests are well known. Interpretations of test results are quite easy, given the large literature on divergent thinking. Another strength is the practicality of the tests. They can be used in various settings (e.g., educational, clinical, and organizational) and can be used as exercises or assessments. As noted above, when used as assessments, they are best viewed as estimates of the potential for creative thinking and problem solving.

Glossary

Divergent thinking A kind of thinking often associated with creativity which involves the generation of varied, original, or unusual ideas in response to an open-ended question or task.

Domain The set of representations that underlie and support thinking in a specific area of knowledge; also, any specific area of knowledge, such as art, literature, history, or astronomy.

Domain specificity A theory that argues that the skills, traits, or knowledge that underlie creative performance in a given domain are largely unrelated to the skills, traits, or knowledge that underlie or creative performance in other domains.

g General intelligence, a general factor that governs performance on all cognitive task. IQ tests are designed to measure g.

Microdomain A subset within a larger domain, such as the microdomain of poetry within the larger linguistic domain.

Modularity A theory of domain specificity that claims there can be no exchange of representations among different domains – that information is encapsulated within its given domain.

Task specificity A theory that argues that the skills, traits, or knowledge that underlie creative performance in different microdomains within the same more general domain are different and largely unrelated.

Introduction

Single-factor theories of creativity, like single-factor theories of intelligence, are very appealing because they allow one to paint the full picture of creativity – or at least a large part of it – with a single brushstroke. If creativity were a general trait or a single set of cognitive skills that influenced creative performance of all kinds, it would be much easier to understand, train, and test creativity.

Although single-factor theories of creativity have been popular for many years and continue to dominate creativity assessment, there is growing evidence that they may not explain creative performance across a wide variety of content domains as well as more narrowly defined, domain-specific theories and assessment techniques. In fact, there is considerable evidence suggesting that the skills underlying creative performance are not even so general as to span the many tasks that make up such common content areas as the verbal, mathematical, or artistic domains. This task specific (or microdomain specific) view of creativity argues that the skills that lead to creativity on one task in a broadly defined domain of knowledge, such as writing, are not the same (and show little overlap with) the skills that lead to creativity in another task within the same writing domain. Thus, for example, poetry-writing and story-writing creativity may not rely on the same set of cognitive skills, and creativity in writing plays might call on yet a third distinct set of creativity-relevant writing skills.

Such a fragmented approach to creativity, in which every domain (or even every narrowly defined task within a domain) relies on its own unique underlying set of traits or skills, is naturally less satisfying than a grand, all-encompassing theory of creativity. The most widely held general view of creativity, which posits divergent thinking to be a general, domain-transcending skill applicable in all areas of creative endeavor, has been popular

in creativity theory, training, and testing for many years, and despite doubts raised regarding the possible validity of *any* general theory of creativity by new research suggesting that creativity must be domain specific, divergent thinking theory continues to be used widely both in education and psychology.

After outlining the evidence for domains of creativity and current understandings of domain specificity and domain generality, this article will conclude by examining the implications of domain specificity of creativity for creativity theory, testing, and training. It will also consider theories that bridge generality and specificity and discuss how a newly emerging metatheory of creativity that is rooted in a modified divergent thinking theory and that incorporates a domain specific view of creative-thinking skills can replace earlier general theories as a unifying idea in creativity theory, training, and testing.

Domains and Domain Specificity

The concept of a domain as a set of representations or understandings underlying comprehension of a specific area of knowledge and performance of the tasks associated with that domain is, at the conceptual level, a fairly clear one. Applying this definition in a way that demarcates domain boundaries can be a much more contentious exercise, however.

In 1983 Howard Gardner published *Frames of Mind: The Theory of Multiple Intelligences*, and the domains (or, as Gardner termed them, ‘intelligences’) that he described have become familiar to many readers and are especially influential in the field of education. Gardner has distinguished the following intelligences:

- linguistic intelligence (abilities having to do with understanding and using the sounds, rhythms, and meanings of words and the functions of language);

- musical intelligence (abilities having to do with understanding and employing rhythm, pitch, timbre, and musical expressiveness);
- logical-mathematical intelligence (abilities having to do with finding logical and numerical patterns and producing chains of reasoning);
- spatial intelligence (abilities having to do with understanding the visual-spatial world and transformations within that world);
- bodily-kinesthetic intelligence (abilities having to do with control of one's body movements);
- interpersonal intelligence (abilities having to do with understanding and responding appropriately to the feelings, moods, and motivations of others);
- intrapersonal intelligence (abilities having to do with understanding one's own feelings, moods, and motivations, with assessing accurately one's own strengths and weaknesses, and with drawing upon such knowledge to guide one's behavior);
- naturalist intelligence (abilities having to do with recognizing, categorizing, and drawing inferences about features of the environment; this intelligence was added later and was not part of the original list of seven intelligences).

Gardner's classification is based on such evidence as: (a) the effects of brain trauma, such as strokes, that influence functioning in one domain but not others; (b) the existence of prodigies and autistic savants who show extreme abilities in one domain but not others; (c) psychometric evidence that suggests consistency among the skills that lie within a given domain and independence between the skills that fall in different domains; and (d) the existence of a set of core information-processing operations that can deal with specific kinds of input.

Gardner's eight intelligences are not the only way that domains have been conceptualized, but they will suffice as an illustration of the idea of broadly defined cognitive domains. The term domain is often also used to refer to general fields of knowledge or ways of knowing without specifying clear-cut boundaries between domains, and the breadth of what may be properly called a domain is in most instances not precisely defined. For example, a child's understanding of gravity may be viewed as a different domain of knowledge than her understanding of object permanence, number, animacy, and so on. It is also possible to lump many such understandings together as a single larger and more inclusive domain (in which case, e.g., a child's understanding of gravity and her understanding of object permanence, number, animacy, etc., might be thought of as all falling within the domain of early mathematical and scientific concepts). Overall, as the idea that development is domain specific has increased in popularity among psychologists, the number of such domains has also tended to increase, and the breadth of the hypothesized domains has tended to shrink.

Some writers use the term microdomain to refer to subsets of skills that seem to go together and yet have somewhat separate developmental histories. The use of pronouns, for example, can be considered a microdomain within the larger linguistic domain, and counting skills can be thought of as a microdomain within the larger mathematical domain. There are not clear guidelines for demarcating domains and microdomains, and usages often overlap.

An important area of disagreement among those who argue for the significance of distinct domains of knowledge is the possibility of interaction among the skills and knowledge that make up the various cognitive domains. Some theorists argue for strict modularity; under such an interpretation, each information-processing module is encapsulated and cannot make use of representations from other modules. One oft-cited example of such an encapsulated module is the perceptual system, which is at least relatively immune from input from other modules (and thus one's beliefs or preferences cannot interfere, or can interfere at most only slightly, with what one sees or hears – and the fact that one does not want or expect to see an elephant in one's living room will in no way interfere with actually seeing or hearing an elephant if one should appear there!). Strict modularity is an extreme version of domain specificity, but modularity and information encapsulation are not essential features of theories of domain specificity.

Evidence for Domains of Creativity

Any evidence that there are different cognitive domains, even when that evidence is collected with an indifference to creative performance, is indirect evidence that creativity is domain specific. This is true for the simple reason that creative performance must occur in *some* content domain; and if the basic cognitive skills underlying performance in that domain are domain specific, this will necessarily have an impact on creative performance in that domain as well as the performance of more ordinary tasks in the domain (tasks unrelated to creativity).

The larger battle about domain specificity – which includes, for example, disagreements about the degree to which generic intellectual competencies exist and can be tested, as is assumed in standard IQ testing – is beyond the scope of this article. The evidence for domain specificity of creativity goes beyond the assertion that different content domains rely on different basic skills for performance of all kinds, however. Even if there is a significant degree of general intellectual ability (or *g*, which is what IQ tests purport to measure) that influences performance across many domains, creativity may still be largely domain specific as long as *g* accounts for less than half the observed differences in performance across domains. Domain specificity in creativity isn't an argument against general intellectual skills per se. What domain specificity theorists claim is that the skills, traits, and understandings that underlie *creative* performance – which are conceptualized as a set of skills, traits, and understandings that go beyond those skills needed for successful (but not necessarily creative) performance – vary from domain to domain. Under domain specificity, general intelligence might still influence performance across domains, but creativity-specific skills or traits (such as divergent or associative thinking, resistance to premature closure, openness to experience, or intrinsic motivation) are not domain general skills of the kind that general intelligence (*g*) is theorized to be.

Arguments for the domain specificity of creativity are based primarily on research into the creativity of actual creative products, such as works of art, and not on the testing of specific intellectual abilities associated with various content domains.

This evidence suggests that levels of creative performance on tasks in one domain are essentially unrelated to levels of creative performance on tasks in other domains, especially once the effects of *g* (as measured by IQ or similar general aptitude tests) have been statistically removed. This research has even shown that creativity in performing one kind of task within a broad cognitive domain may be unrelated to creativity in performing other tasks within the same domain.

A widely used technique in creativity research is to ask subjects to create something, and then to have groups of experts in that field independently evaluate the creativity of those products. This method is called the consensual assessment technique. It was developed and validated by Teresa Amabile in the early 1980s and has been used widely in creativity research since then. It is based on the idea that no matter what creativity may turn out to be and no matter what theory may someday best explain it, judgments of the creativity of work or products or performances in a given field are most appropriately made by recognized experts in that field. Thus the creativity of poems is best judged by poets and poetry critics, and the creativity of cosmological theories is best judged by cosmologists. Although at the cutting edge of any field and where paradigm-shifting work is likely to be the focus there may be many disagreements about the creativity of a particular work or idea, assessments of more garden variety or everyday creativity – the kind of creativity that occurs in most psychological studies of creativity – tend to produce fairly uniform judgments among appropriate experts. Thus by asking a group of artists and art critics to independently evaluate the creativity of a group of collages, or a group of fiction writers and critics to independently evaluate the creativity of a group of stories, a researcher can obtain a reliable and valid measurement of the creativity of a group of creative products.

Several studies using subjects of different ages ranging from kindergarten to adults have shown that when subjects are asked to produce more than one creative product – such as collages, poems, stories, and mathematical puzzles – the creativity ratings of the products of each individual vary significantly. In fact, there is often little or no relationship between the creativity ratings a subject's various works of different types receive, despite the fact that the level of one's creative performance on a given task is highly predictive of performance on the *same* task, even when the second work is produced as much as a year after the first.

It should be noted that this lack of relationship among creativity ratings on different products is not only true across broadly defined domains – such as the linguistic and artistic domains – but also, in at least some cases, within domains. A prime example of such within-domain task specificity is the lack of correlation between poetry- and story-writing creativity that has been observed in several studies.

Approaching the question of domain specificity of creativity from a creativity training perspective, it has also been shown that training in divergent thinking (which is the most common kind of creativity training exercise) can also be targeted to specific domains, or even to specific tasks within domains. For example, divergent thinking training using only poetry-relevant exercises – such as brainstorming words with similar beginning sounds (alliteration) or words that can stand for or represent a given thing or idea (metaphor) – tends

to increase poetry-writing creativity far more than story-writing creativity.

An important source of evidence *against* domain specificity of creativity – evidence favoring domain generality of creativity – comes from studies using self-report scales of creativity. When individuals are asked to rate their creativity across various domains, the levels of creative achievement they report in the various domains tend to be moderately correlated. Critics of this research point out (a) the questionable validity of self-report scales and (b) the response-set bias that may lead individuals to systematically under- or overestimate their own creative activities in all or most domains.

Creativity theorists and researchers are far from unanimous about how best to interpret the available evidence regarding domain specificity of creativity, and although the trend in recent years has favored a more domain-specific approach, this could change depending on the results of future research.

Common Misunderstandings About Domain Specificity: The Puzzle of Polymaths

There have always been a few people of exceptional talent who are highly creative in many domains. Some observers focus on the rarity of such polymaths and take this as evidence in favor of domain specificity; others home in on the existence of polymaths, however rare they may be, and take it as evidence for domain generality. Either way, such arguments are misleading. Domain specificity does *not* predict there will be no polymaths; in fact, it predicts that some such multitasking people should exist. And domain generality theorists can explain their rarity just as easily.

What domain specificity claims is that creativity in one domain does not predict creativity in other domains. It thus claims that correlations between creativity in different domains should, on average, be zero. This means that one should expect some people will have high levels of creativity in many areas and some should demonstrate very low levels of creativity in many areas, not that everyone should be creative in the same number of domains. Some creative painters might also be creative poets, while other creative painters might exhibit no creativity as painters whatsoever. (By way of analogy, think of any two unrelated traits, such as having green eyes and being tall. The fact that a few people with green eyes are also tall does not show these traits are related. When two factors are unconnected, they will appear together in some cases. This is what randomness predicts.) If domain specific creative abilities are randomly distributed, one would *expect* a few people to be creative in many domains, some people to be creative in several domains, and some others to be creative in few domains or none, based on a normal distribution of unrelated abilities. The existence of a few polymaths does not disprove domain specificity. It is *exactly* what domain specificity predicts.

For very different reasons, the scarcity of polymaths can be explained by domain generality theorists. If creativity is domain general and a person has enough of it to be highly creative in any domain, then it might seem that one should be creative across the board. Most genius-level creators are *not* immensely creative outside the one domain in which they show excellence, however. This is probably best explained but what creativity

researchers call the ‘ten year rule,’ which argues that it takes many years of preparation in a field before one can do groundbreaking work in that domain. If it takes ten years of hard work in a field before one can produce works of genius, it is hardly surprising that few people manage to reach the highest levels of creativity in a variety of fields. There simply isn’t time.

So the presence of creative polymaths tells us nothing about domain specificity, and their rarity tells us nothing about domain generality. In this case, both theories predict well the world as we find it.

Mixed and Hierarchical Models

Creativity theorists needn’t choose simply between domain generality and domain specificity. There are theories of creativity that incorporate aspects of both positions.

At the most basic level, one can simply posit the existence of both creativity general and domain specific skills and traits. Amabile’s componential model, which argues for three factors – creativity general skills and knowledge, domain specific skills and knowledge, and task motivation – does just that.

James Kaufman and John Baer’s APT model is a hierarchical theory of creativity that includes both domain general and domain specific elements. The central idea of a hierarchical model is that there are varying degrees of domain specificity and generality ranging from the most general, such as general intelligence (*g*), to the most specific (e.g., microdomains or task specificity) There are four levels in the APT hierarchy:

- *Initial Requirements* are completely domain-general factors that influence creative performance to some degree across all domains (e.g., intelligence);
- *General Thematic Areas* are broadly defined fields or areas that include many related domains, such as Artistic/Verbal, Artistic/Visual, and Math/Science. The seven General Thematic Areas that they have identified are shown in [Figure 1](#).

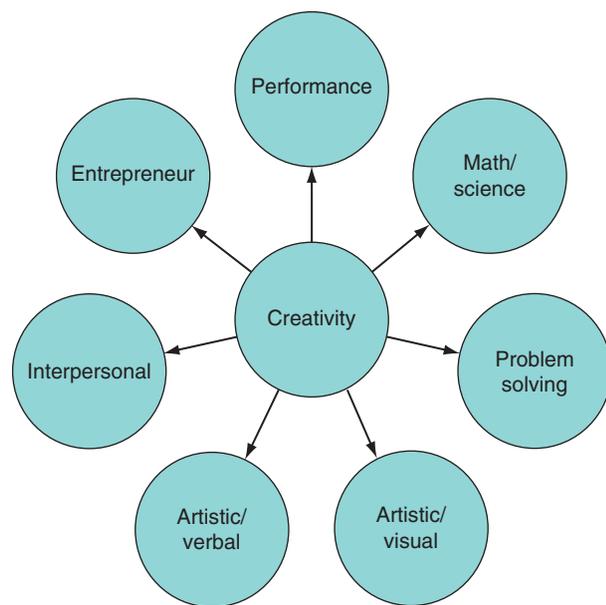

Figure 1 General thematic areas of the APT model of creativity.

- *Domains* lie within larger General Thematic Areas and refer to more limited ranges of creative activities. For example, in the General Thematic Area of Artistic/Verbal one would find subdomains such as narrative fiction, drama, and poetry.
- *Microdomains* refer to more specific tasks within domains. For example, within the domain of poetry one might find haiku, epic poetry, and sonnets.

A hierarchical model such as the APT provides a bridge connecting domain generality and domain specificity and argues that aspects of both theories should be not only acknowledged but incorporated fully into a complete theory of creativity.

Conclusions and Implications

If creativity is domain specific, it means that a single theory of creativity – such as the theory that divergent thinking is a basic component of all creative thinking – cannot account for the diversity of creativity across domains. Creativity theories must either become domain specific themselves or find some general approach to dealing with these domain-based differences. Similarly, domain specificity of creativity means that creativity testing as currently practiced is necessarily inadequate and of limited validity. And finally, creativity training programs cannot be assumed to increase creativity across all domains simply because they successfully promote creativity in one domain.

Baer has proposed a divergent thinking metatheory of creativity that, although encompassing all domains of creativity in a single conceptual scheme, nonetheless takes into account the domain specificity of creativity. According to this metatheory, divergent thinking is an important creative thinking skill, but the cognitive mechanisms underlying divergent thinking are different in each domain (or possibly even for each task within a given domain). Thus there are many *different* divergent thinking skills rather than a single divergent thinking skill. Divergent thinking as a general class of thinking skills is still a useful construct, however, both (a) because it makes this wide range of skills more coherent and easy to conceptualize and (b) because it makes it simpler to postulate and identify the appropriate domain-specific divergent thinking skills that will be important within any given domain or microdomain. Thus in terms of what is happening inside a creative thinker’s head, divergent thinking skill may actually be many unrelated, domain specific cognitive skills; but in terms of how psychologists can understand these many diverse skills (viewing divergent thinking from the outside, as it were), divergent thinking is a coherent class of skills that bear a strong family resemblance.

Moving from the implications of domain specificity for creativity theory to its implications for creativity testing, a domain specific understanding of creativity provides a very direct challenge to existing notions of how to test creativity. Simply put, to the extent that creativity is domain specific, creativity testing becomes that much more difficult. If creativity is domain specific, what exactly is one to test? Creativity testers will necessarily have to determine in which domain(s) of creativity they are interested, because under a domain-specific theory of creativity, general creative thinking skill becomes an empty

construct. Tests of creativity in specific content domains – which might use the consensual assessment technique to evaluate the creativity of products, or might instead find simpler (perhaps paper-and-pencil) techniques for assessing domain specific skills – would still be possible in principle, but they could be of only limited range and applicability. Major test developers may not be willing to support extensive test development efforts for tests of such limited potential use.

Creativity training, on the other hand, can accommodate domain specificity of creativity rather easily. Most creativity training programs already use a wide variety of tasks, spread across various content domains, in the exercises they use to improve divergent thinking and other creative thinking skills. Creativity training programs aimed at a particular domain can easily limit their training exercises to ones connected to that domain, while programs aimed at increasing creativity in general – the vast majority of programs – must be careful not to limit their training exercises to just one or a few content domains.

Creativity theory has only recently begun to accommodate research evidence suggesting that creativity is task specific, although the hierarchical approach discussed above is promising. General, domain-transcending theories – if true – would have far greater power than domain specific theories that account only for creativity in a limited content domain. For this reason, and because creativity theories have historically been one-size-fits-all theories, domain general theories of creativity continue to have great appeal.

It should be noted that the research evidence pointing toward domain specificity of creativity is fairly new, and, like the research that preceded it, this research may not tell the

whole story. As noted above, self-report scales of creative behavior suggest more generality of creativity than do assessments of the creativity of actual creative products. It is quite possible that both domain specificity and generality are true, each in part and in its own way. More research will be needed to clarify the conditions under which generality or specificity of creativity is the more valid perspective. In the meantime, both views will continue to claim adherents among researchers and theorists.

Glossary

Creativity The English word creativity is linked, historically and etymologically, with the Latin word *creare* (to make) and the ecclesiastical Latin word *creator* (Creator); therefore, both refer to the concept of origin itself (consider the related term *originality*). One of several useful psychological definitions was given by Csikszentmihalyi in 1996, when he suggested that the term creative could be applied to “any act, idea, or product that changes an existing domain, or that transforms an existing domain into a new one.” A more subjective, but also useful, definition was given by Martindale, who wrote that a phenomenon is creative if it is novel and, in some manner, useful or appropriate for the situation in which it occurs. The noun *creativity* is used if a process or phenomenon is being discussed, while the adjective *creative* is used if a behavior, an experience, a product, a person, a group, or an environment is being described. In all these instances, there is the assumption that something is both novel and culturally appropriate to a given task.

Dream A series of images, reported in narrative form, that occurs during sleep. These images are usually visual and kinesthetic, but they can also be auditory or even gustatory or olfactory. They can be recalled spontaneously upon (or somewhat after) awakening, or can be evoked if someone is awakened from REM (rapid eye movement) sleep or even from non-REM sleep.

Dream interpretation An attempt by someone (often the dreamer) to attribute meaning to the content of dream reports for purposes of counseling, psychotherapy, or personal/social growth. Various approaches to dream interpretation exist, many of them contradictory; and some investigators insist that dream images are randomly evoked and dream content is essentially meaningless.

Electroencephalogram (EEG) A graphic depiction (voltage vs. time) of the brain’s electrical potentials recorded by scalp electrodes and usually delineated by ink tracings (as are the electromyograph (EMG) and electro-oculogram (EOG)).

Hypnagogia The pattern of phenomenological properties immediately preceding sleep. Hypnagogic reports typically include imagery (visual, auditory, kinesthetic, etc.) but little narrative.

Hypnopompia The pattern of phenomenological properties immediately preceding awakening.

Hypnopompic reports typically include imagery (visual, auditory, kinesthetic, etc.) and are more likely to contain narrative than are hypnagogic reports.

Lucid dream reports Characterized by claims that the dreamer was aware that he or she was dreaming during the

ongoing dream. Several techniques exist that purport to cultivate dream lucidity.

Nightmares Reports of anxiety-provoking dreams, marked by confusion, fear, horror, and other types of unpleasant affect.

Non-REM sleep Consists of four sleep stages that occur in a cyclical pattern. Stage 1 sleep occurs immediately after sleep begins, with a pattern of low amplitude and rapid frequency EEG tracings; Stage 2 sleep has characteristic EEG tracings of 12 to 16 cycles per second known as sleep spindles; Stages 3 and 4 have progressive, further slowing of EEG tracings, and an increased amplitude. Over a period of about 90 minutes after sleep begins, most people have passed through the four stages of non-REM sleep and have emerged from them into the first period of REM sleep. Non-REM sleep is also referred to as orthodox sleep or S-sleep (because of its characteristic synchronized EEG tracings).

Primary process In psychoanalytic theory this term refers to unconscious mental activity that operates without regard to logic or consensual reality, but provides for wish fulfilment, governed by the ‘pleasure principle.’

Rapid eye movements (REMs) Conjugate, coordinated horizontal or vertical eye movements, occurring rapidly during sleep and, less frequently, during napping, daydreaming, and hypnotic imagining, and at other times when one’s attention is turned inward rather than toward the external environment.

REM sleep A recurring stage of sleep, characterized by rapidly occurring conjugate eye movements, loss of muscle tonus, and desynchronized EEG brain wave activity. REM sleep is also referred to as Stage 1 REM sleep, Stage REM, D-sleep (because of its characteristic desynchronized EEG tracings), and paradoxical sleep (because its EEG tracings resemble wakefulness). REM sleep recurs in ~90- or 100-minute intervals in humans; it also occurs in nonhuman sleep, for example, among most mammals.

Sleep The recurring period of relative physical and psychological disengagement from one’s environment characterized by cyclical brain/body activity.

Sleep terrors (or night terrors) Episodic conditions usually occurring during Stage 4 sleep, marked by panic, confusion, and poor recall. Characteristically, the reports of sleep terrors do not include imagery or narrative. They occur developmentally, peaking by two years of age, but sometimes may occur later.

Wakefulness The recurring period of relative physical and psychological engagement with one’s environment and the presence of various patterns of phenomenological properties.

Creativity, Dreams, and Culture

From the perspective of Western psychology, *creativity* is a term that can be used to describe the process of bringing something new into being by becoming sensitive to gaps in human knowledge, identifying these limitations, searching for their solutions, making guesses as to a potential resolution, testing one's hypotheses (sometimes modifying and refining the results of these examinations), and communicating the final product. However, the creative process is imperfectly understood; these steps may be linear or may overlap, they may occur in a planned sequence or spontaneously, or they may be intentional or operate outside of one's awareness. It could also be said that people, groups, or cultures are creative during those periods of time when they exhibit activities, innovative for them, that yield concepts, objects, or behaviors that address human needs (e.g., for survival, for enhanced work performance, for enjoyment, for aesthetic satisfaction, for enriched quality of life) in ways considered valuable by a social group. These novel concepts, objects, and behaviors (e.g., a scientific discovery, mathematical theorem, philosophical insight, an artistic masterpiece, technological product, military victory, or diplomatic accomplishment) can be termed creative, although one social group might arrive at a different consensus from that of another group. In other words, the term *creativity* is a social construct used to describe various processes and outcomes.

The word *creative* has several possible meanings. To most observers, this adjective describes something new that has been brought into existence. Definitions of *creative* and *creativity* range from simple problem solving to the full realization and expression of all an individual's unique potentialities. There appear to be at least four aspects of creativity: the creative process, the creative product, the creative person, and the creative environment.

Dreams may play a role in the creative process, identifying problems, searching for solutions, testing hypotheses, and communicating the results to the dreamer. In 1996, Strauch and Meier discussed how the creative transformation of memories is an expression of human consciousness that can take place during both wakefulness and dreaming.

Ullman, in 1965, listed four reasons to explain why dreams partake in a creative process. All dreams are original; no two are alike. Dreams combine various elements to form new patterns. Like many creative processes, most dreams are involuntary experiences. Dreams contain metaphors and symbols that have creative potentials. Many non-Western societies have also appreciated the creative aspects of dreams. Among Australian aborigines, the Laws of the Dreaming were laid down during what they call the Creative Period. Each species has its own set of laws, and all of these laws are a part of the Dreaming, the ground of all existence. Humans can obtain new information (e.g., new songs and rituals) from the Dreaming; thus the Dreaming is dynamic, not static, in nature.

In *The Tempest*, Shakespeare wrote about "such stuff as dreams are made of." Many of the images that appear in dreams can be symbolic in nature. Images are mental representations of objects or persons not physically present. Whereas an image directly represents the object it pictures, a symbol is an image that stands for something else. In much the same way,

activities in dreams may be metaphorical, a metaphor being a narrative or an activity that stands for something else. Sometimes dream content makes no sense if the dreamer presumes that the images refer directly to the people or objects they depict. In those instances, the dream might make more sense if allowances are made for the possibility that its images are referring to something other than themselves. Freud complicated this issue by asserting that the symbols occurring in dreams differ radically from other symbols because dreams express, in disguised form, wishes the dreamer has repressed. However, this assertion implies a sleep/wakefulness discontinuity. Most contemporary dreamworkers believe that the symbol-making process in dreams exhibits more commonalities than differences with the symbol-making process in waking life. This emphasis on the continuity between waking life and dreaming life can be found even in the writings of Thomas Aquinas, who wrote, "Those things that have occupied a man's thoughts while awake recur to his imagination while asleep."

This continuous, cognitive-psychological position has also been taken by Adler, Hall, and Foulkes, all of whom described dreams as meaningful but not as containing preplanned encoded messages that need to be translated the way a linguist would work with a foreign language. According to Foulkes, the dream is "knowledge-based" and "bound to reflect some of the ways in which the dreamer mentally represents his or her world." Indeed, almost anyone awakened after a dream is able "to identify *some* events as having rough parallels in her or his waking experience." A body of research indicates that dreams often are characterized by complex thinking processes. Some differences between waking cognition and dreaming cognition exist, but they are continuous rather than discontinuous. In 1979, Rycroft mused that, if dreams are poetry, their creative efforts are imperfect. Poets and artists need to cast their meaning in metaphors and symbols that are a part of the shared legacy of their culture. But dream imagery tends to be too dependent on the dreamer's personal experiences to convert easily into works of art with wide appeal. Some dream theorists urge the dreamer to accept dream images and stories as creative experiences in their own right. However, writing from a neuroscience perspective in 1983, Crick and Mitchison proposed that dreams function to purge unnecessary, even parasitic, brain cell connections produced during wakefulness; dream content, therefore, is best forgotten.

On the other hand, Hobson, also taking a neurophysiological and neurochemical perspective, wrote in 1988 that, since virtually everyone dreams, the dream report stands as testimony to the universality of the artistic experience. In dreams, all become writers, painters, and film makers, combining extraordinary sets of characters, actions, and locations into strangely coherent experiences. Hobson concluded, "I strongly object to any implication that the artistic experiences of waking or dreaming are fundamentally pathological, defensive, or neurotic," adding that the brain is so determined to find meaning that it creates dreams out of images that have been randomly evoked by its own neurochemical activity.

It can be seen that dream specialists do not speak with one voice on the topic of creativity and dreams. But non-Western traditions lack uniformity as well. Among pre-Columbian Native American dream traditions, some saw dreams as having the same meaning for every member of the tribe, whereas

others felt that dreams conveyed meanings personal to the dreamer; some believed that dreams served problem-solving functions, whereas others felt that they forecast the future; some believed that dreams dictated actions that needed to be taken in daily life, whereas others believed that dream events took place in the spirit world. In some tribes, dream messages were direct and undisguised, whereas for others they required interpretation. However, few North American tribal groups neglected dreams; they were seen as sources of knowledge, power, inspiration, and what today would be called creativity.

Research on Creativity and Dreams

Weisberg, in 2006, stated that creative problem solving has occurred when a person produces a novel response that solves the problem at hand, but then he went on to debunk many highly publicized accounts of problem solving in dreams and other altered states of consciousness. A critical perspective needs to be taken regarding not only anecdotal accounts but also formal research programs. These phenomena are difficult to investigate for several reasons. Even if a useful definition of *creativity* can be implemented, an investigator never works with a dream, but rather with a dream report. These reports, whether obtained from archives, from field research, or from laboratory research, are subject to so many vagaries of memory, unconscious distortion, and deliberate omission or elaboration as to pervade the field with a well-deserved sense of modesty when even tentative results are announced.

Anecdotal Data

Keeping Weisberg's caveat in mind, many instances of creative breakthroughs in dreams have been well documented. They include Mendeleev's conceptualization of the Periodic Table of the Elements, Howe's invention of the lock-stitch sewing machine, Blake's development of a process of copper engraving that he later used to illustrate his songs, Tartini's composition of his most celebrated sonata, and famous fictional works by Robert Louis Stevenson and Daphne du Maurier, among others. Some dream-inspired books are nonfictional; the mathematician Jerome Cardan had a recurring dream that ordered him to write *De Subtilitate Rerum*, which was to become his most celebrated book. Whenever Cardan became lax in his writing habits, the dream returned with great force. Many creativity researchers have discussed creativity within the framework of preparation, incubation, inspiration, and verification, although these four stages may not always develop in a predetermined order in creative work and problem-solving, and some stages may not occur at all. It has been suggested that, when the problem-solver's deliberate efforts to evoke solutions are abandoned during sleep, dreams can impart clues and novel approaches that elude individuals during wakefulness. Many researchers cast doubt on the credibility of anecdotal reports of this nature, noting that many of them were made long after the event; hence there is the risk of distortion and elaboration. Even in cases that appear to be credible, a period of considerable preparation is required; however, simply taking a break from the problem is a more likely explanation than unconscious

processing, because during the break people typically mull over a solution. Many of the most frequently cited cases of dream creativity did not take place in dreams at all, but actually occurred in transitional states of consciousness, not sleep. Rarely do dreamers record their dreams and secure them in such a way that their creative potential can be assured.

Formal Research Data

Several investigators have used tests, questionnaires, and interviews to obtain information about creative problem solving in dreams. Some representative studies demonstrate the direction that formal research has taken; the journal *Dreaming* is an excellent resource for those who are interested in following developments in this field.

Barrios and Singer, in 1982, queried 48 volunteer subjects about their creative impasses, finding that most had been blocked for more than three months. The subjects were divided into four groups and randomly assigned to one of four conditions: exposure to either a waking imagery or to a hypnotic induction procedure, participation in a focused and collaborative examination of their projects in which task-irrelevant thoughts were avoided, and a control group encouraged, in a nondirective fashion, to discuss their projects.

Results indicated that the waking imagery and hypnotic imagery conditions were most effective in promoting the resolution of creative blocks.

An experiment reported by Brodsky, Esquerre, and Jackson in 1991 asked students, while they were awake, to apply an operational definition of dreaming to four problem-solving tasks. All proposed solutions were rated on a five-point creativity scale by raters, working independently. No gender differences were noted, nor was frequency of dream recall associated with the creativity ratings. However, students who attributed considerable importance to their dreams received higher creativity scores, as did students who reported having had lucid dreams. It was suggested that dreaming consciousness is a permission-giving format for eliciting active imagination, bypassing typical goal-oriented thinking processes.

A series of experiments reported by Cartwright in 1984 demonstrated that problem solving in dreams probably is more successful when the material to be processed is emotionally or personally meaningful.

Other studies have shown that dream reports of highly creative people exhibit more primary process thought than less creative individuals but also show greater symbolism and more unusual combinations of dream content elements.

Highly creative individuals also endorse beliefs that dreams have hidden and symbolic meaning, can produce inventions and artistic creations, can sometimes predict the future, and can be programmed (or 'incubated') more so than less creative individuals. The creative people also claim to make a greater effort to remember their dreams than the other group. Highly creative persons relax more easily and fall asleep more rapidly, and more of them claim to be able to solve problems in dreams than do less creative individuals.

The association between nightmares and creativity has long been a matter of conjecture. A questionnaire survey of college students found that art majors report the most nightmares,

whereas physical education majors report the fewest, with mathematics and science students in the middle. Furthermore, students with frequent nightmares tend to report more visual imagery during awakening, become easily absorbed in aesthetic stimuli, and score higher scores on a hypnotizability scale than do other students.

Other studies have found a close relationship between the frequency of nightmare reports and psychopathological scores on personality tests for dreamers reporting frequent nightmares. Furthermore, these high nightmare individuals have more primary process material in their dream reports than low nightmare individuals.

Cross-Cultural Considerations

It is not the dream itself that is available for interpretation, but the individual's or group's report of the dream experience. The visual, sensory, and emotional aspects of a dream are often lost in Westerners' accounts of dreams, but indigenous dreamworkers generally consider these qualities to be among the most important.

Remembered dreams and performed myths are both forms of production that bridge the verbal, logical characteristics of rational thought with the visual-sensory-spatial-emotional images that reach their most elaborate level of integration in art. The recounting of a dream brings the nonverbal, nonrational imagery of the dream to awareness, and begins to link it with logical reasoning.

Possible Mechanisms

Contemporary sleep and dream research has demonstrated the elaborate, entirely intrinsic mechanisms of *state* control. In other words, a change in the brain's state while asleep causes a change in the dreamer's mental state. Sensory input can be internally controlled so that even the transforming mechanisms do not operate alone to protect the system from overload. Three features of the modern conception of the nervous system – its intrinsic plasticity, its autoregulation, and its creativity – give us a very different set of operating principles on which to construct a scientific psychology. This model depicts a nervous system that can turn itself on and off, regulate the flow of internal information in diverse ways, and control external information's access to the system. It is in the context of this model that the incorporation of presleep stimuli, dream incubation, and lucid dreaming assume importance for the understanding of creativity and dreams.

Incorporation of Presleep Stimuli

The influence of presleep stimuli in dream content has been successfully attempted in experiments using hypnosis, subliminal stimulation, emotionally arousing films, and real-life stress situations. The results indicate that it is relatively easy to influence dream content in predictable ways. It has been suggested that dreams may serve the purpose of assimilating emotionally arousing information into problem solutions that are already embodied in existing memory systems.

Dream Incubation

If it is possible for an experimenter to influence the course of a subject's dreams, then it should also be possible for dreamers themselves to influence their dream content.

Dream incubation was common among the American Plains Indians, among artists in ancient China, and in the practices of ancient Egypt, Greece, and Tibet. Foulkes and Griffin moved from the anecdotal level to more rigorous types of inquiry, teaching 23 subjects 'dream control' methods, and asking them to dream about randomly selected topics. The subjects kept daily records of their dreams for 10 nights. Judges attempted to match dreams with the suggested topics; their matching did not exceed what would have been expected by chance.

The same investigators designed a second study using 29 highly motivated subjects who claimed some previous success in dream control or an interest in the topic. They spent ten nights attempting to dream about assigned topics, but in this case they were allowed to select the nights on which they felt they could successfully control their dreams. Again, judges were unable to match the dreams with the topics. Other studies have reported more encouraging results in projects in which incubated dreams focus not on abstract topics but on real-life concerns. Some people expect too much when they assume their dreams will become springboards for feats of artistic creation. Nevertheless, such former presidents of the International Association for the Study of Dreams as Barrett, Delaney, and Garfield have cited case studies indicating how dreams can help many people live more fully integrated lives and augment their capacity for adaptation and personal growth.

Lucid Dreaming

When a dreamer realizes that he or she is dreaming, the dream is considered to be lucid. The Tibetan Buddhist practice of 'dream yoga' focused on the ability to retain awareness and lucidity during night time dreaming. However, the Hindu yogic dream tradition eschewed such dream manipulation in favor of a waking meditation practice described as 'merging with the light.'

Aristotle wrote about lucid dreams, noting that when one is asleep, there may be something in one's awareness that declares what is presented is a dream: "The sleeper perceives that he is asleep, and is conscious of the sleeping state during which the perception comes before his mind." In the second edition to *The Interpretation of Dreams*, published in 1909, Freud noted that some people are clearly aware when they are dreaming and are able to direct their dreams.

First hand reports from lucid dreamers have produced a list of methods thought to be useful in facilitating dream lucidity. Presleep reflection is frequently mentioned; in other words, one can often incubate a lucid dream. Asking such critical questions as 'Is this a dream?' and 'Am I dreaming?' during a dream will often produce lucidity. Some dreamworkers encourage people to ask these questions during the day at regular intervals, with the expectation that these questions will later arise during the night. External stimulation is sometimes incorporated into a dream and triggers lucidity; again, this can be deliberately programmed.

Gackenbach has estimated that about 58% of the population experience a lucid dream at least once, while about 21% report one or more per month. Instruction in lucid dreaming has been used therapeutically, especially to help people who suffer from chronic nightmares. Studies have shown that lucid dreaming can be 'learned' by those who wish to use it for creative problem solving. There are anecdotal stories of more specific skills being learned as a result of lucid dreaming.

Neurophysiological and Neurochemical Mechanisms

Several studies with animals indicate that the frequency of time spent in REM sleep increases as a result of new learning, such as finding the way out of a maze. This relationship is evident in work conducted with cats, mice, rats, and newly hatched chicks. Therefore, rapid eye movement (REM) sleep may play an important role in the consolidation of such cognitive activities as learning, memory, and problem solving for both humans and other organisms that engage in REM sleep.

The role of learning in REM sleep production may be connected to an underlying biological process. It has been suggested that new protein structures are being synthesized in the brain during REM sleep. Evidence indicates that the initiation of REM sleep does come from the brain stem, and then extends itself over the entire brain cortex. Because animal experiments indicate that protein synthesis is present in new learning, it has been hypothesized that it also takes place during REM sleep.

Some theorists have used computer analogies to describe REM functioning as akin to 'off-line processing.' The acquisition of input information is placed in temporary storage, until processing components are available. Information about the day's events is gathered and stored until the onset of REM sleep, when it can be 'processed' (i.e., integrated with memories and formed into strategies for the future).

The spiny anteater, or echidna, is an early mammal whose sleep pattern shows no REM activity. The echidna's brain has a large prefrontal cortex, presumably to integrate new experience with older experience. The mammals that evolved later were able to handle this task more efficiently during REM sleep; as a result, their brains were smaller – a more productive direction for evolution to follow. This problem did not exist in the earlier reptilian species; their behavior was largely reflexive, and this activity was adequately handled by a small brain with a neo-cortex. Dreams, then, can serve as a window on the neural processes whereby – from early childhood on – strategies for behavior are being set down, modified, or consulted. This process and the mechanisms involved, which were termed the 'unconscious' by Freud, can be used advantageously in the clinical setting by both Freudian and non-Freudian psychotherapists and other dreamworkers.

A model that has tried to be inclusive in regard to incorporating physiological discoveries about dreams is that proposed by Hobson and his associates in 2000. They proposed that during both waking and dreaming states there is an *activation* of the brain, a source of *information* that is evoked during the waking or dreaming process, and a biochemical *modulation* that differs radically from wakefulness to sleep. Dream experiences are, in part, a product of self-organizing tendencies in

the brain during which the randomly evoked informational data are creatively patterned into a narrative to which meaning can be attributed. The cells deep in the pontine area of the brain stem are *activated*, generating REM sleep and randomly stimulating the forebrain, which then evokes *information* by using stored memories to make sense of the incoming neural firing. On the one hand, Hobson and his associates have connected dreaming to a *modulation* of biochemical events in the brain, but, on the other hand, they have evidenced a keen understanding of dreams as imaginative creative events.

In 1988, Hobson pointed out that Freud insisted that wishes and repressed desires caused dreaming, but that this notion has been discredited due to data that it is brain stem mechanisms during sleep that cause dreaming. Even though brain mechanisms trigger REM sleep (and dreaming), wishes may be expressed and may even shape dream plots, but they are in no sense causative of the dream process. Hobson concluded that dreams are not the result of an attempt to disguise repressed wishes but are a direct expression of a synthetic effort. One's memories are scanned for images that will match these internally generated patterns. This model sees dreaming as the pre-programmed running of an internal system. The bizarre features of a dream are naturally associated with the mode of operation of the system during dreaming sleep, and there is no need for a mechanism that would transform information. Since the system is capable of selecting what computer scientists would call the 'store' or 'no-store' modes, there is no need to postulate an active energy-consuming mechanism for the restoring of dream material in the unconscious. It can simply be the no-stored mode that is unremembered.

For once, wrote Hobson, contemporary scientists can agree with Freud's assertion that dreams are the 'royal road' to a scientific understanding of consciousness. Hobson's model is seen as unduly reductionistic by those researchers who hold that REM sleep and dreaming are two separate but related processes; indeed, dreams can be obtained from non-REM sleep as well as from REM sleep. Krippner and Combs have noted that in both REM and non-REM dreams, the formal analysis of activity patterns in complex neural networks can be carried out in terms of chaotic attractors. In 2002, they proposed that the dreaming brain 'relaxes' into natural patterns of self-organized activity that often reflect the residual moods, stresses, and concerns of waking life.

During dreaming, the brain is immersed in something like a sensory isolation tank, cut off from the influences of external sensory input. In this situation, patterns of brain activity can slip into forms that are primarily dependent upon internal considerations. This environment, they maintained, is especially conducive to the production of novel associations, as *chaotic attractors* produce unusual but potentially valuable dream narratives.

In the creative process, small changes in cognition or behavior can trigger an avalanche of new insights or novel creative products. Krippner and Combs have found this 'butterfly effect' to characterize many dreams that lead to a creative solution of an ongoing problem.

The human brain with its many chaotic patterns of activity is subject to the butterfly effect; the introduction of 'noise' into such a system can produce a response too small to be

ordinarily noticed. However, the presence of this 'noise' or 'vibration' keeps the system in motion, following the signal, rather than allowing it to become stuck. Termed *stochastic resonance*, this seemingly paradoxical effect has been demonstrated in electronic signals as well as in nerve cells. On the other hand, the dreaming trajectories may be more under autopoietic (displaying both divergent and convergent thinking) control than it is in those systems attempting to follow a repetitive signal, as in most examples of stochastic resonance. As in problem solving, they have a goal in mind, and use divergent trajectories and bifurcations to solve it.

Further Research

Future research studies need to identify the genetic markers for creative behavior, reconcile personality and cognitive research data in creativity, evaluate the part played by the dreaming process in creative ideation, determine the role of mental illness in blocking or facilitating creative expression, and specify what home and school variables are key factors in the development of highly creative individuals. The study of dreams can play an important role in each of these agendas; dreaming appears to have been adaptive in the evolution of the brain, and dream content can provide cognitive and affect clues in the understanding of creative processes.

It is apparent that individual differences exist in dream creativity, and that there are cultural differences as well. The vast preponderance of studies in the field are devoted to the neurophysiology and neurochemistry of sleep and dreaming as opposed to the psychosocial variables in dreaming; of the latter, only a handful concern themselves with creative aspects of dreaming despite the near-consensus of dream researchers that the two phenomena are linked in several ways. The unanswered questions posed by existing research data are legion: for example, why is color spontaneously reported in the dreams of half of art students studied, 16% of the science majors, and virtually none of the engineering students? Why do research participants, in general, tend to report color in their dreams more frequently if they claim to place greater reliance on feelings than on thinking? What is the nature of dreams in which color is greatly intensified, radiating with phosphorescent hues? What are the mechanisms that determine shifts in dream color when people wear colored goggles during every waking moment for a week? Why do recurring post-traumatic nightmares differ so radically in dream content from other dreams?

The answers to these questions can be sought from psychosocial, neurophysiological, and neurochemical investigations, as can the answers to dozens of additional questions relating to creativity in dreams. In the meantime, for the Australian

aborigines, the Amazon Kagwahiv, and other tribal people, the Dreaming still exists. They believe that, if other human beings would begin to make their own dream journeys, re-establish their links with nature, and creatively invoke Dreamtime songs and dances, many of the world's current dichotomies and discontinuities could be accommodated and transcended. For both the mind/brain and the individual/group, this has been one of dream's creative functions over the millennia. The need for creative solutions to the world's many social, economic, and environmental problems reflects the importance of creativity and of the researchers and dreamworkers who see creativity in dreams as a critical frontier in understanding and assisting human development in a world – and a species – currently at risk.

Glossary

Collectivism The core element of this dimension is the assumption that groups bind and mutually obligate individuals.

Confucianism An intellectual and spiritual tradition based on Confucius' teachings that emphasize self-cultivation through effortful learning and the attainment of social harmony through virtuous and beneficent rule by the government.

Daoism An intellectual and spiritual tradition based on Lao Zi's teachings that emphasize the prepared mind, letting-be

and noninterference, and the attainment of enlightenment through meditation.

Human creativity The notion that creativity originates from the mind of human beings.

Individualism The core element of this dimension is the assumption that individuals are independent of one another.

Supernatural creativity The notion that creativity emanates from divine deities, God, or cosmic forces.

The Western and Eastern Perspectives

Creativity may mean different things to different people. However, if we ask around, few will disagree that it involves bringing something new into being. On closer examination, we understand that when we call something new, we attribute value to it. And this value attribution may in turn be associated with other judgment and criteria involving appropriateness, usefulness, or desirability. Despite that we seem to have a relative consensus on viewing creativity, it has to be noted that this conception of creativity is only the modern Western perspective. Indeed, it is said that the word creativity has come to be more widely used only in the past 60 years in the English-speaking world, and there seems to be no words that easily translate as creativity in other non-Western cultures.

When we speak of the Western perspective and the Eastern perspective (as distinct from the Western perspective), we are referring in broad generalities to views of people from two relatively distinct intellectual and cultural traditions. By the West or Western culture, we generally refer to the culture of Europe, North America, particularly Canada and the United States, Australia and New Zealand. There are undoubtedly many important cultural and subcultural differences among these Western countries or societies. But there are also similarities due to their continuing economic and political alliances and conflicts. Perhaps, the major distinguishing feature of the West is its 2000 years of cultural continuity with ancient Israel and Greece, that is, its common Greco-Judeo-Christian heritage. The same can be said about the East. By the East or Eastern culture, we generally refer to the culture of East Asian countries like China, Japan,

and Korea. These societies, although in many ways distinct, bear notable similarities in their cultural heritage due to the strong influence of Confucianism, Daoism, and Buddhism.

Bearing in mind that the East-West reference is a sweeping generalization, it is of interest to know that contemporary studies generally suggest that Easterners and Westerners do hold similar but not identical conceptions of creativity, and they do perform significantly differently on specific tasks requiring creativity. Thus, in this article we will examine these East-West differences. Specifically, we will first discuss the philosophical roots of Eastern and Western perspectives, which lead to the different ancient views and modern conceptions of creativity. We will then look at the empirical findings based on studies of East-West comparison. Finally, we will explore whether there are valid cultural and cognitive bases for the East-West differences.

Supernatural Creativity: Ancient Western and Eastern Views

Philosophical inquiries into the origin of creativity in the West as well as in the East generally follow one of two approaches. One approach is based on the belief that all things exist independently of human activity. Therefore, it is supposed that all creativity emanates from supernatural cosmic forces, from the divine power of God, or from the inspiration of gods. Creativity can thus be viewed as with supernatural or divine origin. The second approach is based on the belief that human beings are responsible for the existence of things, at least in certain realms such as morality. This approach

emphasizes human as opposed to supernatural or divinely inspired creativity, and is based on the notion that creativity originates in the human mind and in the individual's ability to bring something new into being. In this connection, creativity can be viewed as with human origin, and human creativity is the focus of study by contemporary scholars.

Although the notion of supernatural creativity emerged first in the history of both Eastern and Western thought, the Eastern view did differ somewhat from the Western view, probably due to the different philosophical and cultural traditions, and the different stories of human origin or different creation myths.

The Ancient Western View

Western philosophical inquiries into creativity can be traced back to ancient Israel and ancient Greece. The Hebrew root is the Biblical idea of God's creation. The Greek root is the ancient Greek expression of the inspiration from the gods of invention or the Muses.

According to the Bible in the Hebrew tradition, human beings do not have the ability to create new things. All things, including human beings, are God's creation. The Book of Genesis clearly describes God's original act of creation: "In the beginning, God created the heavens and the earth." The description also includes God's creative process in bringing into being the heavens, the earth, the living beings, and everything else. Particularly worthy of note are three features of God's creation. First, God is the sole creator of everything. Second, God brings new things into being from nothingness. Third, God's creation represents all goodness, including moral goodness. The second and third points naturally give rise to the emphasis of novelty and moral goodness in the ancient Western view of creativity.

In contrast to the Hebrew tradition, the Greek tradition does not have a clear creation myth by one God. Rather, there are diverse philosophical speculations on the origins and nature of things. The ancient Greeks believed that there are many gods, including the Muses or the gods of invention, and all human activities and destinies are controlled by the will of gods. Accordingly, people do not invent, gods do. Even artists do not make new things, and they are only inspired to imitate things that already exist in nature. This idea that creativity is divinely inspired is very similar to the Hebrew Biblical notion of creativity. In this tradition, any creativity beyond the external will of the gods could be interpreted as bad or immoral, and as posing a potential danger to society.

Supernatural creativity as described above was the dominant view in the history of Western thought for a long period of time, probably until the time of the Renaissance and even beyond. During this period, it could be said the most important creative activities in the West were all religious or Church-related. Creative artworks at the time, such as painting, sculpture, architecture, and metalwork, were always based on themes from stories of the Bible or Greek mythology.

The Ancient Eastern View

Supernatural creativity was also the dominant view in ancient Eastern thought (as represented by ancient Chinese thought) similar to the ancient Western notion of divinely inspired

creativity. However, there was a slight difference. For the ancient Chinese, there was no anthropomorphic God analogous to the Western God of creation, although they did believe in a supernatural moral authority and ultimate force they called *Tian* (Heaven). However, *Tian* was largely not personified, and the depersonification was complete when *Dao* (The Way) replaced *Tian* in the Daoist classics of *Dao De Jing* (which contains the teachings of Lao Zi) and *Zhuangzi* (which contains the teachings of Zhuang Zi).

Parallel to the Western Bible in the Book of Genesis, the ancient Chinese classic *Yi Jing* (*The Classic of Changes*) describes the story of creation. The following is my free translation from the original Chinese text.

Dao is manifested in the interaction of *yin* and *yang*.
What follows from *Dao* is good, as what is produced is a realization of the nature of goodness . . .
Abundant production is an achievement, and everyday renewal or renovation is a virtue.

Accordingly, there is an ultimate origin of everything. *Dao*, as represented by the constant changes and interactions of *yin* and *yang*, creates the world and brings everything into being. The nature of the changes of *yin-yang* is the ability to produce all goodness, including moral goodness.

This idea is also tersely expressed in Chapter 42 of Lao Zi's *Dao De Jing*. There are however a number of interpretations of this passage. My free translation of the Chinese text follows one of the meaningful interpretations.

Dao manifests itself holistically as the One or the totality.
The One manifests itself as the Two in *yin* and *yang* forces.
Yin and *yang* interact and manifest as the Three or *yin*, *yang*, and *he* (harmony).
And the Three gives rise to the ten thousand things.
The ten thousand things carry different degrees of *yin* and *yang*.
And this blending allows the achievement of a state of harmony.

East-West Comparison

Thus, it seems that ancient Chinese or more broadly ancient Eastern supernatural creativity shares some similarities with ancient Western supernatural or divine creativity. For both traditions, there is a representation of the ultimate origin of everything, and the nature of this ultimate origin lies in its ceaseless changes and renovations. Creativity was universally believed to come from a supernatural source outside human beings. Human beings do not create, and all creations are by God (gods) or by *Tian* (*Dao*). In addition, since the ultimate origin or *Dao* is good, creativity implies the creating of all goodness. For the Eastern tradition and in the Chinese mind, for example, this defining feature of goodness also includes goodness to the collective being or contribution to the whole society.

Taken together, the Eastern and Western traditions are similar but not identical. Perhaps, there are two noteworthy differences. One important difference is in the source of supernatural creativity. For the ancient Westerners, creativity emanates from an anthropomorphic God (gods), and human beings imitate through divine inspiration. For the ancient Easterners, creativity emanates from nonanthropomorphic

forces, and human beings only need to follow or discover the nature of *Dao*, as there is nothing new to create. Another important difference is that the Western supernatural creativity always involves newness, whereas the Eastern counterpart does not necessarily imply producing newness. In other words, novelty is not necessarily a defining feature in the Eastern tradition.

Human Creativity: Modern Western and Eastern Conceptions

The Modern Western Conception

Human creativity, or the conception of creativity attributable to human beings rather than divine forces or deities, also emerged in ancient Greece. In particular, apart from the belief in supernatural creativity, some Greek thinkers also believed that artists and poets need to bear some responsibility for their works. For example, Aristotle valued the imitation of life or nature by artists and poets, and argued against the assertion that all arts merely imitated the work of gods. In *Poetry*, he described the poets' activity of composition as due to their original aptitude and by a process of gradual improvements. However, the notion of human creativity was believed to be limited to a selected few such as the poets, and was not generally appreciated at the time.

The notion of human creativity took a new turn for renewed emphasis at the time of the Enlightenment. This was the time when people recognized and celebrated their individual rights and abilities to understand the universe and to direct their own destiny. These new thoughts were supported by the achievement of new inventions and new discoveries, and other human success especially in areas of science and technology. More specifically, individual creative ideas and products were now publicly recognized and were even officially honored in some European countries. Great Britain, for example, offered prizes and even patents and copyrights to creative individuals for their solutions to technological problems starting from the earlier part of the seventeenth century. This modern Western conception of human creativity was also reinforced by many important new theories and new disciplines formulated in the nineteenth century, distinguishing clearly the notion of human creativity from that of supernatural creativity. Darwin's theory of evolution and Marx's theory of the history of humanity are good examples of these new formulations.

The elevation of the notion of human creativity or the concept of creativity as residing in the individual is the key to contemporary Western conception of creativity. Shifting from supernatural creativity and limited human creativity, the Western conception now recognizes that creativity can be conceived as an activity that might occur in areas other than poetry, such as in science, art, literature, politics, business, and even daily life. Regardless of the specific domains to which creativity is applied, usefulness and novelty are regarded as the two crucial features of creativity. More importantly, creativity is no longer looked upon as the exclusive property of the selected few, but ordinary individuals can apply or exercise it within the mundane experiences of life, and not just in the formulation of important scientific and artistic accomplishments.

The Modern Eastern Conception

Philosophers in the Eastern tradition, as represented by ancient Chinese philosophers, unlike the Greek philosophers in the Western tradition, rarely mentioned human creativity. This lack of mention may be due to the Chinese respect for tradition or more likely to the view of the ancient Chinese that human creativity need not be distinguished from supernatural creativity. However, it has to be noted that this failure to distinguish human creativity from supernatural creativity should not be interpreted as the Eastern or Chinese tradition of not valuing or honoring individual thinking and creativity. Any discounting of the importance of human creativity would seem to run counter to the notion of a Chinese intellectual striving to achieve perfection in his humanity through self-cultivation or effortful learning.

Perhaps, one plausible reason why Chinese philosophers did not see the need for the distinction is their belief in the unity of man and the universe. This belief is shared by all schools of thought, including Confucianism. For example, Meng Zi, a great Confucian scholar, once said (as recorded in Chapter 7 of his book *Mengzi* or *Mencius*), "a man who knows his own nature will know Heaven," and "all ten thousand things are in me, and there is no greater joy than to find that I am true to myself upon self-reflection." Another great Confucian scholar Lu Jiuyuan is credited to have said this more directly in the statement: "My mind is exactly the universe and the universe is exactly my mind." Thus, in this light, human creativity is to be achieved through experiencing and interacting with supernatural creativity. However, despite the common belief in the unity of man and the universe, different schools of thought in Chinese philosophy have different understandings on how this unity could be achieved. We will discuss the approaches of two representative schools, Confucianism and Daoism.

Confucianism

In the Confucian tradition, it is believed that all human beings are born with the potential to learn and the free will with which to determine their future. The process of self-cultivation through effortful learning to achieve enlightenment or unity with the universe is thus the process of creativity. In the commentaries on the Confucian classic *Daxue* (*The Book of Great Learning*), my free translation of the following passage (Chapter 5) should be illustrative.

The purpose of *Daxue* is to teach the principles that govern things, and to facilitate learners to proceed from what they know to what they do not know, and to do so to the limits of learning. Only by effortful learning will the learner experience enlightenment and a complete understanding of the totality of everything.

It is believed that the universe is inherently good in the Confucian tradition, therefore, human beings are born with goodness, and creative activities will always embrace goodness. In this connection, it is also believed that highly creative people will not only satisfy their own needs as human beings but will also serve other people for the interests of the community.

Daoism

While Confucianism seems to suggest that self-cultivation, a gradual learning process, could be a way to enlightenment and

therefore creativity, Daoism advocates a different path for enlightenment and creativity. Specifically, Daoist teachings call upon people to lose themselves through doing nothing, and to meditate for the achievement of sudden enlightenment. The Daoist path and similar Buddhist path to enlightenment through meditation have also been incorporated into practice in some schools of Confucianism.

According to the Daoist classics, to become enlightened or to become creative is to have an inner apprehension of *Dao*, with the vanishing of all the distinctions between self and nonself (subject and object). The Master Daoist Zhuang Zi captured this in his story of two old men's discussion of losing oneself. My free translation of the passage from Chapter 2 of *Zhuangzi* is as follows.

Nanguo Ziqi sat at his desk, staring at the sky, breathing slowly, and as if he was losing himself, completely unaware of people and things around him. Yancheng Ziyou who was standing in attendance said, "What happened? Could you really make your body like a withered tree, and your mind like dead ashes? The man sitting here now is not the one who sat here before." Ziqi replied, "Good question, Yan. Do you understand that I have lost myself? You might have heard the music of man, but you haven't heard the music of the Earth. Or if you have heard the music of the Earth, you still haven't heard the music of Heaven."

In the story, Ziqi is described as having reached the stage of losing oneself, in which he could actually listen to the sound from Heaven, and the music must have been highly inspirational for him at this stage of harmony or union between man and the universe. Thus, losing oneself starts when people approach the realm of tranquility and enter the realm of nonbeing.

Zhuang Zi in the same chapter of *Zhuangzi* also referred to this losing oneself as "Heaven and Earth and I co-exist, and the ten thousand things and I are one." Zhuang Zi also ended the chapter with the well-known Daoist story of the butterfly dream as the poetic presentation of the realm of nonbeing.

Once Zhuang Zhou dreamed of being a butterfly, dancing freely and not knowing who Zhou was. On awakening, he found himself to be Zhou. It was not known whether Zhou dreamed of being a butterfly or the butterfly dreamed of being Zhou.

Accordingly, through losing oneself in meditation, one is able to connect with the universe, and once connected, all one does will be highly creative. This Daoist notion of losing oneself has had a great impact on Chinese intellectuals and their creative activities throughout Chinese history, especially in poetry and painting. It is said that many great Chinese poets and artists have produced a large amount of truly great works through meditation and self-cultivation, which allowed them to penetrate to the great tranquility and achieve union with the universe.

In summary, in the Chinese view, human creativity and supernatural creativity could be the same, insofar as human beings can live in *Dao* through a lifetime of self-cultivation and/or meditation. Perhaps, the modern Chinese perspective differs from the ancient view in that human beings become more central in initiating and bringing forth the creative process. More importantly, any human beings can produce creative artworks through the practice of meditation and self-cultivation.

East–West Comparison

Modern Western conception of creativity is the result of a complete shift from the ancient notion of divinely inspired supernatural creativity to the notion that creativity resides completely within the individual. This somewhat radical shift was reinforced by the rise in individualism and capitalism, along with major changes in science and technology, which have brought forth new discoveries and new inventions. In this connection, usefulness becomes an important defining feature of creativity in addition to the notion of novelty.

In the Eastern world, the parallel shift however is less complete, with a stronger continuity connecting the ancient view and the modern conception. Human beings have now a more important role in bringing forth the creative process. Rooted in Confucianism and Daoism, the modern Easterners especially the Chinese start to believe that meditation and self-cultivation can lead people to achieve a connection to heaven or greatness, and therefore, to a high level of creativity. In this Eastern tradition, while moral goodness and usefulness in terms of social values to society are stressed, novelty remains not the most important defining feature of creativity.

Contemporary Studies on the Conceptions of Creativity and Creative Performance

Since Easterners and Westerners may have different conceptions of creativity due to their distinct cultural beliefs and heritage traceable to distinct Eastern and Western philosophies, it is of interest to explore the similarities and differences in conceptions among Easterners and Westerners in their contemporary real-life settings. To address this concern, researchers have conducted studies investigating lay conceptions of creativity among people in the East and the West. These lay conceptions of creativity are also called implicit theories of creativity.

On the other hand, since contemporary people in modern Eastern and Western societies tend to have more interactions across cultures, it is conceivable that Easterners and Westerners will come closer on their views of creativity. More specifically, given the more dominant ideology in the West, with its advances in science and technology and its positive valuation of novelty, it is likely that contemporary Easterners could be strongly influenced by Western ideology and even come to adopt the Western perspective in viewing creativity. In this regard, researchers have also conducted studies on the assumption that East–West differences could be investigated on common creativity measures designed for Westerners. We will discuss in the following these two bodies of research to understand East–West differences, studies on the implicit theories of creativity and studies on East–West differences on performance on tasks requiring creativity.

Implicit Theories of Creativity

In the studies of the implicit theories of creativity, laypersons, psychologists, teachers, or experts in different domains are asked about their views of creativity. Typically, participants are requested to describe the characteristics of creative individuals or rate the importance of specific personal characteristics relevant to creativity.

Research with Western populations

Most of the studies in this area are with Western populations, particularly Americans. People's implicit theories of creativity were investigated across different social and age groups, including undergraduate students, teachers, parents, psychologists, artists, managers, and laypeople of different professions. These studies have suggested that people's implicit theories of creativity had a number of core characteristics that included innovation/imagination, intrinsic motivation, independence, risk taking, breadth of interests, intelligence, high activity/energy level, and a sense of humor. Interestingly, people's implicit theories of creativity, intelligence, and wisdom were found to overlap to a certain extent, but the ideal creative person as opposed to the ideal intelligent and wise person could be distinguished by the characteristics of imagination, aesthetic taste, intuition and inquisitiveness, freedom of spirit, and an unwillingness to be bound by the rules of society.

At a more refined level, apart from the distinguishing characteristics of the general implicit theories, studies have also indicated that there might be other additional distinguishing characteristics for implicit theories of creativity in different domains, suggesting that implicit theories could be domain-specific. For example, being logical and willing to experiment could be important for scientific creativity, being expressive and emotional could be relevant to artistic creativity, and being helpful could be necessary in everyday creativity. There is evidence that there could be greater variability of implicit theories among professional groups, such as artists, scientists, teachers, and politicians, than among Westerners in neighboring countries, such as Germany and Austria.

Research with Eastern populations

Research studies on implicit theories of people in the East are fewer in number than those of people in the West, and they were mostly conducted with the Chinese population. Specifically, similar studies on people's implicit theories conducted in the West have also been conducted with people in Mainland China, Hong Kong, Taiwan, and Singapore across different social and age groups that included college students, teachers, and other laypersons. These Chinese participants were found to report, as the American participants in other studies, similar core characteristics of creativity, such as innovative ideas, imagination, intelligence, independence, and high activity/energy level. However, it is noteworthy that aesthetic appreciation and a sense of humor, two distinguishing characteristics of creativity in the West, were not reported among the Chinese. In contrast, three characteristics, being inspiring to people, contributing to the progress of society, and being appreciated by others, reported as salient for the Chinese were not reported for the Americans in Western studies.

Thus, taken together, studies on implicit theories conducted separately in the West and the East with Western and Eastern populations allow some indirect comparison. These studies do suggest that Easterners seem to emphasize the social and moral components of creativity whereas Westerners tend to emphasize individual characteristics such as humor and aesthetic appreciation. This difference might reflect the different worldviews held by people in the East and people in the West.

Studies on East–West Differences on Creative Performance

Apart from the studies on the implicit theories of creativity, another body of research studies aimed to examine East–West differences sought to investigate differences in creative performance and expression among Easterners and Westerners. In this body of research, two distinct approaches could be distinguished. One approach is based on the assumption that the conception of creativity is relatively common across cultures, and differences in levels of performance on tasks reflecting creativity could be assessed using a standardized test that is universally meaningful. The second approach is based on the assumption that the concept of creativity is relatively culture-specific and domain-specific, and any measurement of creativity or East–West differences on creative performance needs to take into account the factors of culture and domain.

Research based on the notion of a common conception of creativity

In these studies, creativity is often assumed to be assessed by divergent thinking using standardized tests such as Guilford's Unusual Uses Test, the Torrance Tests of Creative Thinking (TTCT), and the Test for Creative Thinking – Drawing Production (TCT-DP). TTCT is by far the most widely used divergent thinking test, especially for school-age children.

In general, it was found that Americans performed at a higher level of creativity than did Asians. For example, in one study using TCT-DP with children from eleven countries, children from England, Germany, and the United States scored higher than those from India, Indonesia, and China. While in some studies the level of modernization has been employed to account for the performance differences between Westerners and Easterners living in less modernized societies, the explanation seems to break down when it is applied to East Asians living in more modernized societies in Japan, Hong Kong, Taiwan, and Singapore.

However, there were also studies with results favoring Asians, especially Japanese and Chinese, rather than Westerners. These studies employed the figural form of TTCT, or other divergent thinking tests that required applications of knowledge of mathematics and natural sciences. One explanation is that the figural form of divergent thinking tests would favor East Asian children due to their exposure to the graphical characters of the Asian or Chinese language, which might enhance East Asian children's general spatial ability. Another explanation has to do with the Asian educational system that emphasizes domain-specific knowledge in mathematics and natural sciences, leading to Asians' being more creative in certain domains, for example, the domains of mathematics and natural sciences in China.

Research based on the notion of culture-specific creativity

With the assumption that creativity could not be understood as relatively common or universal across cultures, the use of a standardized divergent thinking test for assessing creativity would appear inappropriate for studies investigating East–West differences on performance on tasks requiring creativity. Therefore, these studies use product-oriented tasks and consensual assessment of creativity. The primary feature of this approach is to ask participants to create a product (a poem,

an art design, or a scientific invention during an experiment), and judges (experts in a specific domain or laypersons) are then asked to evaluate the creativity level and other qualities of each participant's product with those of the products of other participants.

While the product-oriented approach with consensual assessment has been recognized as providing real-life and more authentic assessment to take into consideration domain-specific and cultural-specific creativity, few studies have been conducted under this approach. For example, in a pioneering study with American and Chinese college students, collage making and pencil drawing were judged by American and Chinese judges. American participants were judged to produce more creative and aesthetically pleasing artworks than Chinese participants, and Chinese participants with explicit instructions to be creative were found to perform at a higher level of artistic creativity than Chinese participants not primed to be creative. The findings were interpreted as consistent with cultural differences.

East–West Comparison

The studies on the implicit theories of creativity of Easterners and Westerners seem to suggest that contemporary Easterners do hold similar but not identical conceptions of creativity as Westerners. Thus, far from being universal or common across cultures, the conceptions of creativity are in part cultural-specific, meaning that Easterners and Westerners do share some common views but may also differ on other views. Specifically, Easterners are more likely to view creativity as having social and moral values, and they value the connection between the new and the old more than Westerners do. Westerners on the other hand tend to focus more on the specific individual characteristics of creative individuals.

The studies on comparing the performance of Easterners and Westerners on tasks requiring creativity yielded conflicting results. Easterners or Westerners did not seem to consistently outperform the others. The differences in results favoring Easterners or favoring Westerners might not be due entirely to differences in the conceptions of creativity of Easterners and Westerners. Rather, approaches to assessment, domain-specificity, social values, education, levels of modernization, and many other factors might account for the East–West differences on people's performance on tasks requiring creativity.

Nonetheless, contemporary empirical studies focusing on East–West comparison do suggest that there are real East–West differences. There are probably multiple plausible explanations for these differences. For example, Easterners are said to be more process-oriented, more intuitive in knowing, and more concerned with relationships and interdependence, whereas Westerners are said to be more product-oriented, more logical in knowing, and more concerned with individual self and independence. Very often, the discussion of these differences is included as the discussion on cultural differences, implying that people's cultural heritage could influence their worldviews and their understanding and evaluation of creativity. In addition, it might also be argued that cultural differences could lead to East–West differences in cognitive processes that might at least reinforce the cultural differences in the understanding and conception of creativity. We will now turn to the discussion of these issues.

Basis for the East–West Differences: Culture and Cognition

Individualism and Collectivism

Given the reality of East–West differences in the conceptions of creativity and performance on tasks requiring creativity, researchers have sought explanations of such differences in terms of particular dimensions of cultural variation. Among the different dimensions, the dimension of individualism–collectivism has received the most attention and has been most extensively studied. Some researchers have even suggested that this dimension is the deep structure of cultural differences from which other differences evolved, and the dimension can explain to a large extent differences in creative activity levels for Westerners from individualistic societies and Asians from collectivistic societies.

The essence of the individualism–collectivism dimension is the definition of the self as independent or interdependent with some in-groups (e.g., family, tribe, coworkers, and nation). People in individualistic cultures see the self as stable and the environment as changeable, thus focusing more on the development of self. In contrast, people in collectivistic cultures see the environment as stable and themselves as changeable, and therefore they are more motivated to find a way to fit themselves in with relevant others.

With reference to creativity, in a Western individualistic society, people may be more willing to defy the crowd, which may be central in creativity, because a person's sense of worth is defined largely by what he or she does as an individual. In contrast, in an Eastern collectivistic society, one's sense of worth is determined with reference to the group and may be seen as commensurately reduced if one alienates oneself from that group. Thus, defying the crowd in the East may be seen as less valuable than making contributions to society. Consequently, an individualistic Westerner might see more of the value of personal success with individual characteristics as a creator, whereas a collectivistic Asian might see more of the social and moral value an individual can bring to society. In this connection, one would expect that these differences in values are likely to be reflected in the differences in Easterners and Westerners' implicit theories of creativity.

Along the same line of generalization, one would expect that a collectivistic Asian culture, which tends to encourage interdependence of relationships, and conformity to societal norms and tradition, may be less conducive to the development of creativity. In contrast, the more individualistic culture of the West, which tends to encourage self-exploration and individual achievement, may be more supportive of the development of creativity. Thus, it is no surprise that Westerners may perform better than Easterners on tasks requiring creativity.

However, caution must be exercised in interpreting this generalization. It has to be noted that there are often a great deal of within-group differences in virtually every comparison of East–West differences. It means that despite the significant differences in group averages, it may happen that some individuals within each group are more typical of the other group. For example, some Americans may have strong collectivistic tendencies, and some Chinese may be quite individualistic.

Cognitive Processes: Contextual and Focused Mindsets

Richard Nisbett, in his book *The Geography of Thought: How Asian and Westerners Think Differently and Why*, reports numerous studies showing that Westerners and various groups of Asians (Chinese, Japanese, and Koreans) respond very differently to a wide range of cognitive tasks. He challenges the general assumption that everyone, Asians and Westerners alike, perceives, thinks, and reasons the same way, and argues convincingly that culture influences how Asians and Westerners perceive and think in powerful (and experimentally verifiable) ways.

For example, in one categorization task, participants were asked to decide which two of the three things (e.g., a panda, a monkey, and a banana) go together. Westerners typically categorize by types (animals) where Asians typically categorize by relationships (monkey eats bananas).

In another memory task, Japanese and American students were shown pictures of aquariums containing one big fast-moving fish, several other finned swimmers, plants, rock and bubbles. Japanese students spontaneously recalled 60% more background elements than did American students, and referred twice as often to relationships involving background objects (e.g., the little frog above the pink rock). Japanese students also did much better than American students at remembering correctly whether they had seen a test object before when it was shown in the context of its original surroundings.

These and other experiments by Nisbett and his colleagues have led Nisbett to conclude that Westerners and Asians literally see different worlds through their focal and contextual mindsets, respectively. Accordingly, Westerners attend to the focal object, while Asians attend more broadly to the overall surroundings and to the relations between the object and the field. In other words, Westerners tend to focus with tunnel vision whereas Asians or Easterners tend to see the big picture with a wide-angle lens. Nisbett does not discuss creativity in his book, but the general conclusions are probably as true for creativity as they are for the kinds of cognition he has discussed.

The social structures and sense of self that characterize individualism and collectivism seem to fit well with the respective worldviews and cognitive mindsets of Westerners and Easterners. The individualistic or independent nature of Western societies seems to work together with the Western focus on particular objects in isolation from their context, and is consistent with Westerners' belief that they can know the rules governing objects and therefore can control the behaviors of the objects. Similarly, the collectivistic or interdependent nature of Asian society is consistent with Asians' broad and contextual worldview, and their belief that events are highly complex and determined by multiple factors.

It is likely that the East–West cognitive differences originate in child rearing and social practices. There might be a cyclical

process among social practices, worldviews, and thought processes or mindsets. Thus, the social practices might promote the worldviews, the worldviews in turn dictate the appropriate mindsets, and the mindsets both justify the worldviews and support the social practices. However, people's mindsets seem to be somewhat malleable. Studies examining Asians living in Western societies and Westerners living in Asian societies often find that their mindsets go native. On the other hand, bicultural people who live in two cultures, like those in Hong Kong with its British and Chinese heritage, tend to show mindsets or thinking patterns intermediate between Easterners and Westerners, or at least they can alternate between the two mindsets. These results suggest cognitive modifiability by living for a time in another culture.

Thus, the contemporary East–West differences on the conceptions of creativity and creative performance are real, and there is evidence to support the basis of differences in culture and cognition. However, social interactions across cultures, changing social practices, and greater exposure and experience living in the East or the West in another culture different from one's own might combine to contribute to a shift in mindsets relevant to creativity. East and West are going to meet with each moving in the direction of the other, and perhaps in the convergence, the future blended conception of creativity will contain the best of both cultures.

Eccentricity

J Piña, University of Georgia, Athens, GA, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Curiosity The intellectual intrinsic motivation; the force which drives us to seek new knowledge.

Diathesis Inherent proclivity to a condition, often used to connote vulnerability to a disease.

Idealism An intrinsic motivation concerned with improving the world, upholding justice, and extending compassion to others.

Imagery Sensory impressions, often visual, created by the mind.

Transgression Behavioral acts not in accord with established dictates of social propriety.

Eccentricity is a socially variable concept that encompasses attitudes and beliefs about nonconforming personalities and behaviors that do not easily match the normal expectations of a society. Eccentrics are lifelong creative nonconformists who value their independence of thought over social conventions and display little functional impairment related to their eccentricity.

Historical Evolution of the Term

Eccentricity is not a stable concept throughout history. Various, eccentricity has been taken to mean “insane,” “odd,” “perverse,” or “wild” with any number of intermediary denotations and a host of connotative subtexts. The term itself is derived from mathematical metaphor, and in the physical sciences it is still used to characterize mathematical data that deviates from expectation. Eccentric personalities pervade the creative spheres of both the arts and sciences, providing the archetypes for such stereotypes as the misunderstood artist and the mad genius. Understanding eccentricity requires first acknowledging the fact that it is a plastic concept that depends on shifting social norms for its definition. Beliefs that might be considered odd or bizarre in today’s society might have been conventional only a few generations ago or might be considered normal at some future date. Similarly, behaviors displayed by some cultures, such as a predilection for nudity or a desire to eat raw fish, might be normal in that context but would be considered strange and noteworthy in a different social environment. Miranda Gill provided an excellent summary of the problems inherent in classifying a person or group as eccentric. She wrote:

Contrary to what is often assumed, the meaning of eccentricity is neither timeless nor self-evident. The very synonyms used to define it – bizarre, singular, original, peculiar, odd – suggest the frustration of rationality and the failure of the codes by which social and mental life is interpreted. Indeed, the concept owed its success precisely to its ability to adapt to new contexts. Eccentricity is always defined in relation to something it is not, but the imaginary ‘centre’ (or ‘centricity’) from which it departs is far from stable.

The elusiveness of a single historical definition of eccentricity confounds our view of popular figures to whom we would

attach the label. Simultaneously, however, it is true that an interest in famous eccentrics is largely responsible for our understanding of the term. Eminent artists and scientists have long been the subject of popular inquiries regarding their eccentricity, as famous individuals seem especially prone to retellings of anecdotes regarding their odd behaviors. One does not have to look too deeply to find exhaustive accounts of Albert Einstein’s eccentric penchant for lecturing to his infant nephew, Andy Warhol’s private caricatures of popular media which include a homosexual reinterpretation of the relationships in the Batman comic, or rumors about Nikola Tesla’s mad genius, including designs for an infamous (thankfully unsuccessful) “Peace Ray.”

These stories become part of the legend of great creators and inventors, but they reflect an idealized image of the eminent figure that contributes to the distortion of the historical truth of the person’s character rather than a contribution to the collective understanding of eccentricity. Popular figures do, however, feature in the development of related stereotypes of eccentric behavior, as their definitive example influences others to adopt their behavior.

The Victorian Era

Clearly, public fascination with eminent eccentrics is far from new. However, the roots of its current incarnation are most firmly bedded in English norms and values present just prior to and during the Victorian era. Indeed, it has been argued by Gill and also in some depth by Victoria Carroll that the historical adulation of eccentric personages during the Victorian era, more than any other recent epoch, has molded the expectations of what it means to be eccentric for much of the rest of the Western world.

As Carroll described it, the development of Victorian interest in eccentricity began some decades earlier at the turn of the eighteenth century, when popular interest in the subject fed an explosion in the proliferation of books in the then-new genre of biographies, of which eccentric biographies was a sub-genre. These anthologies detailed, in a fashion similar to modern accounts of eccentrics, noteworthy individuals whose actions were outside the realm of normal morality or behavior.

Though they were extremely popular, these works were not known for their accuracy or integrity. Carroll notes that most were produced using anecdotes drawn from newspapers, magazines, and journals available at the time, and were put together as a sort of “cut-and-paste” collage of unverified stories. Nevertheless, Carroll argued the impact of these biographies with the following:

more than merely being an indicator of the prevalence of a discourse of eccentricity in the first half of the nineteenth century, eccentric biography served, first to propagate this discourse amongst ever diversifying readerships and, second, to popularize new ways of organizing and presenting biographical material about remarkable persons, thus shaping how eccentricity was subsequently understood and represented.

Contemporaneous with eccentric biography was the depiction of eccentricity in popular Victorian literature, the interest in which was driven to a much greater extent in this medium by the phenomenon of transgression. The concept of transgression, developed by Peter Stallybrass and Allon White, posits that acceptable (normal or conventional) behavior involves a complex interplay between standards of propriety and fascination with the forbidden. This included, as Gill puts it “anxiety about the body, filth, and deformity.” In essence, because Victorian social codes were exceedingly strict, the desire to view or experience nonconformist behavior was, at least for the repressed middle class, very great. The obvious parallels to psychodynamic theory serve to underscore the pervasiveness of this effect as well its ability to draw mass appeal. No implication is made that transgression supplied an environmental cause for eccentricity or any other nonconformist behavior during the Victorian era; rather, the theory asserts that transgression provided an impetus for more conforming individuals to appreciate and respond (and perhaps to over-respond) to eccentric behavior as it became, by virtue of its abnormality, to be viewed as increasingly provocative.

During the height of transgressive interest in all things eccentric, the term acquired a broad range of meanings ranging from “exuberant” to “grotesque.” Periodicals, magazines, and etiquette manuals featured sections devoted to “eccentric” topics, but the word was used in ways barely reminiscent of the relatively harmless modern sense. As Gill made clear, in France at the time of expansion in Anglophile Victorian literature, monsters, deformities, prostitutes, and homosexuals were all given the moniker “eccentric” at one time or another. In more tame print, novels featured eccentrics to lend flavor to stories and the meaning of the word in this context was subdued, almost quirky. These characters did cross the lines of propriety, but they did so in small, creative ways. Dickens, especially, was fond of the eccentric older person archetype and featured it in many of his novels. As the public imagination grew weary of forbidden experiences, gradually the term shed its more explosive connotations and settled again to something akin to the current definition.

Modern Era

Popular interest in eccentricity persists for much the same reason that it always has: Entertainment value. Though Victorian compendia of eccentric biographies are largely relegated to the

lonely world of obscure historical texts, the practice of printing anthologies of eccentric notables continues. Today’s eccentric biographies include such titles as *The Reader’s Digest Great British Eccentrics* and Karl Shaw’s *Mammoth Book of Oddballs and Eccentrics*. Among these texts, the one anthology stands apart is Edith Sitwell’s *The English Eccentrics*. This work exemplifies the class of literature as a whole including, unfortunately, the fact that, like its historical forbears, it was poorly researched and contains both factual inaccuracies and gross mischaracterizations. What stands out, however, was the fact that the book was first published in 1933 and, unlike many of its kind, the book bravely refuses to go out of print. As such, it provides clear evidence of a bridge between Victorian era eccentric biographies and the popular works produced today. Additionally, the book garners attention because of the oddness of its author, who was a controversial eccentric figure in her own right.

Scholarly interest in the topic of eccentricity is currently less well formed, a fact that is mentioned, to different degrees, in the independent works of Gill, Carroll, and Weeks. This is understandable, for understanding eccentricity is no easy task. As the development of the term demonstrates, the challenge of comprehending the causes and expressions of eccentricity is only exacerbated by the uncertainty of the term. Scholars who use historical accounts of eccentricity in an effort to understand the phenomenon must not only be vigilant regarding their own perspectives about eccentricity, but also those biases present within the material itself.

Characteristics of Contemporary Eccentrics

Who, then, is an eccentric? In his landmark study of the topic, David Weeks sought to tease out those motivations and factors that would move someone away from normal, well conformed behavior and toward the socially marginal (but arguably much more interesting) world of eccentricity. His methods, as described in his book *Eccentrics* were relatively straight-forward. Using open advertisements, word-of-mouth references, and third party referrals, Weeks was able to compose a group of 789 eccentric individuals (309 men, 480 women). He then interviewed these eccentric individuals and administered to them tests of personality (the 16PF test), IQ (multiple standardized test were used), and mental health (the PSE inventory).

From his interviews, psychological tests, and informal conversations with eccentrics, Weeks composed a series of traits he saw as threads held in common across the diverse tapestry of eccentricity. These traits served, on the whole, to sum up eccentricity as it was expressed by the eccentrics he studied, though it was clear that not all traits were necessarily evident in any one eccentric individual. His description of 25 characteristics published in the previous edition of the *Encyclopedia of Creativity* remains the most comprehensive listing of eccentric characteristics as they are currently understood. They are faithfully reproduced below (note that they are in descending order of frequency as they were observed in study populations):

- Enduring nonconformity
- An enduring and distinct feeling of differentness from others
- Creative

- Strongly motivated by exceedingly powerful curiosity and related intellectual exploratory behavior
- Idealism, wanting to make the world a better place and the people in it happier
- Happily obsessed with a number of long-lasting occupations
- Intelligent
- Opinionated and outspoken, convinced that they are right and the rest of the world is out of step with their ideas
- Noncompetitive
- Not necessarily in need of reassurance or reinforcement from the rest of society
- Unusual in their eating habits and living arrangements
- Not necessarily interested in the opinions or company of other people, or of personal popularity
- Possessed of a mischievous sense of humor, charm, wit, and whimsy
- More frequently the eldest or an only child
- A poor speller, especially in relationship to their above average general intellectual functioning
- Eccentricity noted in at least 36% of detailed family histories of eccentrics, usually a grandparent, aunt, or uncle (it should be noted that the family history method of estimating hereditary similarities and resemblances usually provides rather conservative estimates)
- Eccentrics prefer to talk about their thoughts rather than their feelings; there is a frequent use of the psychological defense mechanisms of rationalization and intellectualization
- Slightly abrasive
- Midlife changes in career style
- Feelings of "invisibility," which means that they believed others did not seem to hear them see them, or take their ideas seriously
- Feel that other people can only take them in small doses
- Feel that others have stolen, or would like to steal, their ideas; in some cases, this is the reality
- Dislike small talk or other apparently inconsequential conversation
- A degree of social awkwardness
- Single.

More than a few of these traits merit further attention, and are discussed in further detail elsewhere in this article, because of their association to other areas of interest, such as mental disorder and creativity, but some stand out because they are vital to understanding the potential causes of eccentric behavior. Specifically, there are traits found in Week's analysis that speak to underlying intrinsic motivators, the existence of which would be necessary to provide a rationale to adopt and maintain the socially marginal, and poorly extrinsically motivated, eccentric lifestyle.

Nonconformity is the foundational characteristic of eccentricity, for nothing so perfectly defines what eccentricity is as a conscious refusal to conform to social norms. Questions of what gives rise to nonconformity and how it is expressed in society are often complex. As Cecilia Ridgeway makes clear, considerations of status, competence, and motivation all influence the interplay between conforming and nonconforming behavior. Status, we must recognize, relates to both perceived status in small groups and, in the long-term, our socioeconomic status. This is a point on which George E Marcus and

David Weeks agree: It's easier to be eccentric if you're in the upper classes. Marcus so closely associates eccentricity and high status that he proposes a theory that eccentricity is nothing more than a defiant, multigenerational display of elite dynastic families, fetishized as a mark of distinction. A full reading of Marcus's work, however, imparts the impression that he has perhaps imbibed too much of the portrayal of eccentrics as they were presented in earlier transgressive eras.

Curiosity and idealism are notable because they have been recognized as basic intrinsic motivators. Weeks acknowledges curiosity as a "human motivation that is primarily intellectual" and refers to it as "the intrinsic motivation." Steven Reiss considered curiosity one of the multidimensional intrinsic factors in his theory of 16 basic intrinsic motivators. He posits that the need for curiosity is derived in humans from a genetic legacy of adaptive animal behavior involved in obtaining food and avoiding predation. Reiss associated curiosity with the intrinsic feeling of wonder. This is compelling because wonder is a potent force in the world of eccentricity. It characterizes the feelings of eccentrics about their world and provides one reason for the eccentric penchant for many long-lasting hobbies and occupations.

Idealism is equally important as an intrinsic motivator, but it is less well understood. Reiss admitted uncertainty concerning the behavioral origin of idealism as it is associated closely with altruism, the existence of which in animal behavior is a topic of debate. Additionally, it seems counterintuitive that some eccentrics display idealistic desires simultaneously with antisocial behavior. When one considers Reiss's assertion that social contact and idealism are unrelated intrinsic motivations and that motivations naturally prioritize themselves, the conundrum partially resolves itself, for while eccentrics may have a motivation to improve the world, it doesn't necessarily imply they place equal value on social engagement.

One final item not included in Weeks' 25 characteristics of eccentrics is their relative happiness and contentment with their lives. In Weeks' own words "eccentrics appear to be happier than the rest of us. This is not to say that they are happy all the time . . . But nearly everyone we met seemed to be pretty contented with his lot in life." Though this is a subjective evaluation of eccentrics and therefore not empirically measurable, the persistence of joy in the character of eccentrics bears some scrutiny, especially in regard to any consideration of eccentricity as a potentially pathological condition.

Mental Disorder and Eccentricity

There is an undeniable similarity between eccentricity and certain mental disorders, especially those along the spectrum of schizophrenia. It is not by accident that early uses of word "eccentric" were polite euphemisms for the word "insane." A glance at the diagnostic criteria presented in the DSM-IV-TR for schizotypal personality disorder, for instance, yields such unfortunate descriptions as "Odd beliefs or magical thinking that influences behavior and is inconsistent with subcultural norms (e.g., superstitiousness, bizarre fantasies or preoccupations)," "Odd thinking and speech (e.g., vague, circumstantial, metaphorical, overelaborate, or stereotyped)" and the damning "Behavior or appearance that is odd, eccentric, or peculiar."

Addressing eccentricity as a phenomenon is, in part, a process disentangling the stigma of madness from the behaviors that eccentricity engenders. Weeks, mindful of this burden, examined mental illness as one part of his study of eccentrics. As part of a series of interviews with 130 of self-identifying eccentrics, he administered the Present State Examination. The PSE is a form of mental-state examination, generally administered as a series of quasi-structural interview questions, used as a component of the diagnosis for mental disorders. His results indicated 8% of the examined eccentrics displayed mild-to-moderate symptoms of either schizotypal or schizoid personality disorder. This is somewhat higher than the generally accepted lifetime incidence for the disorders which, in a recent systematic meta-analytic review of the literature by Elliot Goldner and his colleagues, was shown to be, on average, 1.45% with a variation between two and five fold among studies. While this does give cause to believe that eccentricity might increase the diathesis of schizophrenic disorders, it helps confirm that eccentricity is not by itself an expression of disorder.

Eccentricity Versus Functional Impairment

For a deeper understanding of why eccentricity isn't a pathological condition, we must look at what it means to have a mental disorder. Like eccentricity, the definition of the term mental disorder has undergone a number of historical vicissitudes; however, these fluctuations in meaning are not relative to any one society's view of the condition, but instead indicative of an underlying change in the philosophy of the nature of illness. For the better part of the century, the guiding principle in any attempt to define mental illness has centered around the concept of functional impairment. Spitzer and Endicott, for example, require in their definition of mental disorder for specific demonstrations of "distress, disability, and disadvantage." Wakefield's "harmful dysfunction analysis" theory, which has been a guiding principle of psychopathology since the revision of DSM-III, defines mental dysfunction using very specific terminology, his definition includes not only disability, but "failure of a system to perform as it was designed to perform by natural selection."

A full discussion of the permutations and underlying philosophies involved with the history of these definitions is beyond the topic of eccentricity, but what is hopefully made clear by this elaboration is that each of these definitions rules out any behavior that does not functionally impair the individual or, by contagion, society. In consideration of this, Weeks' observation, mentioned earlier, that the eccentrics he interviewed were happy and content becomes a salient point because it denies the argument that eccentricity meets the functional impairment criterion for mental disorder. Weeks also contributes to the discourse on this topic directly in his observations of the eccentric capacity for mental imagery. He writes:

One common trait of eccentrics is that they often experience mental images that are more vivid than those of normal people. Some extreme eccentrics have visions, which is a not uncommon symptom of schizophrenia. The important distinction is that the schizophrenic has no control over his visions and the voices he hears; they intrude themselves upon him forcibly and give rise to a terrifying sensation of powerlessness. The eccentric, on the other hand, is likely to find his visions a source of delight, and he has much more control over them. The psychotic state severely disrupts

thought processes, leaving the person dysfunctional, whereas the eccentric's brain usually functions perfectly well – it just does so in peculiar and largely unknown (and unknowable) ways.

Creativity, Eccentricity, and Mental Disorder

As creativity is one of the most important, widely seen traits in eccentricity, the degree to which eccentricity, creativity, and mental disorder are related is a pertinent field of inquiry. Daniel Nettle has argued that creative traits share a genetic component with schizophrenia and affect disorder, and that expression of mental disorder is an unfortunate by-product of the otherwise extremely adaptive trait of creativity. The proclivity for creativity, affect disorder, and schizophrenia, according to his theory exist along a continuum wherein epigenetic and environmental factors interact with a variable genetic penchant for all three behaviors. Thus, according to this model, eccentric behavior might be an expression of creative behavior further along the spectrum toward mental disorder. Two distinctions would have to then be made to define the "space" of eccentricity with regard to both creativity and mental disorder. On one end, the degree to which nonconformity separates creativity from eccentricity would need to be determined, and on the other would be a boundary defined by functional impairment. In an similar argument, R. A. Prentky argues that "optimal degree of deviation from normal patterns of information processing is necessary for creative work." Here, we see hints that eccentricity might be a behavioral correlate to the theoretical framework of creative optimization. Alternatively, we might conclude by synthesis of both theories that creativity is itself a protective factor that lowers the diathetical predisposition that eccentrics might otherwise display for mental disorders. Sadly, these positions, though supported in theory by extant literature, have yet to be verified.

To present a contrasting view, we can look at argument wherein the case against the assumption that either eccentricity or creativity are inherently related. Judith Schlesinger recently tackled the topic by way of her critique of the "mad genius" stereotype. In her article, she explained how the concept of the "mad genius" was originally founded on fearful misconceptions of genius and how it was supported, even endorsed, by bad science. She cited self-selection bias, poor research standards, and over-representation of mental illness in historical data as causes for our continued belief in the concept. The most compelling aspect of her argument is the meticulous degree to which she scrutinizes the works of the three modern proponents of "mad genius," Nancy Adreasen, Arnold K. Ludwig, and Kay Redfield Jamison, and the glaring errors she found in their data. In direct opposition to the theories proposed by Nettle and Prentky, she concluded her analysis with the opinion that creativity and mental disorder are not in any way meaningfully related, but rather appear to be correlated through the same means of empirical distortion that originally gave rise to the "mad genius" concept. Further, she argued that self-identification as a "mad genius" or eccentric serves a protective role for creative individuals as it provides them a "semblance of consistent identity in a life full of occupational stops and starts."

Creativity and Eccentricity

If nonconformity describes who an eccentric *is*, then creativity tells us what an eccentric *does*. The products of eccentricity, be they a poem, a particular style of dress, or a way of living, are known for their striking originality, if not their outlandishness. Surprisingly, it is in the area of creativity and eccentricity that the greatest number of opportunities for research still exist. The reasons for this are simple. Both our understanding of eccentricity and creativity have grown enormously in previous decades, and though creativity is widely researched, eccentricity remains a relatively small area of study. Much of the work done in the past decade, though established on valid premises, has used methods that are primarily biographical, autobiographical, or historical in nature, as such the data have not been tested or collected in a controlled fashion. These data still require objective validation in order to prove that the original observations are repeatable and empirically verifiable. Also, the data need to be reviewed in order to explore new connections in our evolving knowledge. The dichotomy of what eccentricity is and does has therefore become a dichotomy between our present understanding and what we hope to learn in the future. The goal of this section is to demonstrate aspects of eccentricity that are known to be interrelated with creativity. Those elements established as more or less valid will be noted as such; gaps in the literature, too, will be identified.

Intellectual Traits

The high level of intelligence demonstrated by many eccentrics, in the range of 115–120 points on standardized measures, is reliably related both to measurements of giftedness and creativity. Often, as the current research makes clear, eccentrics are identified early by teachers or psychologists as being intellectually gifted. This level of intelligence, while shown in many eccentrics, is not a uniform predictor or precondition for eccentricity. Like in any other population, eccentrics display a variable range of intelligence; however, the skew toward higher intelligence on average does suggest a more optimal intellectual capacity for creative thought within the group of eccentrics as a whole. Weeks notes, too, that in regard to convergent thinking tasks, eccentrics generally approached solutions to problems through synthesis, conceptual analysis, symbolism, and constructive modeling.

In addition to being highly intelligent, eccentric individuals display a remarkable capacity for experiencing and consciously directing detailed mental images. The degree to which eccentrics can actively control their mental images not only supplies evidence for their relative lack of psychopathology (an argument seen above), but also correlates to a host of mental capabilities observed in creative individuals. The depth to which eccentrics can imagine is enormous. Weeks contends that the quality of the mental imagery displayed by eccentrics is not only sufficient to allow for near eidetic recall of an image, but powerful enough to allow the eccentric to immerse themselves completely in imaginative creations to a degree not unlike a lucid dream. While deeply imagining, eccentrics may use their ability to transform mental images to generate novel associations between ideas or images. Eccentrics accomplish

this feat either visually by rapidly fusing mental images in successive generations or multi-modally by altering information across the senses, in a manner similar to a transitory experience of synesthesia.

Weeks proposes a shared neurological basis for the mental imagery process utilized by eccentrics and the process by which dream images are formed during REM sleep. To this he contributes the additional observation that eccentrics are also very commonly vivid dreamers. REM is the period of sleep during which dreams are experienced, and it stands to reason that the transmutational effects of dream imagery might closely resemble those put to use by eccentrics during waking hours. Knowledge gleaned from fMRI and PET studies of the brain while engaged in these activities indicate, counterintuitively, that this is actually not the case. In their study of waking mental imagery, D'Esposito et al. found the most reliably activated portion of the brain during imagery exercises to be the left inferior temporal lobe, an area largely involved in processing visual information. Hobson, Strickgold, and Pace-Schott's REM sleep study found alterations in brain activity, not in visual areas of the brain, but in a large number of other areas, including "the pontine brain stem and of limbic and paralimbic cortical structures involved in mediating emotion and a corresponding deactivation of dorsolateral prefrontal cortical structures involved in the executive and mnemonic aspects of cognition." These data suggest that while waking imagery is likely a manipulation of brain areas used in normal visual processes, our dreams use uninhibited primal, emotional processes to form the images we experience during REM sleep.

Surprisingly, what we've learned about REM sleep from PET data may support the existence of an otherwise obscure creative tactic displayed by some eccentrics, an ability described by Weeks as "empathic problem solving." This entails empathy not directed toward another person but to a creative concept or idea. Essentially, empathic problem solving is accomplished by investiture of a certain degree of one's own personality and intellect into a project in order to penetrate the concepts involved. It requires a total immersion in a creative endeavor to the extent that the individual's subjective internal state is modified in order to "get inside the problem." The idea that a greater proclivity in eccentrics to clear, life-like dreams and the emotional and inhibitional freedom this offers makes plausible a thesis regarding the relationship between intense REM sleep and the ability to empathically problem solve, but this concept has yet to be fully developed.

Further validating current observations regarding the impressive mental imagery generating and emotional problem solving abilities of eccentrics becomes a matter of determining the veracity, most especially the degree of hyperbole, inherent in the self-reports and autobiographical accounts current research has made available. Indicators of mental image vividness such as the VVIQ or other diagnostic inventories have not yet been applied to the special case of eccentrics, and so we can not easily conclude that eccentrics do indeed benefit to the degree that they report from mental imagery. As has already been alluded, there are social reasons why self-identifying eccentrics would report dishonest degrees of mental capability. For one, eccentricity is sometimes adopted as a form of social

protection by otherwise creative but unsuccessful individuals. Also, it remains an open possibility that some claim eccentricity as a deliberately constructed identity for reasons authored by certain elite members of society. It seems possible, even likely, that individuals in either category would embroider accounts of their creative abilities in order to better wear the trappings of their eccentric self.

Personality Traits

Flexibility is a trait that bridges both intellectual and personality domains in eccentricity. Intellectually, eccentrics are extraordinarily flexible in the manner in which they approach and carry out creative endeavors. In spite of this, current research makes plain the fact that eccentrics can sometimes prove persistent and intractable to a disadvantageous degree once they've dedicated themselves to an idea or solution. Even in the face of expert opinion, eccentrics are often not dissuaded from their preferred methods. Certain of their own "rightness," eccentric individuals face the peril that, as they grow more frustrated with the failure of an idea, so too, do their inflexible personalities exacerbate the problem. Eccentrics have been observed to engage in sporadic, temperamental outbursts resulting from creative frustrations when they find themselves stuck in a blind alley. Such frustrations perhaps provide a reason why eccentrics prefer, on the whole, to remain noncompetitive, as the rigidity of competition can only exacerbate a frustration with failure.

On the flip side, flexibility is often seen as a positive trait in the personalities of eccentric individuals with regard to playfulness and humor. Humor is a common, understated trait common among eccentrics. Wit and whimsy allow for eccentric individuals to express their divergent views in a playful manner, upsetting expectations in a way that is not only socially appropriate, but socially desirable. The willingness to play with new ideas and to invent playful ways to look at a problem contributes to the childlike nature of some eccentrics. Both humor and play are good candidates for protective factors in the make-up of the eccentric personality. By refusing to take society seriously, the eccentric can, at least in theory, disregard some of the negative regard they might perceive. Similarly, a light-hearted, flexible attitude might allow an eccentric who would otherwise be overwhelmed with bizarre thoughts or ideas to playfully respond to the gestalt. However, the degree to which humor and play may or may not be seen as a protective factor in eccentricity, either from external or internal forces, is as yet unexplored.

The role of curiosity in creativity is relatively well understood, and the important part curiosity plays in motivating eccentrics has already been elucidated. To expand on the relationship, Weeks points to novelty as an expression of creative curiosity. Both creative and eccentric individuals prefer novel associations to a greater extent than more normal populations. Eccentrics are fluent in many different forms of expression, the drive for which originates from their curious, novelty-seeking natures. Weeks' research indicates that as many as 20% of eccentrics demonstrate talent in multiple modes of creative endeavor and most eccentrics retain active intellectual interest in about five separate topics. Certain social factors impact the expression of curiosity in eccentric individuals. Age and gender

perhaps play the largest role, as it's clear that older eccentrics do not report curiosity as much as youths do and that women are more likely to actively display curiosity in social environments than men. Cross-cultural factors, too, impact the heterogeneity in expressions of curiosity, but in a more diffuse manner. Current research seems to point in the direction of creative curiosity being impacted by social and developmental variables, but the degree to which intrinsic and extrinsic factors modulate the development and expression of curiosity and novelty-seeking behavior over the lifespan is not well understood.

No account of eccentric personality traits, especially those considered in regard to creativity, would be complete without mention of the negative social characteristics exhibited by eccentrics. To one degree or another, this has been discussed earlier in relationship to intrinsic motivation, idealism, psychopathology, and flexibility, but there are aspects that fall under none of those topics and so have not received adequate mention. Foremost among these is the eccentric individual's social awkwardness, which can take the form of odd manners of speech that complicate conversations for practical reasons, bizarre manners of dress or maintaining personal appearance, and a general disinterest in common topics or those social elements not related to their intellectual or creative interest. Future understanding in this area must consider not only the traits inherent in the eccentric individual, but what divide exists between that individual and society. No current understanding of eccentricity can accurately describe how eccentric traits develop, but more so with regard to antisocial traits, conceiving the essence of eccentricity will require a broad understanding of what interpersonal competencies (or incompetencies) and interactions have an effect on the outcome of eccentric development.

Fewer connections exist in the current literature linking empirical research to personality traits inherent to eccentricity. In one sense, this is liberating, because it allows us to freely evaluate all of the personality characteristics and behaviors in association with eccentricity to in light of creativity. In another, it introduces the lingering specters of error and bias thereby making these analyses unscientific. A systematic review of Weeks' original 25 characteristics would most concisely put to the test all of the theories inherent in the relationship between creativity and eccentric personality traits, but such an endeavor is, for the time being, a goal yet to be realized.

Glossary

Benefits Something that increases well-being.

Buying low Pursuing a new or undervalued idea that has growth potential.

Costs Resources expended in producing an output.

Demand Quantity needed or desired of a commodity or service.

Depreciation Loss in value of an asset over time.

Human capital Skills, knowledge, and abilities that people possess and can use in a productive fashion.

Investment Outlay of assets for future income or profit.

Marginal utility Benefit obtained from one additional unit of a good.

Psychic costs Intangible mental or social expenses, such as emotional stress.

Resources Available assets useful for production.

Selling high Releasing a novel production (such as an idea) on the market when it has gained value.

Supply Quantity available of a commodity or service.

Concepts from the investment domain and other economic considerations such as human capital, and supply and demand offer insights into human creative activity. Furthermore, some recent theories consider novelty generation and the creative process to be directly involved in economic growth.

Psychoeconomics of Creativity

Investing in Ideas: The Principle of Buying Low and Selling High

Robert Sternberg and Todd Lubart, in their ‘investment’ theory of creativity, proposed that creative people are like successful investors in the financial marketplace: they buy low and sell high. Buying low in the realm of creativity means pursuing new or undervalued ideas that have growth potential – that may be successful for solving one’s problem. Selling high means releasing a novel idea on the market when it has gained value and not holding an idea so long that others eventually have the same idea. Rather than jump on the bandwagon, producing work that may be good but similar to what others are doing, people who seek to be creative must deviate from the crowd, generating and advancing ideas that may eventually be recognized as new and valuable. Thomas Kuhn observed that for scientific activity, most researchers work within established theoretical or methodological paradigms rather than pursuing ideas outside such paradigms, ideas that have initially a low value but could lead to a paradigm revolution.

The buy low–sell high principle is partly descriptive of what creative people do (naturally) and partly prescriptive of a strategy that people may try consciously to implement to improve their creativity. In other words, people can develop a ‘buy low–sell high’ attitude, similar to the ‘contrarian’ attitude advocated for stock investors. Engaging in ‘buy low–sell high’ behavior may involve an analysis of potential of ideas and of the marketplace for launching these ideas. Thus creators may use strategies similar to market analysts for choosing among several

possible ideas. One strategy is fundamental analysis, in which key elements of a new idea may be evaluated for their intrinsic quality, originality, appropriateness to the problem-solving goal, as well as other qualities such as the aesthetic appeal of the idea or its coherence. This strategy can be seen in some accounts by inventors, in which they debate the strengths and weaknesses of their ideas before fully engaging work on a project. An alternative strategy is technical analysis in which trends in the problem domain may be examined in order to predict where a field is moving and what will be considered by the target audience as novel, appropriate, or aesthetic. This strategy can be observed in some accounts of artistic creativity, including work in fashion design and advertising. According to the buy low–sell high principle, people fail to be creative because they: (a) buy high, pursuing ideas that are already valued or known (perhaps to avoid risk); (b) buy low, pursuing ideas that do not have growth potential; or (c) sell low, exposing an idea before the audience is ready, before the idea has gained in value, or, inversely, hold the idea too long so that it becomes commonplace. Of course, it is important to note that the investment analogy does not map entirely, in all aspects on the phenomenon of creativity.

Human Capital: The Resources for Creativity

Capital refers to assets that enter into the productive process and lead to income. Although we think often of physical capital (e.g., land, machines) or financial capital (money), there is also human capital. Human capital can be defined broadly as the knowledge, abilities, and skills of workers as well as their time and energy. For creativity, the necessary human capital consists of a set of cognitive, emotional, and conative resources. These resources are specific intellectual abilities, cognitive styles, knowledge, emotion, personality traits (e.g., risk taking) and motivations. Individuals vary in the extent to which they possess each resource. For example, one person may be a risk taker whereas another person is rather

risk averse. The resources are hypothesized to develop and change over the lifespan.

A large body of research in psychology has examined the precise nature of the intellectual abilities, cognitive styles, knowledge, emotion, personality traits, motivations, and environmental circumstances favorable to creativity. This work can be synthesized within the economic perspective on creativity: each person possesses a portfolio of resources (skills and traits) relevant to creativity. As Herbert Walberg noted, this portfolio of psychological resources for creativity is part of a person's 'human capital', which may be actively invested in creative projects. From this perspective, the level of creative performance observed depends on: (a) a person's level on each of the resources necessary for creativity; (b) the person's active engagement of his/her resources; and (c) the match between the portfolio of resources that a person has and the profile of resources required for creative work in a domain (or a task) (i.e., the market demands).

With regard to the specific resources for creativity, such as knowledge, Daniel Rubenson and Mark Runco suggested that some fundamental economic principles may account for observed nonlinear relationships between the resources and creative performance as well as lifespan changes in the resources. For example, some studies suggest that a greater and greater amount of certain resources is not always best for creativity. Knowledge and specifically formal education seem to show an inverted-U relationship to creativity, with an intermediate level of education being preferable to a very advanced level. There may be a trade-off between two desirable but conflicting attributes. For example, knowledge is beneficial because it permits an individual to avoid re-inventing existing ideas (which already have a high value) and to avoid errors that others have already made in trying to work on a problem. However, increases in knowledge towards an expert level tend to have a negative effect on another desirable attribute, namely flexibility of thought. Experts often get stuck into using certain techniques for attacking a problem. Indeed, they have spent so much time and energy in acquiring these advanced techniques that it only makes sense to capitalize on their initial investment. In terms of intelligence and creativity, it has often been hypothesized that increases in intelligence contribute greatly to creativity initially, and then less and less, a case of diminishing returns.

With regard to lifespan changes in the resources for creativity, the phenomenon of depreciation may be one of the processes at work. For example, knowledge acquired at a certain moment may become outdated. There is depreciation of the value of the initially acquired knowledge as a field advances. To the extent that a person acquires a substantial knowledge base in their field at their entry to the field, we may expect that their capital in terms of knowledge will gradually become devalued with age. The desire to avoid depreciation of one's existing knowledge may explain results showing that older scientists resist in some cases new theories more than do younger scientists, as observed in a study of the acceptance of Darwin's evolutionary theory by scientists of Darwin's era.

In addition to these explanatory insights offered by the investment perspective, this perspective brings into focus some aspects of creativity more than others (as is the case with any particular point of view). For example, special

attention is devoted to risk taking, part of the personality resource for creativity. Risk taking is generally accepted as a key to investment decisions. Risk taking involves decision making in the face of potential gains or losses when the outcome is uncertain. Greater risks tend to be associated with greater potential gains. Generally, people tend to be risk averse, and studies of schoolchildren suggest that a low tolerance for failure develops starting in elementary school, perhaps because of the importance of obtaining good grades. People may under-invest because the potential rewards of a new idea are somewhat ambiguous as compared to pursuing technically sound but mundane ideas for which the limited rewards are clear. However, work on risk taking in situations framed in terms of losses shows that people would take risks to minimize potential losses. Thus creative ideas may be pursued actively when they represent a possible but risky solution to a bad situation, whereas creative ideas may be avoided when a person faces a choice among options involving potential gains. Some techniques for stimulating creativity help people to frame problems in ways that reduce risk aversion.

Increasing Human Capital

The resources for creativity – human capital – can be also enhanced, at least partially, through training. For example, a person may study creative thinking techniques through a self-help book or by participating in a training program. Most creativity training focuses on enhancing the cognitive resources for creativity. Training is possible with regard to the personality and motivational resources for creativity but this type of training is less common.

An investment in creativity training leads to an accumulation of human capital that can later be put to use. The investment in training depends on the marginal utility (value added) to the individual. Age and occupation are two variables that may influence decisions to pursue creativity training. Younger workers may derive benefits of training for a longer time than would older workers, thus increasing the utility of training for younger workers. Some occupations may demand creativity more than others, thus modulating the marginal benefits of training. The benefits of creativity training, which may vary from person to person, include intrinsic rewards (e.g., personal enjoyment) and extrinsic rewards (e.g., increased job performance, earnings, and opportunities for job advancement). The costs of creativity training include book expenses, tuition for courses, and opportunity costs of work not accomplished during the time spent on creativity training. For some individuals, the costs are reduced because their company sponsors the training program.

The decision to pursue creativity training is based on the marginal utility of each unit of training. A person with little human capital for creativity will benefit more than a person who already possesses many resources for creativity. Each of these individuals, however, can be expected to benefit less and less from each additional unit of creativity training, which is the phenomenon of diminishing returns. At some point, the marginal cost of additional creativity training will exceed the marginal benefit and the individual will not seek further training. With regard to the choice of creativity training versus traditional education, Rubenson and Runco pointed out that

people are more likely to invest in traditional education than in creativity-related education. The former has more predictable, less risky returns than the latter. Thus, even if people think that the effect of creativity training may be potentially more positive than traditional expertise training, the effects of creativity training are less certain than those expected with traditional education.

Similar to traditional economic capital, which enables potential economic productions, creative capital accumulation or enhancement enables potential creative productions. This potential is exploited maximally when productions satisfy some existing or latent needs – in other words, when they find a market.

The Market for Creativity

At the societal (aggregate) level, there is a supply and a demand for creative activity. The supply of creativity refers to the number of novel, useful productions (ideas, inventions, artistic works, etc.) that the members of a social unit (such as an organization or a society) provide. The demand for creativity is the need or desire in a society for creative productions. This demand may vary across domains (art, science, business, etc.) and across time. For example, during periods of political instability or war there may be greater demands for technological creativity than for artistic creativity. In financially tight periods, there may be a greater market for innovations that propose less expensive alternatives than for bold, but costly new products. The demand for creativity also varies from one place to another; some societies value conformity and maintenance of the *status quo* more than others. Sternberg and Lubart characterize environments – markets – for creativity as ranging from those that are bullish, overtly supporting creative activity, to those that are bearish, hindering creativity. A bullish environment can spark creativity by providing financial and social resources for creativity. During the Renaissance, for example, there were patrons who financially supported creative activity. Social interactions between artists of the time and competitions for prizes or commissioned works further contributed to a bullish environment for creativity. We can take the example of bullish markets enhancing the fulfillment of potential for creativity at the end of 1990s with the strong demand for dot-com creative start-ups. The emergence of the internet contributed to the accomplishments of many creative entrepreneurs whose potential would have never been realized in other times. However, some case studies of eminent creators suggest that a bearish environment is not always bad for creativity. A bearish environment provides obstacles that provoke creative solutions, following the motto that necessity is the mother of invention.

Societies may influence the supply of creativity by increasing or decreasing incentives to produce new ideas. These adjustments can be accomplished, for example, through grants to stimulate activity in certain domains, through educational initiatives, or through changes to the patent system. Sometimes, however, the supply and demand become out of balance. First, a society may misallocate its resources for stimulating creativity, as with misguided educational programs. Second, a society may underestimate its need for creativity because it does not adequately take into account the long-term benefits of creative

ideas, instead focusing on short-term, immediate needs. This underestimation of the demand for creativity can result in occasional shortages of creativity, as was perceived in the United States in the 1950s upon the Soviet launch of Sputnik. Of course, societies must balance their need for creativity with other non-creativity related needs such as building roads.

Another dimension of the societal investment in creative human capital is the policy decision of who will receive this investment. Walberg has discussed this societal choice in terms of investing in the education of average children to increase the general level of creativity in the population versus investing in a smaller number of gifted children who could eventually achieve the highest levels in their fields of endeavor. To the extent that a society invests in those who have already succeeded in the past, there is a 'Matthew effect' (from Matthew 25:29 "unto every one that hath shall be given, and he shall have abundance"). Hence, the creatively 'rich' get richer, and the creatively 'poor' stay poor; for example, a grant may be more likely to be awarded to a researcher who already had a grant than to one who is just starting and never had funding. This pattern of investment in human capital increases the probability that investments in creative human capital will yield some returns. However, some authors have argued that a society may derive a greater benefit from enhancing the creativity of the 'average' person (through educational programs) rather than investing the same amount in a restricted group of highly creative people who may show a relatively small increment in their creativity.

Finally with regard to the market for creativity, Sternberg and Lubart's investment approach highlights additionally the social consensual nature of creativity. John Maynard Keynes noted that the value of stocks on the stock exchange or other financial instruments depends on the extent to which those actively involved in the market value and collectively desire a stock. In a parallel way, the value of an idea depends on the audience and the extent to which the audience collectively values the idea. Thus ideas (or productions) can appreciate or depreciate in value with time or with a change of audience. We are able therefore to understand better why some creative geniuses are 'discovered' posthumously and other 'greats' in their day disappear into oblivion.

Depending on whether person's creative activity fits the market it may involve diverse benefits and costs.

Costs and Benefits of Creative Activity

An individual may derive extrinsic benefits such as recognition and financial gains, and intrinsic benefits, such as satisfaction with one's work and a feeling of accomplishment. Also, creative accomplishments can open the door to further opportunities, creating a positive effect of expected future gains. However, there are also costs to creative work. First, there are pecuniary costs such as time and resources expended during the work. Though often considered under the term of constraints, time is surely the most precious of human resources. Second, there are psychic costs such as emotional wear and tear of overcoming the obstacles often encountered in creative work. The initial negative reaction that often accompanies creative work may affect one's self-confidence or task motivation. Psychic costs may furthermore include social

isolation for one's 'deviant ideas'. Peers, whose own work is devalued by the appearance of the new, creative ideas, may seek to punish or ostracize the person who calls established dogma into question, ultimately devaluing it if the novel idea is accepted.

There are opportunity costs as well: the individual could have been pursuing other projects that may have provided some positive results themselves. Finally, there are transaction costs – costs that the creative person pays to a third party to facilitate the exchange with the audience. These transaction costs may be tangible, such as a commission paid to art gallery owners for displaying an artist's work, or intangible, such as limitations that one places on one's thinking to express ideas within the implicit rules of a discipline. In addition to the costs already mentioned, there are 'taxes' that are collected after a creative success. For example, following a creative success a scholar may be asked to review grant proposals or articles, serve on administrative committees, or give presentations summarizing previous work, which all take time from future creative work.

Parallel to the level of individual creators, there are also costs and benefits to creative work at the societal or macroeconomic level. The benefits of creativity include an enhanced quality of life for the society in general, as well as possible stimulation in the economic sphere. Each creative idea may have a trickle-down effect in which new supplementary products and services result from an initial idea. For example, the invention of the microcomputer fostered the emergence of many new computer-related services that have enhanced economic growth in recent times. The costs include direct financial costs and the use of physical and human resources. The opportunity costs refer to foregone advancements on other activities of the society (e.g., maintenance of roads). Opportunity costs also include the foregone advances on alternative creative domains. For example, given limited societal resources, if scientific creativity is promoted then artistic creativity may suffer a lack of advancement. Some historical analyses suggest that the value of creative work varies across disciplines and societal domains, over time. For example, political creativity may be valued during the emergence of a new society or religion, but less valued afterwards, scientific and technical creativity may be valued during times of war or facing a lack of environmental resources, requiring new technologies.

In this first part of the article, we reviewed some economics concepts that shed light on creativity. In the next section, we review some economic theories that incorporate creativity as a basis of economic activity.

The Economics of New Ideas

Endogenous Growth Theory

In the 1950s, a theory of economic growth was proposed in which technological change and innovation was the main factor – growth residual – explaining the permanent per capita growth since the industrial revolution. Specifically, it explained the paradox that from the 1870s to the 1950s the growth rate of capital and labor accounted for only about 10% of the growth rate in per capita output. Essentially due to the difficulties of mathematical formalization, this growth theory did

not consider the nature of the innovation factor, postulating instead that it is determined by inputs external to the economic system (e.g., research in universities); it became known as *exogenous* growth theory.

In the late 1980s, a new, *endogenous* growth theory was advanced; this theory emphasized the critical role of technological change and innovation but viewed them as determined by inputs internal to the economic system and not external to it. Endogenous growth theory seeks to explain how economic systems' or countries' internal choices relevant to technological change and innovation (e.g., regarding investment in R&D) account for the variation among these systems on the rate of the growth residual.

According to Paul Romer's 'economics of ideas' version of endogenous growth theory, new ideas embedded in technological change and innovation are the main factor of economic growth and the unbounded amount of potential new ideas is a main reason why growth after the industrial revolution has been constant and may continue to be so in the future. To illustrate this proposal, the 'factory' metaphor used traditionally in neoclassical growth theory is replaced by a 'computer' metaphor. Take for example, growth in agricultural output. Viewed through the 'factory' metaphor, this growth could come from an increase in 'raw materials' (arable land) and in 'equipment' (agricultural equipment, fertilizers). However, viewed through the 'computer' metaphor, this growth could come from new 'software' (methods of farming and farm management and methods to produce better equipment and fertilizers) rather than from an increase in amount of 'hardware' (arable land, agricultural equipment, and fertilizers). This metaphorical shift allows Romer to change the common view of the main growth factor and of growth itself. In the 'factory' metaphor, instructions are provided and fixed by the external state of technological knowledge and nonproduction workers are considered as overhead; growth may come only from increases in 'raw materials', 'equipment', and 'production workers'. In this metaphor, because of the scarcity of the latter inputs, growth is viewed as limited. In contrast, in the 'computer' metaphor growth comes from inventing and accessing new and better 'software' – new ways to combine raw elements to create valuable things; because of the unbounded amount of potential new 'software' and because of the minimal costs for producing an extra 'software' copy, growth is seen as unlimited.

It seems that human creativity can be postulated as part of the core of economic growth and its nature is thus of much relevance.

Homo Creativus: The Economic Agent for Endogenous Growth

The creative process, at the heart of endogenous growth, is conceived as a function of the resources (in particular, human capital) devoted to research and development (R&D). The relation may be linear and continuous, or discontinuous with research effort leading to occasional leaps in change and innovation. Creative ideas may result from a combinatorial discovery process; new ideas are combinations, hybrids of existing ideas or elements. This view is specially appealing to endogenous growth theorists because the combinatorial dynamics of possible new ideas evolve faster than the

exponential dynamics of potential diminishing returns of the two other production factors – capital and labor. However, only a fraction of potential new ideas is transformed into useful, actually implemented ideas, and resources are required for this transformation. Thus the growth residual depends on resources devoted to generating possible idea combinations, selecting the best among them, and then developing and implementing them.

Based on psychological studies of creativity, we can postulate that certain cognitive, conative, and affective resources will foster the generation of new ideas, the selection of potentially useful ideas and the development and implementation of these ideas. For example, Isaac Getz and Todd Lubart found that emotional information is a key resource in the preconscious process of concept combination; furthermore, task-specific, domain-relevant knowledge will help a person to recognize and use chance combinations and events as sources of ideas, and perseverance will contribute to implementation. Thus, *Homo Creativus* possesses a set of specific characteristics, a psychological profile, with an economic value that can vary from one sector of activity to another, and over time. These individuals include those whose economic activity involves, by its nature, creative thinking, or more generally designing. Examples are writers, scientists, engineer-inventors, musicians, artists, designers including industrial and architectural designers. Richard Florida proposed that this creative class prospers under conditions that provide a diversity of fields of creative activity (talent), access to technology to exchange and develop ideas, and tolerance (to reduce the psychic costs of novelty production). However, according to Isaac Getz and Alan Robinson, any individual, in any profession can be creative provided the appropriate organizational environment.

Some evolutionary economists have suggested that the societal value placed on creativity and the development of creative people is part of an evolutionary need for growth and change and, at least in the technological sector, a desire for convenience (reduced physical labor, enhanced quality of life). Thus, novelty becomes a goal in the economic action plans of individuals, organizations, and institutions. The individual agent who introduces the novelty into the economic system is the entrepreneur. Entrepreneurs may be *Homo Creativus* themselves but more often they connect novelty generated by another *Homo Creativus* to the economic matrix, leading to a market reaction, incorporation of the novelty in the economic sphere and the following evolution of the market.

Overall, the availability of such psychological resources as well as physical and financial ones means that people *can* engage in the creative process of developing new ideas, not necessarily that they *will* select and pursue potentially creative ideas. The engagement of resources will depend on individual's perceived costs and benefits of pursuing creative work, including opportunity costs of other uses of their resources. However, not only societal level but also organizational level economic theories can be useful to illuminate the phenomenon of creativity.

Organizational Economics

Acknowledging that many organizations have tremendous cognitive and emotional resources for ideas, and thus a high

creative potential, research shows that very few put in place a set of managerial practices to lead people to express and implement their ideas. An idea management system, as described by Getz and Robinson, allows every employee to express, implement, and be recognized for his or her ideas. First, employees are encouraged to express their ideas, thus increasing the likelihood that one employee's ideas will be known by others. Second, because employees are encouraged to implement their ideas by themselves, the likelihood of cooperation around the ideas of several employees, and thus of their combination, is increased. Finally, because employees are encouraged to consider that 'good is never good enough', the likelihood that one employee's implemented idea will be further improved with an idea of another employee is increased. This increased likelihood of combining employees' ideas has important implications for endogenous economics: the assumption of a steady flow of ideas, in general, and of their combination, in particular, can be made only for some – excellent – companies, but not for entire industries or economies. Finally, it shows that the assumption of a small fraction of generated ideas being actually implemented is paradoxically true for companies who do little to facilitate their employees' creative ideas; it is wrong, however for the companies with excellent idea management systems in which most ideas are, on the contrary, implemented – up to 99% in certain cases.

Organizational economists have also explored what organizational forms are best for economic productivity and innovation. For productivity, the multidivisional form, the matrix form, the network form and others have been studied. Concerning innovation, internal hybrids – a mix of a typical organizational hierarchy with market mechanisms and other practices have been investigated. For example, companies may introduce market mechanisms to create an internal 'market for ideas' in which employees' most useful, and in many cases innovative, ideas are put in place, instead of remaining untold or unimplemented in a typical hierarchical structure. The hybrid character remains because the 'buyers' of ideas, those who listen to, evaluate and authorize the implementation of ideas, are still in the hierarchy. 'Hybrids', however, prove to be unstable, the hierarchy often reclaiming the authority it left out to market forces within. Brian Carney and Isaac Getz explored an organizational form, they called *Freedom Inc*, which is completely opposite to traditional hierarchical forms with all employees completely free and responsible to take initiatives they, not their bosses, decide are best for the company. This organizational form – that Getz called the F-form – provides an ultimate, ideal environment for people's creative potential to be fulfilled and the companies who built them consequently found themselves at the top of their industries.

In general, the question of organizational level institutions most appropriate for economic growth and human fulfillment is a part of a larger question of society level appropriate institutions.

Institutional Economics

This field of economics examines how institutions shape the capabilities and behavior of economic actors, and thus influence economic productivity, including heightened

innovation. Historically, the scale of institutions studied has varied. Research has examined:

1. whether a market economy or a planned economy is best for innovation and productivity;
2. specific institutional aspects that influence productivity;
3. how businesses are structured and the financial and labor market systems supporting them, such as Total Quality as an institutional factor for superior productivity and innovation; and
4. start-ups, venture capital, and fluid labor markets that influence innovation and productivity.

'Innovation systems' proposed by Richard Nelson is an example of an institutional economics theory focused on innovation; it explores how companies are imbedded in and supported by a variety of nonmarket institutions, leading to corporate innovation. A typical example is universities funded by the government to undertake research and training in fields relevant to an industry thus supporting the latter's companies' innovation. Another example, offered by Amar Bhidé, is consumers' willingness to try new things that support corporate innovation. Finally, Edmund Phelps investigated what kind of society-level institutions are appropriate to both higher initiative, and hence growth, and increased human fulfillment, or in classical terms, happiness.

Conclusions

To summarize, we have examined how economic concepts are relevant to creativity in an effort to expand our understanding of this complex psychological phenomenon. The economic perspective treats creativity at the microeconomic and macroeconomic levels of analysis. Microeconomic phenomena include the investment in ideas that are unknown and/or undervalued, human capital as an input in the creative process, the notion of actively increasing human capital through creativity training, and the costs and benefits of creative work for the individual. Macroeconomic phenomena include the market for creativity, the supply and demand for creativity, societal policies toward investing in creativity, and the costs and benefits of creativity at the aggregate level.

Economic approaches such as endogenous growth theory, organizational and institutional economics enrich research on creativity by extending and deepening the understanding of the person, process, product, and press (environment) components of the phenomenon of creativity. For example, institutional-level economic analyses of creativity and innovation suggest that most innovations acquire their full market usefulness through a – an often decades' long – string of complementary useful inventions building up an 'eco-system' for innovation; the study of validity criteria should view the initial idea's usefulness not as something given but evolving, based

on further inventions that enhance it. For example, the first PDA, Apple's Newton, invented in the early 1980s, has been seen as a market failure. However, the spread of the PC, and a possibility to synchronize the PDA with it, increased the PDA's usefulness and the internet has increased even further the possibility for the PDA to access and download a variety of data and software. All those posterior inventions increased the PDA's usefulness to the level at which it became fully recognized by the market. Institutional economics highlight how environments relevant to creative organizations involve an array of aspects beyond the context of home, work, and local cultural settings, such as funding bodies, public research, and even consumers open to trying new things. Another implication for creativity studies is that, in addition to past and present environmental aspects, future ones may be critically important, as they may add value and bring to fruition initial seminal creative work.

Glossary

Cognition Faculty within the mind which allows for the processing of information, applying stored knowledge, and adapting to various situations and events.

Collaborative learning Learning which takes place in any kind of group setting. This type of learning can comprise learning in pairs or small groups (although these two are often considered distinctly in the research literature). The group context is emphasized in this type of approach, and roles among group members, as well as how interactions among individuals, comprises the nexus of foci and interests.

Convergent thinking Concept introduced by Guilford which indicates a student's ability to provide a predetermined correct answer.

Creativity myth Widely circulated belief that society and educational spheres subscribe to concerning creativity.

Divergent thinking Process of learning in which students are encouraged to produce as many possible

solutions to a problem as possible, so they can have a plethora of material to consider in their analysis of a problem.

Problem-based learning An instructional approach which focuses on students working in collaboration to solve problems posed to them. The problems are typically practical in nature, and teachers facilitate learning in these contexts.

Schema Concept related to educational psychology proposed by Jean Piaget, which asserts that individual possess mental structures which correspond to existing elements in the world. These structures are organized according to existing idea sets within an individual's mind. The structures are also classified based on a particular theme or element which is then impacts how that individual uses information and knowledge in processing abilities.

Self-efficacy A student's belief in his/her capacity to fulfill on a particular learning objective.

The Complex Nature of Creativity Within Education

Creativity is a primary concern within education for a number of reasons. Business leaders, both nationally and internationally, stress the importance of innovation, and many leaders from all walks of life stress the importance of being able to solve problems creatively, either in individually or in small, diverse teams. Others note the importance of creativity in the arts or in everyday life. Some scholars even make a strong case that an emphasis on creativity in a community has a number of important cultural and economic benefits. Furthermore, it can be argued that learning is not just related to creativity; rather, the construction and use of new knowledge is a special case of creativity.

Given these benefits and the strong relationship between learning and creativity, it is natural to turn to formal education in an attempt to encourage and foster creativity – where better to reach the most people at a young age? Yet the relationship between creativity and schools is, in most countries, a complex, tenuous one. This is due to the widespread belief, even among educators, that creativity cannot be enhanced. Add this belief to the prevalence of test-focused education systems in many countries, and the reasons for little emphasis on innovation in schools become clear.

Despite these concerns, literally hundreds of techniques have been developed to teach creativity. Indeed, in both the early 1970s and later 1980s, Torrance classified over a hundred creativity enhancement studies into nine categories of strategies for teaching children creativity. In approximate order of effectiveness, they included Creative Problem Solving (CPS) programs based on the Osborn–Parnes model; other

'disciplined approaches,' such as training in semantics and conducting research; creative arts programs; media and reading programs; packaged programs for creative thinking; modification of testing conditions; use of motivation, reward, and competition; teacher–classroom variables, including level of control and classroom climate; and curricular and administrative arrangements to facilitate creativity–fostering conditions. Other scholars have reviewed the creativity education literature and arrived at similar classification schemes.

Torrance and others have found that research support on the effectiveness of individual techniques is generally lacking – although prepackaged creativity programs are supported by more robust evidence of effectiveness. However, the vast majority of the conducted research has used divergent thinking as an outcome variable, suggesting a narrow focus in program intent and desired outcomes. Indeed, several techniques may actually harm creativity: for example, research on brainstorming questions its efficacy as the technique is traditionally applied in educational settings.

In this entry, the focus is placed on larger, systemic approaches to educating for creativity, especially those models that have been or are meant to be implemented in traditional K-12 education and higher education settings.

Approaches to Creativity in Education

SOI-Based Approaches

In 1968, J. P. Guilford addressed the then somewhat controversial proposal that creative performance in individuals could be enhanced. As he observed, much of our problem solving in

everyday life involves divergent thinking. However, educational practices predominantly encourage students to seek conventional answers. He proposed that more attention be given to development of skills in divergent thinking and also that we show more tolerance of outcomes of divergent thinking. Guilford further stressed that the belief creativity could not be learned had hampered educational cultivation of this trait, and further, that the somewhat unpredictable characteristics of some creative students could frequently be discouraged by teachers, based on the dominant goals of education.

Guilford created the Structure of the Intellect (SOI) model, in which he expanded and reconfigured E. L. Thorndike's classifications of intelligence, and proposed five major functions and processes associated with the ability to think. He broke down thinking abilities into the following categories: (a) cognition – the ability to discover or know, and to rediscover or recognize figural objects, their properties, and also, symbolic objects and other types of meanings; (b) retention – or the numerous abilities associated with memory; (c) convergent thinking – or thinking which produces a single, 'correct' answer; (d) divergent thinking – a process which involves searching that could result in numerous answers; and (e) evaluative abilities – these involve our capacity to distinguish suitability, adequacy, and success of information, memories, and products of thought. He further described various ways that these abilities could be tested and developed in ways which could help transform how teachers view learners and even, according to Guilford, how people view the process of learning itself. The SOI model presents a way by which the discontinuities he observed in the educational system could be rectified by revolutionizing the skills and abilities emphasized by schools and encouraged in educational institutions and settings.

Mary Meeker elaborated on Guilford's theories by further applying his model to educational settings and conditions. As cofounder of the Structure of Intellect Institute, she developed SOI exercises that were designed to help both children and adults enhance their performance in the various types of cognitive abilities conceptualized in Guilford's model. In Guilford's model, these dimensions are the operations in which it is employed, the content with which it is involved, and sort of product which results from it. In 1968, Meeker systematically moved through the figural, symbolic, and semantic dimensions of each of the cognitive functions identified by Guilford, and then she provided examples of tests which could be used to evaluate this ability in students. She designed curriculum exercises and activities that could be used with students of all ages, from pre-school up through adults. The SOI Institute curricula were among the first attempts at a systematized approach to teaching creativity in school settings.

A similar approach was introduced in the early to mid-1970s by Joseph Renzulli and his colleagues in their *New Directions in Creativity* series. These five manuals served as a curriculum that focused on the divergent thinking axis of the SOI model, with activities devoted to each of the various manifestations of divergent thinking as classified in the model, with emphasis on the standard divergent thinking dimensions of fluency, flexibility, originality, and elaboration. Each manual contains a series of 48 reproducible worksheets, with each worksheet addressing one cell in the SOI model. Renzulli

stated that the curriculum, which was revised and updated in 2000, was an effort to provide educators and students with a range of strategies for increasing creative potential, and the series was initially well-received and remains in print.

Torrance's Influence

Perhaps the individual most responsible for elevating the discussion about the proper place of creativity within education was E. Paul Torrance. Torrance's creativity work focused on the 4 'P's' of creativity: the creative person, the creative product, the creative process, and the creative press. He delineated several characteristics of creative people. Positive characteristics of creative people, in Torrance's findings, include being intelligent, independent, energetic, having a strong sense of humor, being artistic and open-minded, and perceptive about one's environment; negative traits included the potential to be egotistical, impulsive, argumentative, childish, absentminded, neurotic, and hyperactive. Furthermore, Torrance proposed the idea that creativity processes are suprarational: this term means that creativity involves, not only intentionality and cognitive factors, but also depends upon nonrational tendencies, including the predilection to be playful, fanciful, illogical, farfetched, or even emotional. These factors also encompass a person's motivation to engage in innovative approaches and thinking.

Torrance describes creativity as a process which consists of steps similar to those in the scientific method, and he proposed that people: (a) become sensitized to difficulties, gaps in information, or missing elements; (b) establish theories about these shortcomings; (c) test the theories and reformulate them; and (d) circulate the results of their findings. Torrance engaged in considerable efforts to strengthen the relationship between research conducted on creativity, and implementation of activities in classrooms and other educational settings. He reviewed 142 studies describing efforts to teach creativity, and he concluded that various creativity enhancement exercises did increase student creativity within educational settings, including those associated with divergent thinking, training in the Creative Problem Solving model, being trained in creative art or writing, the importance of sustaining a creative climate, and using various workbooks or programs. As a result of this work, he proposed that creative thinking be rewarded in schools because it allowed students to understand how better to achieve her potentialities. Torrance also believed that creativity served psychotherapeutic goals, allowing students to work through emotions and other psychological issues which could not be alleviated in a traditional classroom environment. For example, he suggested that creativity allowed students to develop more comprehensive self-concepts and to be able to engage in more accurate and more effective self-evaluations.

Torrance identified particular characteristics of educational environments which could successfully prepare students for lives of proactive citizenship. He proposed that environments should not be inhibiting, that teachers should remain aware of the considerable impact their approach, attitude, and evaluation had on students. Torrance also gained widespread notoriety by proposing that children experience a drop in creativity at two points in the educational system: during kindergarten, when students learn about rigidity associated with rules and expectations, and again in the fourth grade, when students

become susceptible to increased social pressure from peers, and also, increasingly self-conscious about identity and social status. He felt that both creativity roadblocks were avoidable.

Torrance also conceived of the Incubation Model of Teaching, which uses three steps to encourage collaborative learning: (a) students become aware of a dilemma, challenge, or problem, and cultivate a curiosity about it; (b) they accept their need and desire to learn more about it; and (c) they incorporate the new knowledge they've received into their existing schema. Ultimately, this model represents a dynamic and active process, which allows for productive debate instead of fostering a factionalizing approach; it also does not presume any sort of prior expertise.

The Schoolwide Enrichment Model

In the mid-1970s, Joseph Renzulli developed the Enrichment Triad Model (ETM), a gifted education model that focuses on helping students learn the creative process as it occurs in the real world. Students move through three stages of enrichment, in which they initially become exposed to unusual topics outside traditional school curriculum subjects (Type I). They then broaden their horizon of familiar contexts by cultivating a broad range of thinking and feeling processes, including cognitive and affective thinking, 'how-to-learn' skills, advanced research skills and reference material usage, and fostering written, oral, and visual communication skills. These abilities, in turn, assist them as they embark upon independent research or artistic study, with the ultimate goal of producing their own knowledge or other creative contribution. Given that the ETM is based on Renzulli's observations of real-life, adult creative achievement, the fact that some educators consider ETM and subsequent, related programs (e.g., the Schoolwide Enrichment Model, developed with Sally Reis) to be models for creative education is not surprising. Research on the model has demonstrated its efficacy with high-level students and student populations from widely diverse ethnic and socio-economic backgrounds.

Creative Problem Solving

One of the most common and useful models for integrating creativity into education is the Creative Problem Solving model (CPS). The model was created in the 1950s by Alex F. Osborne and further developed by Sidney Parnes and other researchers associated with the Creative Education Foundation, and it is still in wide use today. The model consists of six distinct stages: (a) mess finding – locating a problem needing a solution (which is sometimes omitted); (b) fact finding – examining what you already know about the problem; (c) problem finding – selecting a specific problem definition; (d) idea finding – brainstorming; (e) solution finding – evaluating ideas; and (f) acceptance finding – implementing ideas. Osborne and Parnes' work has been revised and expanded by a number of educators and researchers, including Treffinger and Isaksen, in order to increase the model's efficacy for teaching creative problem solving.

Isaksen and Treffinger's modifications included the addition of the extra first stage (mess-finding), the broadening and renaming of the data-finding stage (previously labeled

fact-finding), the acknowledging of the need for both divergence and convergence, and also, expanding the 'scope and methods for solution development and implementation planning' (in the solution-finding and acceptance-finding stages) (Treffinger, 1995: 303). In addition, they also articulated a more precise conception of the term 'problem' as it can be applied in the CPS model. Specifically, they identified problems as potential opportunities which could foster positive outcomes by allowing students to work through changes and engage in constructive action; further, a 'problem' could be any "important, open-ended, and ambiguous situation for which one wants and needs new options and a plan for carrying a solution successfully" (Treffinger, 1995: 304). The important step of viewing a 'problem' in this context greatly expands the ways that creativity can be conceptualized as a potential skill to solve a broad spectrum of problems (and not simply those traditionally associated with 'creative' disciplines like the arts). By extension, these revisions further ensured that the CPS model could also be used in many more settings and situations than might have been previously thought during its earlier inception.

Teachers and Creativity

According to Plucker, Beghetto, and Dow in 2004, four persistent myths limit progress in studying and applying creativity. These include that people are born creative or uncreative, creativity is intertwined with negative aspects of psychology and society, creativity is a soft, fuzzy construct, and creativity is enhanced in a group. Teachers are not immune to these misconceptions or myths about creativity. As Guilford and Torrance predicted many decades ago, recent research provides evidence that teachers employ a variety of definitions of creativity, some of which that do not align with expert opinion (i.e., they conceptualize creativity as a negative influence in the classroom).

For many teachers, an ideal student does not have highly creative characteristics. When asked to select characteristics of their ideal or favorite student, many teachers do not select items such as being courageous or curious, which experts list as highly creative. Teachers prefer qualities such as doing work on time and being courteous or good-natured, some of which may not be indicative of creativity in many classroom contexts. This however may not be true for teachers of gifted students whose descriptions of an ideal student more closely align with the expert opinion of highly creative people.

Sternberg has provided a theoretical model for these observations in his work with thinking styles. Teachers may not approve of students in their classrooms who are legislative thinkers which is characteristic of creative thinking and problem solving. Subsequently teachers tend to prefer and promote executive thinking, which emphasizes following rules and protocols. This results in curriculum that includes more closed-ended rather than open-ended questions and activities. Recent research with prospective teachers suggests this may be changing, at least with educators who plan on teaching in lower grade levels. When Beghetto asked whether teachers would prefer student responses in classroom discussions to be relevant or unique, prospective middle school teachers tended to favor unique responses compared to their peers planning on

teaching in high school. The only subject area distinction was in math, with prospective math teachers favoring relevant responses because unique responses may be distracting. These and related data suggest teacher education may be transitioning to a more progressive view of creativity in the classroom.

The research suggests that there are a variety of ways teachers can promote creativity in their classrooms. First, they should recognize the myths surrounding creativity and acknowledge that all students have the capacity for creativity. Second, Sternberg suggests teachers should take a careful look at curriculum and personal preference for certain intellectual styles. If schools want to promote creativity, they need to promote legislative thinking in addition to executive and judicial thinking. Finally, research in higher education suggests promoting creativity among students requires teachers to encourage independence, treat students as individuals, and act as creative role models, all of which apply equally well to elementary and secondary education.

An Alternative Model

Based on the history of efforts to enhance creativity in students in educational spheres and settings, Plucker and his colleagues proposed a new model of creativity enhancement that seeks to explain how creativity can be effectively and efficiently enhanced in P-20 education. More specifically, they were troubled by the growing body of research suggesting that traditional creativity education efforts – which focused on teaching students how to use specific creativity techniques – were not effective. Their new, alternative model has multiple stages that form an iterative process for improving creativity-related attitudes, beliefs, and skills. Similar to the work of Renzulli, the model attempts to build on research and observations of adult creators in real-world settings.

The model is based on three primary criteria: a focus on schema change, especially schema related to how the individual defines and understands creativity; the need to assist students in identifying their strengths and weaknesses regarding creativity; and an emphasis on both personal and external factors that impact and catalyze creativity development. These principles stand in contrast to other models for teaching creativity, in that the alternative model places much less emphasis on ‘creativity techniques’ than other models and curriculum. This de-emphasis on specific techniques is based on the belief that techniques are not useful to people who do not believe, for example, that creativity can be enhanced. In order to dispel this and other student misconceptions about creativity, problem-based learning activities are used to cultivate cognitive changes in students by highlighting inconsistencies in their current beliefs.

Throughout the problem-based learning tasks, the teacher and students discuss the various external factors that play a role in both hampering and developing creativity in individuals and groups. Rather than overemphasize the role of the environment in creativity, however, the model promotes a balanced approach to cultivating creativity, with an emphasis on the individual’s ability to shape the environment, and vice-versa. The model has been implemented and evaluated numerous times at the university level, with promising results.

Assessment

The Torrance Tests

The most common assessments of creativity used in education are the Torrance Tests of Creative Thinking (TTCT). Although the TTCT is roughly half a century old, it is still in current use – the TTCT probably remains the most popular creativity assessment in education settings around the world. The TTCT was influenced by Guilford’s extensive work with divergent thinking activities, although Torrance refined and standardized the administration and scoring of divergent thinking tasks to create his assessment battery.

The battery includes Verbal (Thinking Creatively with Words) and Figural tests (Thinking Creatively with Pictures) that each include a Form A and Form B that can be used alternately. Each form contains multiple subtests, with three subtests on the Figural forms and seven subtests on the Verbal forms. The original test produced scores in the traditional four DT areas, but the streamlined scoring system introduced in the 1984 revision made significant changes to the available scores. Under the streamlined system, the Figural tests can be scored for resistance to premature closure and abstractness of titles in addition to the familiar scores of fluency, elaboration, originality. Flexibility was removed because those scores tended to be largely undifferentiated from fluency scores. In general, reliability and concurrent validity evidence is positive, but evidence of construct validity is less convincing.

Product Evaluation Strategies

Another area of creativity assessment that has potential value in education focuses on creative products. Although a number of high-quality product assessments have been developed, including the Creative Product Semantic Scale by Besemer and O’Quin and the Student Product Assessment Form by Reis and Renzulli, the most active area is that of the Consensual Assessment Technique (CAT) developed by Amabile and her colleagues. The CAT is based upon the belief that people know creativity when they see it, a view supported by extensive studies on people’s implicit theories of creativity. When using the CAT, expert judges are asked to evaluate a product’s creativity, with the scores averaged across judges. The CAT’s relative simplicity and approximation of real-life assessments of creative products are appealing to teachers, although finding appropriate expertise for judging can be problematic. Although the CAT is associated with considerable evidence of reliability, validity evidence is not as comprehensive, and considerable debate exists over how ‘expert’ and expert needs to be to judge, for example, the creativity of essays or poems written by fourth graders.

Conclusions

Our recommendations concerning the best ways to enhance creativity in the educational system revolve around the initial step of addressing the misconceptions people harbor about creativity: these misconceptions could be focused on their own selves, other people, and creativity itself as a construct.

We believe one of the most important steps to take involves encouraging students' sense of self-efficacy concerning creativity. By fostering creative self-confidence in students, they will be more amenable and willing to engage in the risk taking necessary to be innovative. In order to accomplish this task, we believe it is crucial to design activities that demand an individual's or a group's attention. Such activities should also excite, stimulate, and increase people's curiosity about the world.

Developing this kind of curiosity then encourages people to develop an intrinsic motivation to be creative, which is an integral component of their being able to enhance their own creativity. This goal can also be achieved by supplying students with information about strategies and creators which proves both useful and interesting. Similarly, if teachers capitalize on teachable moments such as current political, cultural, and community events, students will be further encouraged to foster a sense of curiosity about their environment and community.

Another important aspect of enhancing creativity involves cultivating group awareness of its own learning process, or developing a sense of group meta-cognition. The best way to foster this capacity is to present groups of students with problems which must be solved both individually and in groups. In these types of learning situations, teachers should avoid making assumptions about students, as individuals vary tremendously in their abilities, preferences, and attitudes. This structure also allows students to exhibit their distinctive abilities more easily, and to allow all group members, as well as teachers, to understand that diversity is a critical element of creative production, when it happens both individually and in groups.

This approach also introduces the necessary component of variety into creativity enhancement efforts. A multi-faceted, multi-dimensional setting best helps the unique preferences and interests of participating students and individuals become fostered. This method also promotes diversity in student approaches to identifying and solving problems. It can also provide either skills and/or information that will more easily generalize to other settings, and thereby reinforce and expand the participants' capacity for creativity ability enhancement. To achieve these goals, we advocate that it is extremely important to consider the efficacy and usage of well-established programs that address multiple components of creativity, and which have already been field-tested and refined.

The Future of Creativity in Education

The emphasis on formally applying creativity to education and schooling is roughly 50 years old, which begs the questions of what creativity in education will look like in another 50 years. The future is always difficult to predict, but certain trends appear likely to continue. First, an emphasis on environmental influences will continue to pervade creativity education, although this emphasis will probably be tempered by an understanding that people and environments interact to produce creative behavior, and that focusing on one or the other is likely to prove ineffective.

Second, the growth in technology and access to technology in formal and informal education settings will continue to change education profoundly. For example, distance education

greatly increases the chances that students will have access to a wide range of learning opportunities. However, many of these distance education offerings are rather passive or linguistically focused, raising questions about the ability of such teaching and learning systems to enhance creativity meaningfully. Indeed, the pervasiveness of instructional technology in many countries calls into question whether one can predict how any aspect of education will be designed and implemented in even the mid-term.

Third, countries that emphasized memorization over knowledge production and creativity (e.g., China and many other emerging economies) will continue to transition to problem-based, creativity-friendly instruction and curriculum. However, the transition will almost certainly take longer than anticipated, due to the difficulty in overcoming cultural norms and ingrained memorize-and-test educational traditions.

Fourth, many developed countries, which have done relatively well fostering creativity in their students, may continue to overreact to the economic pressures from developing countries and begin to emphasize knowledge acquisition over knowledge production. Policymakers observe growing economic competition from developing countries and assume that education in those countries is responsible for the new competitiveness; to the contrary, the improvement in developing countries' economies is often due to those nations converting their policies and institutions to models that parallel those in developed countries, and education is not an exception. If developed countries learn the wrong lessons from developing countries about the need to transition to creativity-fostering economies and education systems, the irony will be that the developing countries learned to move to an emphasis on creativity and innovation by watching developed countries make that transition roughly 50–60 years ago.

Finally, looking ahead as far as possible, we remain optimistic that educators and policymakers will strike a productive balance between knowledge acquisition and knowledge production, between testing and learning, and between formal and informal education. Given all that is in flux with the world today, it is likely that the creativity education models that will guide these efforts have yet to be created, but they will almost certainly be based on the models highlighted above.

ALBERT EINSTEIN (1879–1955) is one of the greatest scientists in the history of scientific thought and an icon of the 20th century. His name is synonymous with genius, and exploring his scientific creativity is extremely important toward understanding extraordinary minds.

Albert Einstein. Used with permission from AIP Emilio Segrè Visual Archives.

Early Years

Albert Einstein was born 14 March 1879 in Ulm, Germany, where his father Hermann, age 32, owned a featherbed business; his mother Pauline (née Koch), was age 21. As a child Albert entertained himself, doubtless due in no small part to difficulties with language learning. He did not speak well until 2 1/2 years and showed no early precocity. Albert's sister, Maja, born 1881, later recalled that "those around [Albert] were afraid he would never learn to talk." Einstein's teachers considered him only moderately talented, apparently owing to the length of time he needed to mull over a problem. For the most part, during his childhood Albert was a solitary child, preferring private games that required patience and perseverance, like building elaborate houses of cards.

Einstein had more than moderate success with the violin which he began at age 6, and really started to enjoy at age 13 or 14 when he discovered Mozart's violin sonatas. Until then he had to tolerate teachers who emphasized mechanical or rote learning, a mode of learning that Einstein detested. Although playing Mozart's sonatas was beyond his technical competence as a teenager, Einstein practiced them repeatedly, but not systematically. He also stopped violin lessons at this time.

Einstein began his school career in 1886 at a public school in Munich where his parents had moved in 1880. In 1888 he entered the Luitpold Gymnasium, Munich, where the curriculum focused on rote learning of, for example, classics in Greek and Latin read in those languages.

About age 13 or 14 Einstein demonstrated the ability to solve difficult mathematical problems posed to him by his paternal uncle Jakob Einstein. These diversions, in addition to insightful recognition of young Einstein's talents by a medical student who boarded in the Einstein household, were necessary counterbalances to the disastrous situation he faced at school.

Some years later Einstein described his entire student career as a "comedy." The humor was found only in retrospect. Einstein recalled that the "teachers in the elementary school seemed to me like sergeants and the teachers in the [Luitpold] *Gymnasium* like lieutenants." These remarks were aimed at the rote learning demanded by authoritarian teachers. In what few science classes were available Einstein would sometimes ask a question that Herr Professor could not answer. Instead of admitting this, praising the student for asking such a question, and then promising to come back the next day with a reply, the teacher kept on trying for a solution, thereby exacerbating the situation. In the meanwhile the young Einstein sat with an ever-widening grin. A teacher of Greek told Einstein that he would never amount to anything—he never did in Greek. Another time the same teacher scolded him severely for something he was not at all involved in, asserting that "your mere presence in class destroys respect for me of the other students." Even though he was among the top students at the Luitpold *Gymnasium* in mathematics and physics, this tongue lashing was the last straw. Moreover, the prospect of military service was impending, which Einstein dreaded. If Einstein did not emigrate before age 16 then, according to German citizenship laws, he would have to serve in the army or be declared a deserter.

The electrical business owned by Einstein's father at this time failed and the family moved to Milan, Italy, where business prospects seemed better. (The feather bed business had failed some years earlier.) They left Albert behind in Munich to complete his *Gymnasium* education. The parents' move gave Einstein the idea to resolve both the *Gymnasium* situation and the army problem. Einstein obtained a doctor's certificate to the effect that he was nervous and depressed. On 29 December 1894 at age 15, Einstein withdrew from the Luitpold *Gymnasium* without a diploma. He joined his parents in Milan as a high school dropout. The Luitpold *Gymnasium* was destroyed during World War II. Ironically, it was rebuilt and renamed the Albert Einstein *Gymnasium*.

Until the fall of 1895 Einstein traveled through northern Italy. As had been the case for Goethe some hundred years before, the Italian sunshine and landscape impressed the young Einstein, freeing him of the *sturm und drang* of the Munich years. During this period, however, Einstein did not

neglect his love of science. By this time he knew integral and differential calculus, self-taught at about age 13. In the summer of 1895 Einstein wrote his first scientific essay, which he sent to his maternal uncle Caesar Koch. The essay demonstrates that Einstein was conversant with advanced topics in electromagnetic theory. Even so, there are no signs of genius in the essay. Yet in retrospect the perseverance and self-discipline needed to teach oneself difficult subjects is an indication of things to come. Einstein was an autodidact.

The influence of uncles and aunts is not to be overlooked. As we know these family members hold a privileged position with children at an impressionable age. Being siblings of the parents they can be seen as representing the nonautocratic and so exhibiting the more outgoing side of the parents' psyche. Bertrand Russell recalled an uncle who "did a great deal to stimulate my scientific interests."

As Einstein had promised his parents prior to withdrawing from the Gymnasium, he prepared himself for the entrance examination to the Eidgenössische Technische Hochschule (ETH), Zurich. Einstein failed the entrance examination to the ETH due to deficiencies in foreign languages, biology, and historical subjects, all of which require rote learning. Owing to Einstein's excellent grades in the mathematics and physics portions of the entrance examination, one of the school's most eminent professors, Heinrich Friedrich Weber, encouraged Einstein to attend his lectures if Einstein stayed in Zurich. Instead Einstein decided to take the advice of another professor to spend a year at a preparatory school in the Swiss canton of Aarau, in order to correct the deficiencies that had caused him to fail the entrance examination.

The strong impression made on Einstein by the cantonal school was due to its unpretentiousness and to its seriousness which was in no way dependent on a teacher's authority. The school also emphasized the power of visual thinking, a mode of thought to which Einstein found himself disposed. Sometime during his sojourn in Aarau during 1895–1896, Einstein realized a thought experiment in highly visual terms over which he would ponder tenaciously until, in 1905, he realized that it contained the "germ of the special theory of relativity." The experiment concerned the experiences of an observer who is trying to catch up with a point on a light wave. By 1905 Einstein was able to frame the observational-theoretical situation as a paradox whose resolution concerned his realization that time is a relative concept. Einstein flourished in Aarau, passing out with the highest grade average in his class and gained admission to the ETH.

University Years

Einstein's educational experience at the ETH during 1896–1900 was bittersweet. Almost immediately difficulties arose. The role of visual thinking was deemphasized and the outdated physics curriculum focused on applications. Einstein liked neither the subject matter nor being coerced to memorize large quantities of what to him was unessential material. So at home in the evenings and during cut classes, he studied the masters of theoretical physics like Ludwig Boltzmann and Hermann von Helmholtz. From them he learned the kind of physics not taught at the ETH, as well as the importance of visual thinking in the making of a scientific theory.

Einstein's independence of thought was not appreciated by the professors at the ETH, particularly not by the eminent Professor Weber, with whom Einstein had many intense personality conflicts. The upshot was that Weber, the man who had encouraged Einstein to pursue studies at the ETH, tried to prevent him from graduating. Having failed, he refused Einstein any letter of recommendation upon graduation. Einstein was the only one of four students in his class who passed the final examination to be refused a position as *Assistent* to a professor at the ETH. Einstein recalled that it took him a year to recover from the ETH and to reacquire his taste for scientific research.

During 1900–1902 Einstein had only intermittent employment and was denied positions as assistant to several major physicists. He was convinced that somehow Weber was behind this situation. As Einstein wrote to his girlfriend and wife to be, Mileva Maric, on 4 April 1901, "Soon I will have honoured all physicists from the North Sea to the southern tip of Italy with my offer." He persevered. In 1901 Einstein submitted a doctoral thesis to the University of Zurich which was rejected, but he succeeded in publishing his first paper in the prestigious German physics journal *Annalen der Physik*.

Finally, through intercession of the father of a college friend, Marcel Grossmann, Einstein obtained a position as technical expert third class (provisional) at the Swiss Federal Patent Office, Bern. In reply to someone's comment that he might be bored in this position, Einstein wrote to Mileva in February 1902, "certain people find everything boring—I am sure that I will find it very nice and I will be grateful to Haller [the Director of the Patent Office] as long as I live." And he was. Einstein's personal life was even less settled. In 1902 he married Mileva, with whom he had a tumultuous love affair since 1899. Their unpublished love letters attest to the passion of the relationship. Unfortunately, by around the time they were married the relationship had begun to cool down. They were divorced acrimoniously in 1919. Later that year Einstein married his cousin Elsa with whom he had a liaison for some time. Einstein's love life is a complex and highly interesting topic, but this much seems to be the case—Einstein's liaisons may well have been an inspiration to his research, just like in the lives of artists, musicians, and writers. What other scientist can you think of whose love letters have been published?

Bern Period

Einstein's Bern period (1902–1909) was the most creative of his life. While working at the Patent Office eight hours a day, six days a week, he published on the order of 50 papers. Although during 1901–1904 he had published five papers in the *Annalen*, there was no forewarning of Einstein's creative outburst in 1905. After all, in 1905 Albert Einstein was a 26-year-old middle-level junior civil servant with an academic record that was distinctive in retrospect only by its lack of distinction. His score on the cumulative final exam at the ETH was 4.91 out of 6, good but not superlative. He had failed once to obtain a Ph.D., and was denied letters of reference from his undergraduate school. To make ends meet for his wife and child Einstein gave private classes in physics. Yet at eight-week intervals, starting in March 1905, Einstein submitted

three papers that were published in the September 1905 volume of the *Annalen*. The third one contains the special theory of relativity. Later in 1905 Einstein published a fourth paper in the *Annalen* which contained a result he had overlooked in the relativity paper: the equivalence of mass and energy, $E = mc^2$. These four papers changed the course of physics in the 20th century, not to say life itself on our planet.

Later Years

Einstein's early research results were at first appreciated, mostly for the wrong reasons, if at all, including the 1905 paper on special relativity. That Einstein had an *annus mirabilis* in 1905 became clear only in retrospect from the 1920s when *all* of his contributions from that year were duly acknowledged. Special relativity was not recognized as an achievement until 1911. By this time Einstein had resigned from the Patent Office (6 July 1909) to take up a position as Associate Professor at the University of Zurich. During 1911–1912 he was professor at the German University in Prague. Einstein's reason for leaving was an offer he could not refuse. His old undergraduate school, the ETH, offered him a professorship. In 1914 he moved to the University of Berlin as a Professor with no teaching duties. There he remained until forced to leave in 1933. From 1933–1955 he was a Professor at the Institute for Advanced Study in Princeton, New Jersey. In 1915 Einstein had a second *annus mirabilis* when he formulated the generalized theory of relativity. As was the case with the 1905 special theory of relativity, one of Einstein's key revelations came in the guise of the following thought experiment: Someone jumps off the roof of a house and also drops a stone. They fall side-by-side

even though stone and person are accelerating toward the ground. Einstein's understanding this apparently "simple" phenomenon requires thinking of what it means for the falling person to imagine himself and the stone to be relatively at rest even though they are both accelerating toward the ground. This necessitates assuming the equivalence of acceleration and gravitation, a monumental step. Owing to experimental verification in 1919 of one of the spectacular predictions of Einstein's new theory—the bending of light in the vicinity of massive bodies—his name became worldwide known literally overnight, and synonymous with genius.

Although after 1915 Einstein spun no more grand theories, his contributions, for example, to quantum theory, remain of the deepest importance, spanning physics and its philosophy. His correspondence on scientific, philosophical, and social matters remains of the greatest interest today. And his creativity remains to be fathomed.

Glossary

Creative achievement scale An instrument designed by Arnold Ludwig to score eminent creators according to the magnitude of their contributions. This score considers such factors as originality, universality, versatility, influence, transcendence, and virtuosity.

Cultural configurations The tendency for eminent creators to cluster into particular periods of history. The creators who constituted the Golden Age of Greece and the Italian Renaissance are classic examples. These periods of creative fervor are separated by others with much less creativity, at times descending into a Dark Age, in which eminent creators disappear altogether.

Space measures The objective technique of assessing eminence in terms of the amount of space devoted to the creator in standard reference books, such as encyclopedias, biographical dictionaries, and histories.

Unit replicability Samples of eminent creators have the asset that the same subjects can be repeatedly studied by different researchers, allowing the possibility of exact replication of a given set of empirical results.

Zeitgeist The German word for the 'spirit of the times.' The term indicates the broad milieu in which creativity takes place, such as the political, economic, social, and cultural environment. The zeitgeist appears to be responsible for the clustering of eminent creators into cultural configurations.

Significance

One of the most urgent problems in the scientific study of creativity is precisely how to define the phenomenon. By what criterion does a researcher identify one subject as creative? The published literature is replete with rather diverse operational definitions. Most often, however, individuals are said to display creativity when they score sufficiently high on a so-called creativity test. Yet clearly, such identification only begs the question: How do we know that the psychometric instrument actually measures creativity? Obviously the test must undergo some type of validation. For instance, the test might be validated by determining if those who score high on the measure can generate products or ideas that are judged creative by others. But this merely sweeps the problem under yet another rug. Who shall we rely on to perform these judgments?

One reasonable resolution to this measurement quandary is simply to say that individuals who have received broad acclaim for their creative contributions can be safely deemed creative. Such a definition seems sound on prima facie grounds. In the parlance of psychometrics, an eminence measure of creativity has 'face validity.' Note that creative eminence also solves a host of other methodological niceties as well. For example, another difficulty in the investigation of creativity is how to define different types or levels of the phenomenon. How does the researcher distinguish artistic from scientific creativity? How does the investigator gauge the magnitude of creativity? From the standpoint of the eminence criterion, the response to both questions is direct. Individuals who attained distinction for contributions to the arts are artistic creators, whereas those who earned applause for contributions to the sciences are scientific creators. Therefore Picasso exemplifies artistic creativity, whereas Einstein exemplifies scientific creativity. Similarly, the higher the level of fame achieved, the greater the presumed level of creativity displayed.

By this judgment, accordingly, Johann Sebastian Bach is deemed more creative than, say, Gebel, his exact contemporary and compatriot.

As the foregoing discussion suggests, the eminence criterion of creativity may be employed two distinct ways:

1. In the simplest usage, eminence is adopted as a sampling criterion. Individuals who exhibit sufficient excellence in a creative domain are selected for inclusion in the researcher's sample. For instance, when Ann Roe wished to understand the basis for scientific creativity, she sampled a group of 64 eminent scientists. Sometimes the eminence criterion is also used to single out subjects for the control group. A good example is the approach taken by researchers at the Institute for Personality Assessment and Research at the University of California at Berkeley. Wanting to understand the basis for creativity in architecture, the investigators recruited the participation of some rather renowned members of that profession. But the researchers also obtained the participation of far less successful colleagues who could provide the basis for comparison.
2. The other role of eminence is as a continuous variable used to measure individual differences in creativity. Just as the amount of creativity may vary from person to person, so may the amount of eminence exhibit considerable cross-sectional variation. To the extent that the fame of creators is founded on the magnitude of creative achievement, the degree of distinction should be directly related to underlying creativity. Such an eminence indicator of creativity is employed three major ways in the published literature. First, the eminence measure may be studied alone. The researcher may focus on the degree of variation, the distribution, the stability across time or cultures, and so forth. Second, the eminence measure may be adopted as a dependent variable in a prediction equation. In such cases the

goal is to identify the factors that predict historic creativity. This constitutes the most common use of this type of creativity measure. Third, but less frequently, eminence may be used as an independent variable, especially as a moderator variable in a regression equation testing for interaction effects. For example, one study looked at whether the curves defining the relationship between age and creative productivity varied according to how illustrious were the creators. The interest was not in predicting eminence but in determining whether the same career trajectories held for all individuals regardless of the magnitude of accomplishment.

Measurement

What are the ways that researchers go about assessing the eminence of creative personalities? What are the psychometric properties of the resultant eminence assessments? These are the questions answered next.

Assessment Techniques

Once the investigator decides to use eminence in a particular study, the first issue that must be addressed is how to best assess the eminence of the individuals under investigation. Sometimes a purely informal procedure suffices. For instance, most psychobiographical studies of creative individuals select a particular case for study precisely because that person is obviously famous (and at the same time interesting in some other way). Thus, when Sigmund Freud did his analysis of Leonardo da Vinci, he felt no need to justify the choice of subject. The artist's eminence would be obvious to all. Similarly, when Howard Gardner selected the seven subjects for his book *Creating Minds*, he simply picked a twentieth-century luminary who represented each one of the seven intelligences according to his theory of multiple intelligence. The resulting sample consisted of Albert Einstein, T. S. Eliot, Pablo Picasso, Igor Stravinsky, Martha Graham, Sigmund Freud, and Mahatma Gandhi. Even though someone else might pick a different set of representatives, the distinction of these seven figures is beyond doubt.

One difficulty with such informal sampling methods is that they permit the potential introduction of bias. Because there is so much latitude for subjectivity, it can happen that the eminent are unconsciously selected to be consistent with some perspective or hypothesis. An interesting illustration is the sample that Abraham Maslow collected to study self-actualizing personalities. Because, as a humanistic psychologist, Maslow believed that creativity was associated with superior mental health, it cannot have been mere accident that there are no cases of truly 'mad geniuses' among the creators in his sample. Sometimes the avoidance of the psychopathological made him sample the less famous rather than the more famous. Why else would Maslow choose Camille Pissarro rather than van Gogh or Franz Joseph Haydn rather than Beethoven?

To avoid the potential introduction of bias, many investigators adopt more systematic and objective strategies for sampling eminent creators. Sometimes the researcher will study those individuals who have attained sufficient acclaim that they have biographies written about them or at least articles under their

name in major reference works, such as encyclopedias or biographical dictionaries. Other times the investigator will rely on peer nominations. Experts in a particular domain will be asked to nominate those contemporaries who have made the most creative contributions. Still other researchers will adopt the criterion of the creator having received a major honor, such as the Nobel or Pulitzer.

So far the focus has been on the application of the eminence criterion as part of a sampling procedure. Yet as pointed out earlier, eminence often figures prominently as an individual-difference variable in its own right. Even among the notables of a particular creative domain, the variation in reputation can be quite substantial. The question then becomes how to best capture this dispersion in terms of reliable scores on some eminence measure. One of the oldest and most common solutions is to use standard reference sources to define some type of space measure. For instance, the investigator might count the number of pages or lines devoted to each creator in a biographical dictionary, encyclopedia, or history. Alternatively, the researcher might count the number of books or articles written about each individual in the sample. Such archival indices of eminence have the advantage of being highly reliable and objective.

However, some investigators prefer eminence assessments that allow more room for subjective considerations. A good example is the creative achievement scale devised by Arnold Ludwig. This instrument requires assessments of an individual's contributions in terms of originality, universality, versatility, influence, transcendence, virtuosity, and so on. These assessments are based on biographical and historical information available about each eminent creator. Another approach is simply to ask experts to rate eminent creators on the global level of creativity realized. Sometimes such global assessments are carried out in the form of rankings.

In any case, these subjective measures have certain advantages over the objective measures mentioned in the previous paragraph. For one thing, the subjective indicators can help the researcher understand better what exactly is being assessed, especially when the components of creative eminence are made explicit in the design of the measurement scale, as is the case in Ludwig's instrument. In addition, the objective measures sometimes have biases that are not necessarily present in the subjective measures. For instance, archival assessments of eminence based on space measures often favor some forms of creativity at the expense of other forms. It is much easier to describe in words the contributions of writers and philosophers than it is to give a verbal account of the contributions of painters and composers. As a consequence, encyclopedias tend to devote more space to eminent individuals whose creativity took a verbal form than to those whose creativity required nonverbal means of expression. Fortunately, statistical procedures do exist that permit the introduction of the appropriate corrections, but these procedures necessarily make the data analysis more complicated.

Psychometric Features

It should be pointed out that eminence measures have been shown to have highly desirable properties from a psychometric perspective. In the first place, indicators of individual

differences in creative eminence display quite impressive reliability coefficients, which signify that the amount of measurement error is relatively small. In fact, eminence measures are just as reliable as other, more commonplace measures in psychology, such as scores on intelligence tests. Second, alternative techniques for assessing individual differences in eminence yield quite comparable results. Not only do the diverse kinds of objective measures correlate highly with each other (and the various types of subjective measures intercorrelated highly as well), but in addition the objective and subjective assessments are in substantial agreement as well. Hence, a consensus exists on the relative eminence of creative individuals. Finally, this strong consensus on differential eminence is highly stable over time. Researchers have examined eminence ratings separated by a century or more and still obtain respectable correlations. Indeed, there appears no pronounced tendency for the agreement to decline as the temporal separation between two measures increases. This transhistorical constancy of eminence suggests that differential fame is tapping into some stable individual differences in creative accomplishment. If Mozart is consistently rated as more famous than one of his contemporaries, such as Türk, this contrast no doubt reflects to a very large extent their comparative creativity.

Admittedly, the correspondence between eminence and creativity is by no means perfect. Exceptions to the general rule do exist. Sometimes creators die before they receive the recognition they deserve (e.g., Gregor Mendel), whereas other times creators received far more contemporary fame than they will be granted by subsequent generations (e.g., Trofim Lysenko). Yet these occasions are too few and far between to seriously undermine the reliability and stability of eminence indicators.

It must also be confessed that it is the fairly irreversible fate of every luminary that his or her fame will decline with time. After all, as more and more creative products are added to the cultural store, the competition becomes ever more fierce. Each year there are more paintings to hang on gallery walls, compositions to perform in the concert halls, plays to be produced, books to be reprinted, and so forth. Accordingly, even the most illustrious creators are fated to see their market share gradually diminish. Yet that decline by itself does not attenuate the significance of eminence as a gauge of exceptional creativity. So long as the relative positions of eminent creators remain constant over time, the stability of eminence will persist. Hence, in the theater Shakespeare may have had to yield some ground to Shaw and other more recent playwrights, but so did Marlowe, Jonson, and other Elizabethan contemporaries. Despite the increased competition, Shakespeare's differential standing survives unscathed.

Determinants

Once eminence is accepted as a criterion of creativity, the researcher is tempted to ask: What are the predictors of creative eminence? How do famous creators differ from their less distinguished colleagues? And in what ways do creative luminaries contrast with the rest of us? These questions will be answered by giving an overview of some of the central empirical findings.

Individual Differences

The following four factors are most likely to differentiate the eminent from the noneminent as well as distinguish the comparative degree of eminence among those who have attained some acclaim.

Productivity

The single most important predictor of achieved eminence as a creator is the total lifetime output of creative products. At the very minimum, of course, it takes at least one successful creative achievement to secure a lasting reputation, but many creators are guilty of seeming overkill, creating hundreds if not thousands of works. Thomas Edison, for example, still holds the record for the number of patents granted to any one person by the United States Patent Office. Of course, such massive lifetime output is not really superfluous. A positive relationship exists between the total number of creative products and the magnitude of eminence attained. To be sure, some perfectionists attain fame on the basis of very few works, whereas some mass producers generate tons of totally forgettable creations. But these two classes of creators represent only a very small proportion of the population. In fact, quality (or creativity) of output is a positive function of quantity (or productivity) of output. Those creators who generate the most successful works also, on the average, produce the most unsuccessful works.

Two additional features of this lifetime productivity deserve mention. First, the total lifetime output is typically attained by beginning the career early, continuing the career until late in life, and maintaining exceptional annual rates of productivity. In other words, eminent creators exhibit productive precocity and longevity as well as being highly prolific in any particular unit of time. Second, the cross-sectional distribution of creativity is highly skewed, a small percentage of illustrious producers accounting for a lion's share of the total output. Often those creators who are in the top 10% in lifetime output will be responsible for 50% of all products generated in their fields. This lopsided distribution departs greatly from the normal curve that so often characterizes individual differences.

Intelligence

It was Francis Galton who first argued that creative eminence had a firm foundation in individual differences in natural ability or intelligence. The first empirical study to address this issue directly was conducted by Catharine Cox in her 1926 book titled *The Early Mental Traits of Three Hundred Geniuses*. After first using biographical data to calculate IQ scores for eminent creators and leaders, she then showed that (a) creative geniuses have higher IQs than average and (b) higher IQs are positively associated with the level of eminence attained. Subsequent investigators have replicated these findings, but only after imposing a serious qualification: intelligence tends to operate as a necessary but sufficient factor underlying creative eminence. This means, first of all, that a certain minimum intellectual power is required to support the knowledge and skills that generate creative contributions. Yet a high, and even a genius-level intellectual capacity (i.e., IQ 140) by no means guarantees that an individual will exhibit any creative ability.

Moreover, as intelligence increases beyond this threshold level, the potential for creative achievement increases, but again without any assurance that the full potential will be realized. Thus, an individual with an IQ of 200 has the potential of being more creative than an individual with an IQ of 130, but it may in fact be the latter person who turns out to attain the more impressive creative eminence. The lack of precise correspondence between intelligence and eminence simply reflects the fact that creativity has a great many determinants, intelligence alone only playing a small part.

Personality

Among those additional factors, of course, are individual differences in certain personality traits. Highly eminent creators tend to exhibit a distinctive character profile in comparison to the less eminent colleagues or to control groups of noneminent professionals working in the same domain. The most important components of this profile are motivational in nature. To obtain a conspicuous degree of distinction in a creative activity requires an exceptional amount of energy, enthusiasm, determination, and persistence. The most eminent creators usually must struggle courageously to overcome obstacles in their path, nor are they discouraged from pursuing their creative visions by sporadic setbacks and failures. Along with this drive comes a host of other traits that largely shape how eminent creators interact with their fellow human beings. For example, they tend to be introverted, original, independent, nonconformist, and sometimes even bohemian. In general, the profile seems to consist of traits that would best permit an individual to devote the considerable effort necessary to produce a profusion of original ideas.

Psychopathology

One particular dispositional characteristic of eminent creators deserves special attention. For centuries thinkers have speculated on the possible connection between madness and genius. The general consensus favored the existence of a positive relationship, a relation that was thought to be especially strong for creative genius. The only major dissent from this opinion was that voiced by Maslow who, as noted earlier, thought that eminent creativity was associated with superior mental health. Nonetheless, more systematic investigations that have employed a variety of methods reveal that creative eminence bears a conspicuous link with mental illness. To begin with, the incidence rates of psychopathological symptoms are higher among eminent creators than among the general population. In addition, eminent creative contemporaries score higher on the clinical scales of various diagnostic instruments (such as the MMPI or the EPQ). Furthermore, higher psychopathology tends to be positively correlated with higher degrees of attained eminence. Finally, eminent creators are more likely to come from family pedigrees in which the incidence of mental illness exceeds that found in the general population.

The general conclusion that genius and madness are related must be tempered by four qualifications. First, eminent creators appear to exhibit subclinical levels of psychopathology. That is, their symptoms are usually higher than average without being so high as to cause debilitating distress. Second, the psychopathology is counterbalanced by other traits, such as ego strength and intelligence, which serve to lessen the adverse repercussions.

Third, the magnitude of expected psychopathology varies according to the specific domain of creative activity. On the average, for example, eminent artists display more severe symptoms than do eminent scientists who, as a group, may demonstrate a similar degree of psychopathology to the general population. Fourth, it is not entirely clear what are the causal linkages between illness and creativity. It may be that certain levels of psychopathology support the cognitive style and behavioral disposition necessary for creative activity. Yet it may also be that a highly creative life is much more challenging than an ordinary one, and that these challenges themselves can stimulate mental and emotional breakdowns. Even worse, these two possibilities need not be mutually exclusive, nor are other causal relationships yet ruled out.

Development

Eminent creators tend to come from rather distinct biographical backgrounds. The following six circumstances have perhaps received the most attention in the empirical research.

Family pedigrees

Galton's 1869 classic *Hereditary Genius* was the first systematic study of the tendency for creative genius to run in family lineages. He specifically showed that eminent creators were far more likely to come from families that featured close relatives who attained distinction in the same general domain of creativity. Although others have replicated Galton's finding, the best substantive interpretation is more elusive. Galton believed that this showed that genius had a genetic foundation, but such speculation goes well beyond the data. Especially problematic is the fact that the inheritance appears to be so domain specific. It is very unlikely that a gene or set of genes exists that enables people to do creative science, for example. Hence, the relevance of family pedigrees may reflect more nurture than nature. Parents and relatives are more likely to provide support for talent development in domains in which a family history of distinction exists. Certainly such successful lineages will provide ample models for emulation by developing creative talents. The biological portion of the inheritance, in contrast, may be limited to much broader capacities, such as general intelligence and high energy levels. In line with what was said earlier, another component of this generalized genetic endowment may entail a certain proclivity toward psychopathology.

Childhood precocity

Prior to adulthood, the concept of precocious development is intimately related with that of intelligence. Indeed, the intelligence quotient, or IQ, was originally conceived as a ratio of mental to chronological age. Those who are highly accelerated in intellectual development exhibit higher than normal ratios and thus earn higher than average IQ scores. This linkage is evident in the IQs that Cox calculated for her 301 eminent personalities, because the scores were based on comparing their intellectual capacities in childhood and adolescence with what is normally expected of youths at the same age level. Nonetheless, it should also be pointed out that Cox's assessments were actually much broader than are found in the typical IQ test, such as the Stanford-Binet. The most weight was given to precocity directly related to the domain of

adulthood achievement. Mozart, for example, was credited with a high IQ owing to his phenomenal musical precocity, both as a performer and as a composer. Yet musical ability is not even evaluated by a standard IQ test. Hence, Cox was assessing domain-specific precocious development far more than generalized intellectual precocity. In any case, subsequent investigations, using different samples and techniques, have arrived at the same conclusion: eminent creativity is strongly associated with early manifestations of precocity within a particular domain of creative activity. For example, notable composers are far more likely to begin music lessons at a young age, to begin composition very early, and to experience their first genuine success early as well.

Birth order

In 1874, Galton was the first behavioral scientist to investigate whether ordinal position in the family bore any connection with eminence as a creator. His discovery that firstborn children are overrepresented among eminent scientists has been replicated many times since then. This robust finding is consistent with other studies showing that firstborns exhibit higher than expected frequencies among doctors, lawyers, professors, and other professionals. However, subsequent research also suggests that birth order is most relevant as a determinant of the domain and style of creative eminence. Firstborns are most likely to gravitate to those areas of creativity that impose greater constraints on the creator, whereas later borns are more prone to enter creative activities where the constraints are fewer and conformity to norms less expected. Within science, for example, revolutionary scientists who overthrow traditional paradigms are more likely to be later borns, whereas firstborns have a higher likelihood of making contributions that fit within the received scientific paradigm or tradition. Similarly in the arts: where later borns are overrepresented among creative writers, firstborns are predominant among composers of classical music. Interestingly, this pattern occurs among eminent leaders as well. Firstborns exhibit a propensity for becoming status quo or establishment leaders, whereas later borns display an inclination for becoming revolutionaries. This birth order distribution holds for both political and religious leaders.

Early trauma

Eminent creators do not necessarily emerge from happy, stable, conventional home environments. On the contrary, they tend to suffer more than their fair share of trials and tribulations during childhood and adolescence. Their families may experience big fluctuations in financial well-being, and many grow up in minority or immigrant homes that must overcome prejudice and discrimination. Often future creators have had to surmount some intellectual, emotional, or physical disability, as well as endure extreme loneliness and isolation. But probably the traumatic event that has received the most attention in published research is the experience of parental loss or orphanhood. Eminent people in general, and famous creators in particular, seem to have suffered this type of trauma at incidence rates noticeably higher than what is seen in the overall population. The parental loss rates are especially high for literary creators. At present we do not know how traumatic events contribute to creative development. Three main explanations

have been offered. First, these experiences may disrupt the standard socialization process, and this disruption leaves enough freedom for the emergence of an independent, even iconoclastic intellect. Second, such encounters help the young talent to develop the robustness necessary to overcome the many obstacles and setbacks faced by adult creators. Third, such trauma may produce a 'bereavement syndrome' to which creative achievement serves as a form of compensation or adjustment. It is hoped that once researchers discover exactly how trauma contributes to the development of creative genius, they will also learn why some distinguished creators do indeed manage to grow up in totally normal and pleasant home environments.

Role models and mentors

It is difficult if not impossible for creative talent to develop without a role model or mentor. To a very large extent creativity is a form of expertise that requires the imitation and emulation of other creators who have already made a name for themselves within a particular domain. This social learning process takes two main forms. First, a promising youth may assume a student, apprentice, or discipline relationship with an older teacher or master. This direct influence entails both instruction and modeling. Second, a developing talent can be actively influenced by creators at a distance, an indirect effect that involves modeling only. Not only may these influences not be known personally and only admired at a distance, but in addition these models of creativity may be deceased. The most dramatic illustration of this latter effect is the way that the artists of the early Italian Renaissance were inspired by the rediscovered masterworks of classic antiquity.

It should be pointed out that role models and mentors need not invariably have positive effects on the emergence of eminent creators. The influences can be negative as well. For instance, a student or apprentice may imitate a teacher or master too closely and thereby becomes an intellectual clone incapable of original ideas. For this reason, creators are more likely to attain higher levels of eminence if they take inspiration from multiple models and mentors.

Formal education and training

The instruction may be more formal than what we have so far described. Besides working in a studio or laboratory, developing creators can actually enrol in regular courses at an academic institution or special school. Such formal education and training has a somewhat ambiguous relationship with the attainment of distinction as a creative person. On the one hand, a certain minimal amount of domain-specific knowledge and skills is essential for creativity, and a good proportion of this requisite may be acquired from formal coursework and instruction. On the other hand, excessive formal training and education can severely narrow an individual's expertise, with negative consequences for the capacity for original thought. As a consequence, eminent creators are not necessarily outstanding students in terms of scholastic performance, nor are they always prone to seek the highest degree or diploma available in their field of creative activity. Indeed, sometimes the relationship between level of formal education and creative eminence may be described as a curvilinear, inverted-U function. At the beginning formal education enhances the

development of creative talent, but after a certain optimum level, further amounts of education may undermine the emergence of creative potential. The precise location of this peak depends on the specific type of creativity. For the arts and humanities the optimum may be only a couple of years of undergraduate instruction, whereas for the sciences the optimum may appear in the first few years of graduate or professional school.

Sociocultural Context

One of the recurrent issues in the study of creativity has been the relative importance of individual and situation. How much is creativity a matter of genius, and how much is it a matter of the zeitgeist? Are so-called creative geniuses simply persons who were lucky enough to be born at the right place at the right time? Perhaps the most striking evidence for the causal significance of the larger milieu is the fact that eminent creators are not randomly distributed over history or across cultures. Rather, creators cluster into cultural configurations. That is, at particular times and places, certain peoples may exhibit an emergence or renaissance of creative activity, ascend to a Golden Age of achievement, only to descend into a Silver Age before disappearing into a Dark Age. This story of the rise and fall of civilizations and creative traditions is centuries old, and shows no evidence of ending in the future. Such culture-wide cycles in creative activity suggest that the appearance of eminent creators is very much affected by massive societal forces. For convenience, we may divide these forces into the political, economic, cultural, and ideological.

Political

The creativity of even the most independent genius must take place in a particular political milieu, making it susceptible to some of the dramatic events that sometimes characterize the world of politics. Among the most conspicuous of such influences is international war, a circumstance that has been shown to depress creative output in a diversity of creative activities. Interestingly, even areas that are supposed to be encouraged by warfare are actually harmed. In particular, overall technological innovation is harmed, apparently because the war effort channels resources toward the development of military inventions, to the detriment of other technologies.

The effect of war is immediate, affecting the output of eminent creators during their active careers. Other political effects operate only after a considerable delay. The time lapse occurs because these circumstances determine the environment in which a talented youth grows up. Some of these long-term developmental effects are positive, such as the benefit of growing up under circumstances of political fragmentation. This is the condition in which a civilization area is divided into numerous nation-states, as was the case during the Golden Age of Greece and the Italian Renaissance. Closely related to this relationship is the beneficial impact of nationalistic rebellions and revolts. On the other hand, some developmental effects are quite detrimental to the eventual emergence of eminent creators. The best case in point is political anarchy, when the power elite is torn by internecine strife – when assassination, conspiracy, and coup d'état become the order (or disorder) of the day. The next generation will suffer the

adverse consequences, at least in terms of the absence of eminent scientists, philosophers, and writers.

Economic

A certain level of material well-being is a prerequisite for the appearance of historic creative activity. Creative genius rarely emerges in impoverished nations. In fact, a creative florescence in a civilization usually occurs when the economy becomes prosperous enough to generate sufficient surplus wealth to support creative inquiry, invention, and imagination. However, although economic prosperity is necessary, it is not a sufficient cause of creative eminence. Greece under the Byzantine Empire was far more prosperous than the Greece of Periclean Athens. Yet with the exception of Byzantine achievements in architecture and mosaic, it is the Classic Age that boasts the most impressive creative achievements.

Cultural

Earlier it was pointed out that creative development is dependent on the availability of role models and mentors. Stated in generational terms, the number of eminent creators in one generation tends to be a positive function of the number of creators in the previous generation. One consequence of this intergenerational influence is the clustering of creative genius into cultural configurations – the periods of Golden and Silver Ages separated by Dark Ages. However, this generational continuity also raises a critical issue: If creative development is contingent on the availability of creative models, how do these cultural configurations get started in the first place? Somehow creativity has to get a booster shot to establish the basis for modeling and mentoring. One answer to this problem involves the influx of ideas from outside the nation or civilization. Research has found that when creativity stagnates in any given culture, it experiences rejuvenation if the culture opens itself up to the scientific and aesthetic ideas from foreign cultures. For instance, it was the Greeks' exposure to the culture of Persia, Egypt, and elsewhere that helped set the stage for the Classic Era of Greek civilization.

This alien input explains why eminent creators can begin to appear. But what happens at the other end of the cultural configuration? Once a civilization reaches a climax, the number of available role models reaches a maximum. So why does the level of creative activity decline rather than continue to increase indefinitely? Why must Golden Ages yield to Silver Ages and the latter to Dark Ages? Evidently, the answer lies in the fact that a given culture at a given time is usually confined to a particular paradigm, style, or ideology that sets the pattern for all creative endeavors. Eventually that cultural pattern becomes exhausted, making it ever more difficult to come up with good creative ideas. Decadence and decay eventually appear. It is interesting that the most eminent creators of a given cultural growth tend to appear when the civilization is experiencing an ascent, whereas those who appear after the climax has passed, being left with the residue or 'cultural dregs,' tend to be much less eminent.

Ideological

The general philosophical and moral zeitgeist plays a major role in the coming and going of eminent creators during the

course of history. To begin with, creative activity in any civilization is more likely to appear during times of ideological diversity rather than during times when one single dogma monopolizes thought. In addition, the intellectual milieu helps shape the type of creative achievement that is most likely to appear in a particular time and place. For example, periods dominated by materialism, empiricism, determinism, and individualism tend to be more favorable to scientific eminence than periods dominated by idealism, rationalism, free will, and collectivism. Sometimes the prevailing ideology actually prevents certain kinds of creative talent from appearing at all. A good example is the way that Confucianist ideology – which maintains a very hierarchical view of the place of women in society – has been shown to be antithetical to the appearance of eminent female creators in Japanese culture.

These ideological influences are closely linked to political and economic circumstances. For instance, threatening conditions tend to encourage the emergence of authoritarian ideologies, which in turn favor the appearance of superstitious and occult activities at the expense of scientific rationality.

Evaluation

Besides the face validity of the eminence definition of creativity, this approach has many unique assets. In the case of psychometric studies of eminent contemporary creators, one of the most important advantages is the ability to examine the extreme upper tails of the distribution of creativity. Famous creators are the intellectual analogs of the athletic champions, such as the Olympic medalists, and as such represent the best the human mind can achieve. Historiometric studies of deceased creators take this scrutiny one step further by examining those who have attained even more elite heights, the best of the best, the individuals whose creations have survived the tests of time.

However, the eminence definition of creativity also has three major drawbacks.

1. By conceiving creativity in terms of an eminent elite, research on creators becomes far removed from more everyday forms of creative activity. A person does not have to be famous to engage in creative problem solving. Moreover, it is highly likely that the vast majority of creative acts take place at this lower level, where creativity is personal and anonymous. Yet how does the researcher know that what is found for exceptional creators also holds for more mundane forms of the phenomenon? One answer to this objection is to point out that there does appear to be some degree of continuity from the noncreative to the everyday creative to the eminent creative. That is, they seem to represent different points on an underlying individual-difference dimension. The relationship between psychopathology and creativity provides a good illustration. Everyday creators seem to have a higher level of symptomatology than noncreative individuals, but they also seem to have a lower level than seen in the eminent creators, who in turn fall below the level seen in institutionalized patients. Hence, insofar as there exists such dimensions, the study of eminent creators can shed light on the determinants of creativity.

2. Sometimes research on eminent creators suffers from inferior data quality. Historiometric studies, for example, are invariably retrospective and archival in nature, and therefore must rely on the biographical and historical record. This record may not always be up to the desired task. For instance, when Cox wanted to estimate IQ scores for creative geniuses of the past, she found it necessary to delete several important personalities due to the lack of sufficient data about early childhood and adolescence. Among the figures so omitted was William Shakespeare! Even psychometric studies of eminent personalities must contend with a large number of problems. It may be difficult to obtain the participation of eminent creators, and those who are willing may not constitute a representative sample. In addition, the retrospective information about early developmental experiences may be no more reliable for eminent contemporaries and for historic creators.
3. Eminent creators are not as easily studied as, say, schoolchildren or college students. Investigations into eminent contemporaries often require considerable expenses for travel, food, and lodging, and the logistics of interviewing even a relatively small sample of creators can be extremely difficult. Although historiometric studies of historic creators do not suffer from these problems, they have their own. Often it takes a considerable amount of time to gather all the biographical, historical, and content analytical data necessary for a given study. The statistical analyses required to control for the many potential artifacts in correlational research can also be quite laborious. Such labor may discourage many investigators from studying famous creators, past or present.

Because of the above disadvantages, research on eminent creators will never dominate the literature. The vast majority of participants will always be taken from everyday populations, such as college students. Nevertheless, such studies will always provide an essential component of any complete understanding of creativity.

Glossary

Affect A broad set of events and processes that includes moods, emotions, feeling states, and cognitive–affective structures.

Divergent thinking The ability to generate a variety of associations to a word or solutions to a problem.

Mood induction Refers to research techniques that stimulates a specific feeling state in the individual.

Pretend play Play involving make-believe, the use of fantasy, and treating one thing as if it were something else.

Primary process An early, primitive system of thought that is affect-laden and not logical, such as in dreams.

Definitions of Emotion and Affect

Concept of Creativity

A useful distinction in the conceptualization of creativity is that of the creative product as opposed to the creative process. The creative product is the output of the individual. The output is then judged according to criteria in a particular field as to its creativity. There is a consensus in the field that for a product to be judged as creative it must be (a) original, unique, novel and (b) useful – that is, adaptive and aesthetically pleasing according to the standards of the particular discipline.

Given these two criteria for a product to be judged as creative, the question is often asked, “Can children be truly creative?” Although children can generate new and useful ideas and products, the products are usually not at a level of sophistication necessary to truly contribute to an area. However, if one considers whether or not a product is new and good for that age group, then children can be considered to be generators of creative products. Even though a discovery or idea may have already occurred in a field, if it is new to the individual, then it is a creative act. Ruth Richards has called this kind of creativity ‘everyday creativity.’ Therefore, children and many adults demonstrate creative acts on a daily basis, even though the creative products are not making major contributions to a discipline like art or engineering. This is an important point because it implies that we can study creativity in children and in normal adult populations.

The creative act, which generates a creative product, can involve a number of underlying processes. A major question in studying creativity is “What are the processes that are part of the creative act?” What cognitive, affective, and personality processes are involved in the creative process and increase the likelihood that an individual will generate a creative product?

Concept of Emotion/Affect

It is important to define the terms *emotion* and *affect*. Affect has been described as a broader concept, with emotion as a subset of affect. Emotion is defined as a state of aroused feeling or agitation. Affect has also been viewed as a broad set of events that includes emotions and drives, and involves feeling states that are pervasive. Emotions have been described as interrupting events that are more specific in terms of stimuli and

behavioral responses than are broader feeling states. Moods are often defined as being of longer duration than emotions without a clear trigger or object. The term affect is used throughout this article, rather than emotion, because affect is the more inclusive concept. Affective processes refer to the different dimensions of affect, or types of affect events, that occur within the individual. Most theorists think that cognition frequently is involved in the affective processes, although they differ as to whether affect is always involved, the degree of involvement, and the type of involvement.

Types of Affective Processes

Five affective processes have emerged that are important in creativity based on theory and the research literature. The five affective processes, briefly defined, are as follows:

1. **Openness to experiencing affect states.** This is the ability to feel the affects and specific emotions as they occur. Tellegen and others have found that different types of affect states can be classified as positive affect or negative affect. Individuals differ as to how much they can experience positive and negative affect states. These specific feeling states seem to function differently in the creative process.
2. **Access to affect-laden thoughts, images, and fantasy.** This is the ability to think about ideas, images, and fantasies that include affect. Thoughts involving affect themes such as aggression, sex, affection, or anxiety illustrate this blending of affect and cognition. The psychoanalytic concept of primary process thinking, to be discussed in a later section, is an example of this type of affective process.
3. **Affective pleasure in challenge.** This process involves the excitement and tension that comes with identifying a problem or mystery and wanting to immerse oneself in the task. A combination of positive and negative affect could be involved.
4. **Affective pleasure in problem solving.** This is the tendency to take a deep pleasure in solving a problem or completing an artistic production.
5. **Cognitive integration and modulation of affect.** This is the ability to control, think about, and regulate the affective events one experiences and not be swept away. Although this process is probably more cognitive than affective,

it warrants inclusion because it involves both cognition and affect and it is important in the creative process.

Three other types of affect systems important in creativity are often referred to as broad motivational systems. The whole area of motivation subsumes needs, drives, and affective processes. Drive refers to both primary and acquired drives. Three major motivational systems found to be important to creativity and that include affective components are intrinsic motivation, curiosity, and conflict-resolution and self-expression.

6. **Intrinsic motivation.** This is the motivation that comes from within the individual to perform a task rather than coming from sources external to the individual, such as rewards or evaluation. Amabile has carried out a research program that has found intrinsic motivation to be especially important in creativity. Positive affect is an important part of intrinsic motivation, as Amabile and Henessy have pointed out.
7. **Curiosity.** Curiosity is a motivational state found to be important in creativity. Berlyne has written extensively on this issue. He wrote in 1966 about his view of curiosity as reflecting the organism's striving to maintain an optimal level of arousal.
8. **Conflict-resolution and self-expression.** This is the motivation that comes from the need to resolve an internal conflict or distress or to express intense emotions. In the case of conflict-resolution, a psychoanalytic concept, the individual expresses emotion through creative outlets in an attempt to resolve the problem. Sublimation occurs if the personal conflict is channeled into a specific creative endeavor and is transformed into a more universal issue. In the case of self-expression, there are many anecdotal accounts of individuals using the arts as a form of therapy to deal with emotional problems or daily stresses.

These different affective processes and motivational states work in different ways in different areas of creativity and for different types of creativity tasks. As a field, we are just beginning to learn about the role of these processes.

Theories of Affect and Creativity

Different theories of affect and creativity focus on different types of affective processes and different types of creativity. There is no one comprehensive theory that accounts for all variables and all research findings.

Psychoanalytic Theory

Historically, the first theory of affect and creativity was psychoanalytic. The key concept in the area of psychoanalytic theory and creativity is primary process thinking.

Primary process thinking

Sigmund Freud in 1915 first conceptualized primary process thought as an early, primitive system of thought that was drive-laden and not subject to rules of logic or oriented to reality. A good example of primary process thinking is the kind of thinking that occurs in dreams. Dreams are illogical, are not oriented to rules of time and space, and frequently include affect-laden content and images. Affect is a major component of primary process thinking.

Access to primary process thought has been hypothesized to relate to creative thinking because associations are fluid and primitive images and ideas can be accessed and used.

According to classic psychoanalytic theory, primary process thinking is characterized by mobility of cathexis – that is, the energy behind ideas and images is easily displaced.

In this mode of thinking, ideas are easily interchangeable and attention is widely and flexibly distributed. Therefore, access to primary process thinking should facilitate a fluidity of thought and flexibility of search among all ideas and associations. Flexibility and fluidity of thought are characteristic of two of the most important cognitive processes involved in creative thinking.

Divergent thinking and transformation abilities are the major cognitive processes that are unique to the creative process. Divergent thinking refers to the ability to generate a variety of associations to a word or solutions to a problem. A typical item on a divergent thinking test would be "How many uses for a brick can you think of?" A high scorer on this test would generate a high number of different, acceptable uses for the object. Individuals who can use primary process and the fluidity of thought and breadth of associations inherent in it, should be highly divergent thinkers. They should also score high on a second important cognitive process, transformation ability. This involves the ability to transform or revise what one knows into new patterns or configurations and to be flexible and break out of an old set. Again, the broad associations and flexible thinking characteristic of primary process should facilitate transformation abilities.

Regression in the service of the ego

An important point in psychoanalytic theory is that it is controlled access to primary process thinking that is facilitative of creative thought. The concept of regression in the service of the ego postulates that creative individuals could regress in a controlled fashion and tap into primary process thinking. The creative individual could go back and forth between early, primitive primary process thought and more mature, rational, secondary process thinking. The creative individual could be distinguished from the individual with a thought disorder in that the creative individual was in charge of this regressive process and could critically and logically evaluate the loose, primitive associations and images.

Recently, a number of theorists have proposed that the concept of regression may not be necessary in understanding the relationship between primary process and creativity. Rather, we can think of primary process as a separate cognitive-affective process that one can have access to that then facilitates divergent thinking and transformation abilities. A separate ability to cognitively integrate and modulate primary process thinking would be important in the critical evaluation stage of creative thought.

In summary, the psychoanalytic model of primary process and regression in the service of the ego stresses the importance of two types of affective processes in creativity: (a) access to affect-laden thoughts and images; and (b) cognitive integration of affective material. These processes are important in the facilitation of creative cognitive processes.

Empirical evidence

Primary process has been found to relate to creative cognitive processes in the research literature. Most of the research has used the Rorschach inkblot test as a measure of primary process. In general, as psychoanalytic theory predicted, the ability to give good responses to the Rorschach that contained primary process content was significantly related to measures of divergent thinking and flexibility in problem solving. Using a different approach, good artists were found to have more primitive primary process content than poor artists and top ranked creative architects had more libidinal (sexual) primary process content than lower ranked architects.

Similar results have been found with children, although age, gender, and specific scores emerge as important factors. Primary process on the Rorschach significantly related to divergent thinking and to flexibility in problem solving for boys, but not for girls, independent of intelligence. These gender differences occur throughout the research literature with adults and with children.

In summary, affect-laden primary process thinking is related to cognitive processes important to creativity for males. For females, the results are mixed. A few studies found that pure access to primary process was related to creativity in females. One possible explanation for these sex differences is that females do not have as much access to primary process thought because of cultural taboos and socialization processes. Another explanation could be that the Rorschach is a more valid measure of primary process for males than for females. Indeed, when measuring primary process in children's play, Russ found that primary process related to divergent thinking for both boys and girls. There are many questions remaining to be answered in this research area.

Conflict resolution and self-expression

From a different perspective, psychoanalytic theory has stressed the importance of unresolved conflicts and unfulfilled wishes in motivating the individual to engage in creative work. For example, unrequited love will be expressed in a poem or drawing. Resolving the loss of a loved one will occur as a result of composing a song. The motivating force of transforming one's own pain into artistic creations that have universal appeal is thought to be an important factor in creative work. Although there is little direct empirical evidence for this theory, there is indirect evidence from clinical vignettes from therapists and from descriptions from creative individuals. In addition, Pennebaker's research found that expressive writing can have beneficial effects on mental and physical health.

Cognitive–Affective Models

A more recent approach to affect and creativity has been within a cognitive–affective framework. Research has investigated very specifically how affect influences cognitive processes important in creativity. Much of the research within this framework has used a mood induction paradigm. A specific mood state is induced by having participants watch a film, receive a gift, or think about a memory that is happy or sad. Mood induction provides a way of altering affect states so that the effect on cognitive processes can be observed.

A growing body of research has found that induced affect facilitates creative thinking. Alice Isen has carried out a series of important, carefully controlled studies in the mood induction area. She and her colleagues found that positive affect induction resulted in more creative problem solving when compared to control groups. Other researchers found similar results with a variety of creativity measures. Isen concluded that the underlying mechanism is that positive affect cues positive memories and a large amount of cognitive and affective content. This process results in defocused attention and a more complex cognitive context. This, in turn, results in a greater range of associations and interpretations.

What about negative affect? In general, induced negative affect has had no effect on creative problem solving. As the researchers pointed out, it is possible that the negative affect that was aroused (e.g., by a film of the Holocaust) was too extreme, and that less extreme conditions of negative affect should be explored. A few studies suggest that milder forms of negative affect could facilitate some kinds of problem solving tasks. Different types of affect may have different effects on various dimensions of problem-solving.

In a recent meta-analysis of 25 years of mood-creativity research, Baas, DeDreu, and Nijstad concluded that a number of variables are involved in this complex area of mood and creativity. Specific mood types (not just positive and negative) and aspects of those moods must be considered. They concluded that positive moods do produce more creativity than neutral moods. But this is true for positive moods like happiness that are activating and associated with approach motivation. It is not true for positive but deactivating mood states like relaxation. They point out that an interesting practical implication of this finding is that relaxing in a bathtub or on the beach may not be conducive to creative thinking. How the task is framed is also important. Positive moods lead to more creativity when the task is framed as enjoyable and intrinsically rewarding and to less creativity when the task is framed as serious and extrinsically rewarding. As for negative affect, in general, deactivating negative mood states like sadness were not associated with creativity, but activating negative moods like fear with avoidance motivation were associated with lower creativity. However, there are individual studies like those by Kaufmann that do find positive relationships between negative affect and creativity. Bass, DeDreu, and Nijstad concluded that research should continue that investigates very specific mood states on specific types of creativity tasks under various conditions. We need to learn about the underlying mechanisms that account for the mood–creativity link.

An interesting theoretical model that explains how affect could influence cognition was provided by Isaac Getz and Todd Lubart in 1996. In an emotional resonance model for generating associations, they described *endocepts* that represent emotions attached to concepts or images in memory. These emotional memories are partially interconnected and can activate one another. Endocepts attached to concepts resonate with one another. Endocepts that are stimulated trigger other memories and associations and influence creative problem solving.

The emotional resonance model is consistent with other cognitive affective models such as Bower's associative network theory. In this model, emotion is conceptualized as a memory

unit that has a special node in memory. The activation of the emotion unit aids in the retrieval of events associated with it. It primes emotional themes for use in free association. When activated, it spreads activation through memory structures.

Primary-process thinking might also be conceptualized as mood-relevant cognition, occurring when emotion nodes are activated. Primary process memories could be stored in emotion nodes. Primary process content has been proposed to be content around which the child had experienced early intense feeling states (e.g., oral, anal, or aggressive). Current primary process expressions could reflect these early encodings of emotion. Access to primary process material would activate emotion nodes and associations, thus resulting in a broad range of associations for creative work and problem solving.

Intrinsic Motivation

Intrinsic motivation is conducive to creativity. Intrinsic motivation is defined as having to do with the intrinsic value of attaining a creative solution. Research has found that conditions extrinsic to the task, such as reward, evaluation, being watched, and restricted choice, all have detrimental effects on creativity. Intrinsic motivation is important for task persistence, for seeing a project through, and for ensuring exploration of solutions.

Intrinsic motivation is also accompanied by positive affect. The love of the task is an important component of creative work. Love of the work has been mentioned as crucial by most creative individuals. More research is necessary to explore the positive affect and intrinsic motivation link.

Tension and Creativity

Tension as an important factor in creativity has been conceptualized by Mark Runco. He presented a variety of ways in which tension could be involved in the creative process. The anticipation of the resolution of tension could be an important motivating force in creative problem solving. The tension could be an internal conflict, similar to psychoanalytic theory's idea of conflict resolution. For example, several researchers have found that creative individuals have come from families with problems or have themselves felt marginalized in the society. Tension could also develop from identifying a problem or sensing a gap in an area. Problem identification is important in creativity. Creative individuals could use the tension experienced in seeing the problem as both a cue and a motivator.

Affective pleasure in challenge could also be part of this process. There could be a mix of negative (tension) and positive affect in identifying a problem. The anticipation of the positive affect involved in solving the problem may act as a motivating force. However, there may be an inherent excitement in seeing the ambiguity in the situation that leads to problem identification, which is itself pleasurable. It may be similar to the pleasure that some children feel in discovering "what is wrong with this picture?"

The concept of optimal challenge is relevant here. An optimal amount of challenge is necessary for the experience of flow to occur. Flow is a total involvement in the activity, a deep sense of enjoyment, and optimal challenge. Creative activities involve this sense of flow. Perhaps optimal challenge involves

the best mix of tension in seeing the problem and the anticipated pleasure of the creative act.

Curiosity

Although it is not clear whether or not curiosity has affective components beyond arousal, it is a motivational system important in creativity. Curiosity may be viewed as reflecting the organism's efforts to maintain an optimal level of arousal. Subjective feelings of pleasantness have been associated with the growth of the curiosity drive as a function of increasing stimulus intensity and arousal of the positive reward system. Curiosity may interact with anxiety to determine approach or avoidance behavior.

Curiosity is important to creativity because interest in novelty and exploration aids in problem identification as well as task persistence. Also, the highly curious and risk-taking individual is more likely to gain a wide variety of experience that would add to his or her knowledge base.

Integrative Model of Affect and Creativity

An integrative model of affect and creativity identified the connections among affect, cognitive, and personality processes important to the creative process. This model was based on the research and theoretical literature and attempted to be comprehensive and reflect the current state of knowledge (see [Figure 1](#)).

In this model of affect and creativity, the major cognitive abilities that emerge as unique to and important in the creative process are linked to related specific affective processes and to global personality traits. In some cases the personality traits are behavioral reflections of the underlying affective processes. One assumption of this model is that these specific affective processes and personality traits facilitate creative cognitive abilities. Reciprocal interactions probably occur as well.

This model summarizes all of the affective processes discussed in this article. Because there is no one comprehensive theory of affect and creativity, a variety of theories and underlying mechanisms are represented in this model. At this time, it appears that different mechanisms underlie different components of the creative processes. For example, access to affect themes and affect states facilitates a breadth of associations. Intrinsic motivation should help the individual keep on task and explore alternative solutions. Good cognitive integration of affect should aid the critical thinking process necessary in the evaluation stage of creative work. An important point is that in any creative act, different processes and different mechanisms could be involved.

Future research should add to the empirical base for this model and answer the questions of what specific affective processes are important in creativity and how they are important. It is possible that a larger number of affective processes are involved than are currently recognized or that several of these processes are really the same process. For example, are affect-laden thoughts and mood states different dimensions of affect or are they really the same process? Do they function in the same or in different ways? Can the motivational systems of intrinsic motivation and curiosity be broken down into several affective components? (In this model, because of their global

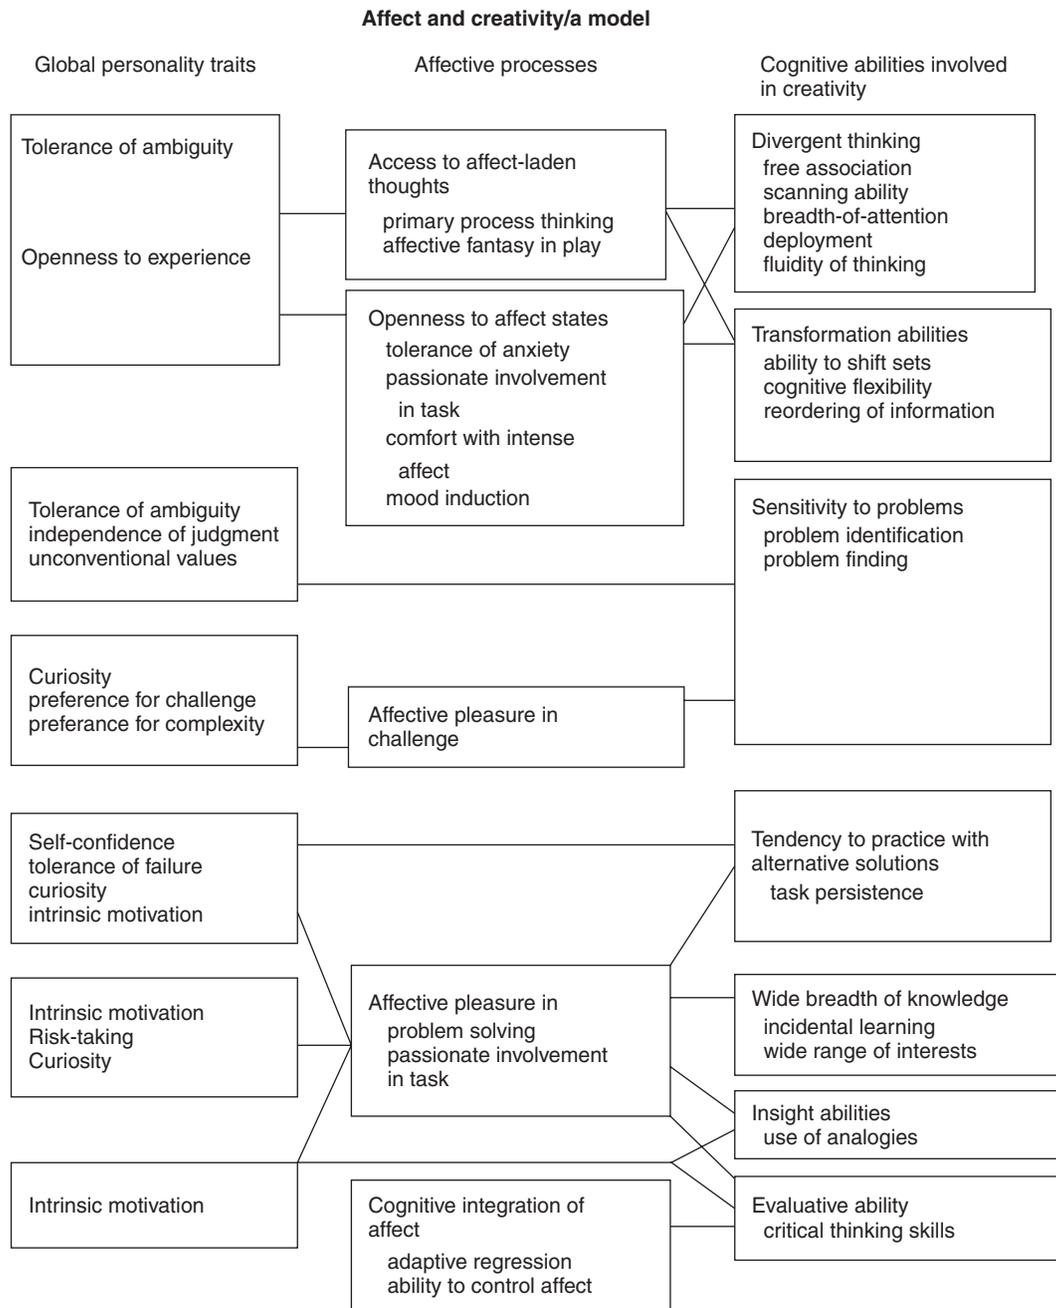

Figure 1 Affect and creativity model. In this model of affect and creativity, the major cognitive abilities that emerge as unique to and important in the creative process are linked to specific affective processes and to global personality traits. In some cases, the personality traits are behavioral reflections of the underlying affective process. One assumption of this model is that these specific affective processes and personality traits facilitate cognitive abilities. From Russ, S. (1993). *Affect and Creativity: The Role of Affect and Play in the Creative Process*. Hillsdale, NJ: Erlbaum.

nature, both were classified under personality traits). Future research will answer these important questions.

Play, Affect, and Creativity

Play is important in the development of many of the cognitive, affective, and personality processes important in creativity. The type of play most important to the area of creativity is

pretend play. Pretend play involves make-believe, the use of fantasy, and treating one thing as if it were something else. Pretend play frequently involves affect. Children express both positive and negative emotion in play. In 1987, Fein proposed that the affect is represented in an affective symbol system. Information about affect-laden events and relationships is coded and stored in these symbols. These symbols are reflected in pretend play and are especially important for creative thinking. From a psychoanalytic perspective, play is

a place where primary process thinking as well as other kinds of affect can be expressed.

Research Evidence

Research supports a relationship between affect in play and creative thinking that is independent of intelligence. A positive relationship has been found between playfulness (that included the affective components of spontaneity and joy) and divergent thinking in kindergarten children. Similarly, a relationship has been found between the amount of affect expressed in play and divergent thinking in several samples of first and second graders and in preschool children as well. In a longitudinal study, affect in play in young children predicted affect in play stories in older children. This longitudinal study suggests that affect in fantasy is a trait that has some stability over a four year period.

It is important to note that both positive and negative affect in play relate to creativity. In play, negative affect is well-controlled in most children and is pretend, after all. The negative affect is not intense and is often enjoyable to the child.

Play has been found to facilitate creativity in children, but there is no conclusive evidence that it is the affect expression in play that is the causative factor. That question continues to be investigated.

Affect, Creativity, Adjustment, and Psychopathology

Research has found that creativity relates to both adjustment and psychopathology. How can both findings be true? If we conceptualize creativity as evolving from a configuration of cognitive, affective, and personality processes that set the stage for creative acts to occur, then the propensity for adjustment could go either way depending upon the mix of processes. If creative individuals are good divergent thinkers, have diverse associations, have access to primary process in a controlled fashion, are open to affect states, and are good critical thinkers, then one would expect them to be sensitive but relatively stable individuals, perhaps with periods of emotional instability. Some research studies are supportive of the hypothesis that creative individuals are adaptive and well-adjusted. Many of the psychological traits that are related to creativity are also indicators of positive mental health.

Other researchers have found a relationship between creativity and psychopathology. In a study of British artists and writers, 38 per cent of the sample sought treatment for mood disorders. Ruth Richards, based on her research, offered three major conclusions about creativity and mental health. She concluded (a) mild psychopathology may contribute to creativity (mild mood swings especially may carry advantages for creativity), (b) intermediate levels of variables may be most optimal for creativity, and (c) affect is important in creativity. She stressed the importance of positive affect for creative accomplishment.

Artistic and Scientific Creativity

Affective processes play different roles in different domains of creativity. In general, scientists have been found to be better adjusted than artists. A higher than normal proportion of artists have been found to have mood disorders. Research with scientists paints a different picture. A number

of researchers have concluded that creative scientists may be a more emotionally stable group than creative artists.

Why would this be so? The personality differences between creative artists and scientists may reflect the differences in the domains of creativity and the cognitive and affective processes that are involved. There are similarities. Divergent thinking is important in scientific problem solving as well as in artistic production. Breaking out of a set and creating new configurations is also important in both types of creativity. Affective process would be expected to function in similar ways for similar creative tasks in artists and scientists.

One of the main differences between artistic and scientific creativity may be the importance of getting more deeply into affect states and thematic material in artistic creativity. This in-depth involvement in the affective processes themselves may not be so necessary in scientific problem solving. Some theorists think that artists incorporate early traumas and conflicts into their artistic productions. Scientists do not usually have to face into and incorporate affect-laden material into their scientific problem solving. For the scientist, good divergent thinking ability, transformation ability, and a flexible cognitive style may be sufficient for creative work to occur. For the writer, the musician, or the artist, the need to get to basic and deep emotions, primary process material, and affect-laden memories and images may be necessary in order to be able to express universal truths that transcend the individual and speak to others.

One often hears artists and writers describe the need to have this kind of experience. One can see how the need to live in that emotional state and to control that process may at times be disruptive, resulting in emotional instability and some personal agony. Writers in particular describe anxiety at uncovering primary process material.

On the other hand, interviews with creative scientists indicate that scientists often feel very strong emotions during the creative process. In a study that gave artistic and scientific problems to art and science students and had them rate their intensity of emotions, art and science students experienced the same intensity of affect before and during insight, but art students reported more positive emotion after insight than did science students.

It is logical to assume that each specific artistic and scientific domain will have cognitive and affective processes that are especially important in that area. Different creative profiles should emerge for different fields. A dynamic (not static) mode of affective-cognitive interaction has been proposed for artistic creativity. Creativity and psychopathology are ever changing continua with a mixture of affect states. Only a dynamic model can capture the complexities of the interactions.

Neurological Processes, Affect, and Creativity

As research on affect and neurological processes becomes more sophisticated, we are learning about the interaction between affect and cognition. With the development of the CAT scan, PET technology, and fMRI technology, we can map cerebral activity and obtain a picture of brain involvement during problem solving. Eventually, we should learn about the actual neurological processes involved in creative problem solving.

Research by Klaus Hoppe has shown that the mutual interaction of the left and right hemisphere is important in creativity. The corpus callosum is involved in exchanging information between the hemispheres. The symbolization and visual imagery in the right hemisphere is available to the left hemisphere in creative functioning. Cognitive representation of emotion occurs in both hemispheres.

Research on the neurological processes involved in affect processes has addressed several important questions in the area of emotion that have implications for the affect and creativity area. It has been concluded that different emotions have different neurological and physiological activity. It appears there are different brain systems that mediate different emotions. Therefore, we need to investigate specific emotions. This conclusion is consistent with the findings in the affect and creativity area that different emotions have different effects on cognitive processes.

It has also been proposed that different emotions are represented in memory. An important point is that these emotions appear to be stored in the amygdala. This is a different area of the brain than that which stores nonemotional memories, the hippocampus. Research suggests that emotional memories are organized differently than are nonemotional memories. The emotional can act independently of the cognitive system. It has been suggested that these precognitive emotions are functional in infants during the early formative years. Behavior is effected, but we have no conscious memory of the event.

The concept of emotional memories functioning as a separate system is consistent with some theoretical explanations about why affect should facilitate creativity. If affect stirs a network of associations and emotion-laden memories, which in turn effects cognitive processes, then the organizational system of those emotional memories becomes very important. The rules that govern how this emotional memory system functions still await discovery. These principles should help us understand the mechanisms that underlie the complex relationship between affect and creativity.

Conclusion

During the past 25 years, there has been a resurgence of research in the affect and creativity area. As it should be in

any science, the research is theory driven, theories are being developed and tested, measures and methods are being refined, and new lines of investigation are opening. The field is interdisciplinary and what we learn in one field informs another. For example, what we learn about affective processes from neurophysiological research will be applied to affect and creativity research. Key concerns for the future in the affect and creativity area are: (a) identifying specific affective processes that are most important for creativity tasks; (b) discovering the underlying mechanisms that account for the relationships between affect and creativity; (c) exploring differential effects of various types of affect, such as positive or negative affect, on creativity; (d) understanding how affect and creativity relate to psychological adjustment and psychopathology; and (e) understanding the developmental processes involved in affect and creativity. As research paradigms and measures of affect continue to be developed, we will continue to learn about this exciting area.

Glossary

Cognitive processes Actions taken by the human mind to process information. At a relatively simple level, includes attention, perception, rehearsal, and encoding. More complex processes include higher-order thinking skills such as problem solving.

Constructivism Learning and cognitive theories that posit that knowledge is constructed, either individually or by groups.

Discretion Process by which potential actions and subsequent outcomes are identified, evaluated, and differentiated.

Functional fixedness Reliance on traditional techniques and strategies for problem solving, even when conditions surrounding problem diverge considerably from previously encountered conditions. Also, inability to consider alternatives when faced with problems, especially alternative uses for traditional problem-solving tools.

Information stores In the traditional two-store model of human memory and information processing, the

locations where bits of information are stored either temporarily (working memory) or permanently (long-term memory).

Metacognition An individual's analysis of his or her own cognitive processes or, more colloquially, thinking about one's own thinking.

Rigidity Lack of flexibility in the application of cognitive processes, especially problem solving. This inflexibility is reinforced by the effects of prior experience.

Schema The organizational framework for information found in long-term memory. Schema theory posits that more complex schema are associated with more efficient recall and information processing.

Self-efficacy Belief in one's own ability. Usually applied to a specific subject area or task, such as mathematical or reading self-efficacy.

Social constructivism Subset of constructivist learning theories that represent knowledge as being socially constructed, either within one's immediate environment or within the broader culture.

Can Creativity Be Enhanced?

In the not-so-distant past, the belief that creativity could not be enhanced was widespread. This notion about the unchanging nature of creativity could be found in academic circles as well as the media and popular press. Although perceptions have changed slightly over the past 20 years, a great deal of controversy still surrounds the nature–nurture issue as applied to creativity.

The relationship between nature and nurture is better conceptualized as a continuum and not as an either–or proposition. Those holding a radical nativist view assume that creativity cannot be enhanced. The extreme nativist view is rare, however, and current consensus holds that potentials can be fulfilled and maximized. It may be analogous to one's height: each of us inherits a *range of reaction* within which our experiences have their impact. One person might inherit a range of potential height between 5 foot 6 inches and 5 foot 9 inches, and given specific developmental experiences (e.g., exercise, vitamins), end up being 5 foot 10 inches. This idea about a range of potential also applies to psychological constructs such as creativity and intelligence. Hence, in response to the question “Can creativity be enhanced?” the best answer is yes, because potentials can be fulfilled. Efforts to enhance creativity will not expand one's in-born potentials but can insure that potentials are maximized.

The broad range of definitions of creativity has traditionally confused discussions about creative enhancement. For example, if one defines creativity as divergent thinking, and another person defines it as both divergent and convergent thinking, the proposed approaches to enhancement will likely be quite different. For the purposes of this entry, we use the comprehensive definition proposed by Plucker, Beghetto, and Dow, which encompasses most definitions and conceptions of creativity: “the interaction among aptitude, process, and environment by which and individual or group produces a perceptible product that is both novel and useful as defined within a social context.”

What Exactly Can Be Enhanced?

When an attempt is made to enhance creativity, what is the exact focus? To answer this question, the multifaceted nature of creativity must be recognized with its cognitive, affective, attitudinal, interpersonal, and environmental components. Taken both collectively and individually, these aspects of creativity suggest targets for enhancement efforts.

Recent theory and research support the inclusion of such diverse components in models of creativity. Although each component has separately been the subject of significant theoretical and empirical investigation, the importance of collectively considering these aspects is reinforced by the recent

predominance of systems, interactionist, and interdisciplinary (e.g., psychoeconomic) theories of creativity. We discuss enhancement by focusing on each of the components.

Cognitive Components

Cognitive components are by definition intellectual. They reflect information-processing models and problem solving. Models of information processing generally include cognitive processes, transfer operations, information stores, and meta-cognitive components, all which are important to consider when attempting to foster cognitive aspects of creativity.

Certain process strategies are very useful when looking for original ideas. As a result, creative process strategies for enhancing creativity are quite numerous and include teaching people to use cognitive heuristics such as lateral thinking, brainstorming, SCAMPER (substitute, combine, adapt, magnify/modify/minify, put to other uses, eliminate, reuse), analogical reasoning (e.g., synetics), and creative problem solving. Other frequently mentioned strategies include identifying and overcoming blocks to creativity, balancing the use of reflection and tinkering, encouraging playfulness, creativity imagery or visualization, assuming multiple perspectives, questioning assumptions, and looking for patterns. Perhaps the most popular techniques of the past 50 years have involved the teaching of divergent thinking and general problem-solving heuristics.

The role of information stores has received considerably less attention during discussions of creativity than that of cognitive processes, but the role may be no less important. Expert problem solvers tend to have better working and long-term memory skills than novices, although this distinction only applies to the memorization of situated knowledge (i.e., information that can be placed into an expert's existing schema) and not tangential or random knowledge. In addition, general knowledge may be very important during the creative process, and such knowledge depends on memory and information storage. Without well-organized information stores (i.e., schemas), knowledge becomes difficult to use and recall during the creative process. Constructivist approaches to learning, in which individuals construct their own schemas based on their personal experiences, should prove especially useful when helping people learn to retain, recall, and apply knowledge during the creative process. Jean Piaget, the well-known psychologist, titled one of his monographs, *To Understand and to Invent*, implying that true understanding depends on personal constructivism. Very often it is beneficial for students to relate new information to prior knowledge (i.e., existing schema), and activities should be based on realistic problems that require application of prior knowledge and new skills. Much new work on divergent thinking and creative problem solving relies on realistic problems.

The importance of prior knowledge can, however, be easily overstated. An individual or group that is embedded in a particular field of study or interest area may be reluctant to consider ideas and solutions that are uncommon, unpopular, or even antiparadigmatic within that context (or within one's personal experiences). This phenomenon is referred to as functional fixedness or rigidity. As a result, creative contributions in a given area are often made by individuals who are not

necessarily experts within that field. A case in point is the numerous early paleontologists who had primary training in the arts. When painting and drawing illustrations of dinosaurs, they realized that the existing knowledge base was quite superficial and provided inadequate answers to many important questions. Their fresh perspective allowed them to move beyond existing paradigms and field-based constraints to make creative contributions to paleontology. Other examples include experts who retain flexible strategies while maintaining their expertise in certain domains.

Although many people believe that exponentially increasing complexity of most disciplines has led to creative contributions to these fields, it is probably an overstated belief. The ability to apply processes and use information from areas of interest other than one's own area of interest is clearly important. The tension between different areas of interest may stimulate creativity as well. When participating in creativity enhancement exercises, people should thus be encouraged to look across fields of study and areas of knowledge for potential solutions to their problems. This act of looking beyond the established parameters to obtain a solution to a problem has popularly become known in business circles as thinking outside of the box and psychology as insight, moving beyond the problem space, or problem finding and redefinition. Other specific strategies in this area include forcing someone to assume a different viewpoint or perspective on an issue, which can be facilitated by a debate or role playing.

Experts tend to exhibit a greater degree of meta-cognition during problem solving than do novices. In this context, meta-cognition involves monitoring one's own cognitive processes in order to manage time effectively, assess progress accurately, and attempt problem-solving efforts efficiently. Suggested strategies for helping students develop metacognitive abilities include providing a variety of creative and problem-solving strategies in a low-risk, constructive environment, encouraging self-assessment of the steps taken to solve a problem, and modeling metacognitive skills.

Affective Components

The affective component of creativity refers to one's emotions. Affect is quite important because creative work very likely has personal meaning. A technique used to enhance creativity should provide more than just a new strategy – it should provide a practical use for the strategy. Benefits to individuals or society should be communicated, and intrapersonal and interpersonal incentives described.

Care must be taken, because – in contrast to the potential of incentives – the positive relationship between intrinsic motivation and creative behavior is well documented in the theoretical and empirical literature. But the question of whether external motivation (especially when created by external evaluations) is detrimental to creativity has yet to be answered. E. Paul Torrance suggested that freedom from evaluation during practice with a creative strategy resulted in more proficient use of that strategy over time, but he found this to be less true with older, late elementary students than with younger students. Other researchers have called into question whether extrinsic motivation is truly detrimental to creativity,

with a few theorists going so far as to say that constraint and external motivation are essential for creativity to emerge. Very likely both are potential influences, with the contribution of each varying across individuals and tasks.

Given the controversy surrounding external motivation, recommendations regarding evaluation and creativity can only be made hesitantly. At this point in time, it seems practical to expose people to reasonable amounts of evaluation, but only when the evaluators are trained in how to provide constructive criticism.

Attitudinal Components

The individual's attitude toward creativity is very important, especially his or her creative self-efficacy. One's belief in his or her ability to create, defined broadly, forms the psychological foundation of creative achievement. Creative self-efficacy can be fostered by providing genuine praise and feedback about a person's creativity and avoiding discouraging statements (e.g., "You can't do that, you're not creative"). But some people may be challenged by competitive statements, again stressing the value of constructing enhancement efforts on a case-by-case basis.

The attitudinal enhancement of creativity may also involve modeling, which can be accomplished in a variety of ways. Individuals can be exposed to information about unambiguously creative individuals, perhaps via biographies or case studies. These can provide a glimpse into the more personal aspects of creativity and provide evidence that even eminent creators "are just human, like you and me." This kind of information can be reassuring and even inspiring, though it does not suggest specific ways to be creative. It is informational in the literal sense, providing factual rather than procedural information about creativity. In a similar vein, teachers, managers, parents, and others who are attempting to foster creative self-efficacy in others should model a can-do, enthusiastic attitude when confronted with problems and tasks that require creative solutions. By explaining their thought process as they tackle the problem, the creative process may be further demystified and made more accessible to the observer.

In order to change perceptions, recently six myths of creativity have been identified. They are as follows:

- **Myth 1: People Are Born Either Creative or Not Creative.** As previously discussed, research suggests that individuals may enhance their own creativity, but this often times is not believed by the individual.
- **Myth 2: There Is Limited Time to Be Creative.** (Aging diminishes creativity.) An oft held conception of creativity is that it is an ability that most children tend to possess. Much research suggests that older adults actually demonstrate the ability to be creative.
- **Myth 3: General Creativity Does Not Exist.** While there are data suggesting creativity is specific to an area, recent theory and supporting data suggest that some types of creative methods move across domains while others may be more limited within domains.
- **Myth 4: Creativity Is a Touchy-Feely Phenomenon.** Many seem to believe that creativity is this magical and mystical

ability; only attained when one is not really trying to find it. Creativity can and has been studied using rigorous methods with well-conceptualized operational definitions.

- **Myth 5: Group Creativity Works Best.** Both group and individual creative strategies have advantages and disadvantages. These differing values are described in the next section of the article.
- **Myth 6: Constraints Hinder Creativity.** Although constraints may sometimes hinder creativity they may also help provide positive guidelines that promote creativity.

These myths also represent a critical part of the framework for creativity enhancement programming via attitudinal change to be discussed later in the article.

Interpersonal Components

Two types of interpersonal skills appear to facilitate the creative process; the ability to gain acceptance for one's creativity and the ability to work with others during the creative process. Although there is considerable debate about whether gaining acceptance for creativity (i.e., persuasion) is a vital component of everyday or only eminent creativity, the ability to market personal or group creative products can be a positive attribute. Students should be encouraged to share their creative work with others. It is hoped that they will receive and benefit from this positive and perhaps even mild negative feedback. This may help them to develop the ability to convince an audience of their creativity.

Working with others can both foster and inhibit creativity. Groups can serve as a detriment to creativity when members are simply told to 'do well,' when group goals are lacking, and when members do not have the freedom to work as individuals within the larger group. Conversely, groups tend to enhance creativity when members are socially comfortable with each other, when both the group and individual members are held accountable for clear performance standards, and when group tasks are meaningful. Recall also the potential impact of evaluation, which can also be interpersonal.

A seldom mentioned aspect of group creativity is the intergroup interaction as each group solves similar problems. By allowing group members to interact with other groups, the informal sharing of information and ideas can help members of a group overcome any functional fixedness that has developed. This perspective, which is based on the work of social constructivists, suggests that intergroup communication should be encouraged.

Problem-based and situated learning is also relevant to the discussion of interpersonal components of creativity. These constructivist-inspired strategies, which allow students to learn content and process skills through the solving of real-life problems, place a strong emphasis on the application of information rather than on simple memorization. Additionally, the realistic nature of problem-based and situated enhancement efforts fosters intrinsic motivation, which can be beneficial for creativity. Although situated learning makes sense in light of constructivist learning theories, situated approaches pose certain problems for the enhancement of creativity. Constructing knowledge and developing creative process

skills may be more applied in a situated context, but they may be constructed and developed in a way that promotes functional fixedness. Problem-based learning activities should be designed so that students are required to apply factual and procedural knowledge in a variety of contexts, to interact with others as part of the learning process, and to engage in some abstract thought (i.e., non-situated thought, which is frequently mentioned as a cognitive characteristic of creative individuals).

Environmental Components

The assembled research from the past 50 years paints a clear picture of the characteristics of a creativity-enhancing environment. The key characteristics are tolerance, moderation, and availability of resources. Although these concepts may seem antithetical, they are (like many aspects of creativity enhancement) more applicable than they first appear. For example, a stimulating environment should be created, with a multitude of diverse materials (i.e., resources) available to stimulate ideas and create solutions. But the common tendency to provide predominantly verbal materials should be avoided. Many individuals prefer to express their creativity through several domains, thus varied input (e.g., visual) should reflect this diversity of expression. In addition, given the importance of problem finding, it may be desirable to expose people occasionally to open stimulus environments, in which stimuli must be sought and problems need to be identified.

The environment should allow and even encourage reasonable risks to be taken, but irresponsible and physically dangerous risks (e.g., consumptions of drugs) should be discouraged. Everyday uses of creativity and problem solving are fostered by the management of risk, not simply by taking any risk that presents itself. In more general terms, the creative environment fosters the use of creative discretion, which separates originality from psychotic ideation.

Deviance and ambiguity are tolerated in the creativity-enhancing environment. Individuals should be encouraged when they think outside of accepted procedures and customs, and not criticized for ignoring cultural and experiential limitations. However, the environment should encourage self-regulation of creative processes so that even the most exhilarating dead ends can be self-identified and put aside. Divergent thinking needs to be linked with convergent thinking in the creative environment.

In general, the environment should be marked by balance: a mixture of structured and unstructured tasks that require divergent and convergent thinking, independent and group work, and procedural and declarative (factual) information.

Increasing Creativity Test Scores

Several researchers have investigated the possible impact of environmental conditions on creativity test scores. Conditions include practice with heuristics before administration, game-like conditions, manipulation of instructions (e.g., telling students to be original when completing a divergent thinking (DT) test, verbal versus nonverbal instructions), allowing students to take the tests home to be completed, different types of tasks (i.e., abstract versus real-world, interesting vs. uninteresting),

timed versus untimed tests, presence of model before or during administration, stimulus-rich versus barren environments, high versus low structure, individual versus group completion, and playing musical or comedic recordings during administration. In general, test-like conditions appear to be associated with the most convincing evidence of reliability and validity, although actual performance effects vary considerable across age and grade levels. For example, although instructions to be original probably result in increased originality and decreased fluency scores on DT tasks regardless of a person's age, working with others appears to produce higher creativity scores than working alone for children after the age of 6 but not earlier.

Drug Use

Conventional wisdom posits that the use of certain drugs (e.g., alcohol, marijuana, LSD) enhances personal creativity. Although certain aspects of creativity (e.g., affective, cognitive, interpersonal) may be positively influenced by drug use, research over several decades provides convincing evidence that – at best – moderate drug use has a negligible effect on long-term creative production and heavy use has a detrimental effect. Even in specific situations where a positive drug effect has been documented, the drug does not appear to encourage creative production. For example, several researchers have observed that alcohol consumption tends to lower a person's inhibitions, which is assumed to result in more flexible thinking and, therefore, greater creativity. However, this research has also shown that the disinhibition does not lead to enhanced creative production, rendering the effect of the alcohol most with respect to long-term creative productivity.

Programs Designed to Enhance Creativity

Over the past few decades, several creativity training programs have been used to help people maximize their creative potential. These programs usually incorporate strategies that address multiple components of creativity.

Two types of programs have been designed to enhance children's creativity. The first involves modifications of the regular school curriculum, such as the Schoolwide Enrichment Model and Mentor Connection, the Talents Unlimited Model, the Cognitive–Affective Interaction Model, the SOI system, and the Purdue Creativity and Enrichment Models. The second includes extracurricular programs that may or may not be affiliated by educators attached to a child's school, including the Odyssey of the Mind and Future Problem Solving programs and numerous local, regional, and national invention programs. However, the distinction between these two types of programs is not universal, and programs frequently and successfully transverse this rather artificial boundary.

Within the business community, programs for enhancing creativity are quite popular. The increasing popularity of creativity in the business sector has led to an explosion in the number and type of programs aimed at this audience. In general, the components mentioned previously in this article are included in these programs, with predictable changes in terminology.

Plucker and his colleagues at Indiana University have recently developed and evaluated a new approach to enhancement, one

that focuses on attitude change as the precursor to enhancement. The model for the curriculum includes (a) changing schemas, (b) identification of personal strengths, and (c) acknowledging personal and external factors that may affect creativity, all addressed through a series of problem-based activities. The developers created two courses: an entry level course titled Debunking Myths and Enhancing Innovation, and Applied Creativity Seminar, a capstone class for undergraduates. Pre- and post-course data suggest that students are able to overcome initial misconceptions and begin to change attitudes about creativity. This was particularly strong for the beliefs that creativity can be enhanced, that creativity can be defined, and constraints may enhance creativity. Although further testing of this model is needed within the framework of the courses or similar courses at other universities, initial evidence suggests that focusing on attitude change rather than specific cognitive skills or behaviors may be a fruitful approach for enhancement programs.

Conclusions

Must all of the components be present in an effort to enhance creativity? As mentioned earlier, aspects of each component have been studied individually; similarly, intervention efforts occasionally focus on only one or two components. Research is mixed with respect to evaluations of the effectiveness of narrowly focused strategies in a manner similar to the way that many people describe different therapies: if you think a specific technique works for you, it does.

However, because each of the components is a necessary but not sufficient condition for creativity, enhancement efforts that consider the components collectively should be more effective than narrowly focused strategies. For example, if a person was to choose one component to exclude from enhancement efforts, which would it be: creating a supportive environment in which people are encouraged to take sensible risks, encouraging people to monitor their creative processes, or stressing the importance of interpersonal skills to creativity and the creative acceptance process? Each is clearly important and overlooking any of them (or any other aspect of creativity) would be difficult in light of the assembled research and theory. Although efforts to foster creativity need not focus on each and every component (and cannot do so effectively), well-designed programs consider all of the components and their interactions.

With the ideal that all facets of creativity should be represented in enhancement efforts, the following general guidelines appear to be reasonable.

1. Consider addressing misconceptions people have about creativity. For example, if a student does not believe she is creative and believes creativity cannot be increased, the best instruction for creativity enhancement will probably have little impact on that student's creativity.
2. Design activities that demand an individual's or group's attention. Capitalize on teachable moments such as current political, cultural, and community events.
3. Supply information about strategies and creators that is both useful and interesting. Information on the difficulties in building a canal or on intricacies of Einstein's general theory of relativity may not appeal to a group of marketing

specialists, but stories about Einstein's struggle to get his ideas accepted or about the political creativity involved with constructing sky-scrapers may appeal (and appear more pertinent) to this group.

4. Provide either the skills and information that will generalize to other setting (e.g., the home, school, workplace) or opportunities to apply the introduced skills and information to different settings and problems.
5. Remove excessive evaluation and supervision from the creative environment. Micromanaging is just as disruptive to young students as it is to corporate managers.
6. Attempt to alter attitudes about creativity and originality and encourage creative confidence (i.e., creative self-efficacy) and risk taking.
7. Design activities that excite, stimulate, and increase curiosity and help people develop the intrinsic motivation to be creative.
8. Require problems to be solved individually and in groups. Have groups critically examine their own processes and attitudes (i.e., develop group metacognition) during and after the creative process.
9. Avoid making assumptions about students. Recent theory and research on intelligence, motivation, personality, and thinking and learning styles provide evidence that individuals vary tremendously in their abilities, preferences, and attitudes. This diversity appears to be a critical element of creative production.
10. Similarly, introduce variety into enhancement efforts. This capitalizes on individual preferences and interests and promotes diversity in one's approach to finding and solving problems.
11. Consider the use of well-established programs that address multiple components of creativity and have already been field-tested and refined.

Glossary

Ambidextrous organization An organization in which exploration and exploitation are separate units with coordination from senior executives.

Demographic diversity Differences in group members in terms of characteristics such as age, gender, or ethnicity.

Entrepreneur A person who has a new business, organization, product, service, or idea and is highly motivated to pursue his/her vision and to succeed in the face of any adversities.

Entrepreneurship The process of creating new businesses, products, services and/or a state of mind that thrives for innovations that have the potential to improve the lives of many people/customers.

Environmental scanning Careful monitoring of a firm's external and internal environments to detect signs of opportunities and threats.

Exploration versus exploitation The variation in creative activities from the explorative generation stages to the development activities of the implementation stage.

Informational diversity Differences in knowledge bases that are job-related, such as educational and functional backgrounds.

Innovation The implementation of a new idea that leads to a change or reorganization in how society works or performs certain tasks.

Innovative entrepreneur A person whose new venture or idea has a unique capability.

Opportunity recognition The process by which a new entrepreneurial idea is identified.

Teams Collaboration of two or more individuals who work together on common goals. They typically have complementary skills and are dependent on one another for the successful completion of the goal.

Team reflexivity The ability to adjust team processes based on changes in circumstances and feedback.

Transactive memory The knowledge among team members of the unique skill or talents possessed by the various team members.

Transformational leaders Leaders who inspire group members by their vision and support and encourage innovative thinking.

Characteristics of Entrepreneurs

An entrepreneur is a person who becomes immersed in an innovative entrepreneurial endeavor, defined as the process of starting a new business, organization, product, or service that fulfills a vision. In this article, we consider only entrepreneurs who innovate in some way. To recognize the characteristics of successful entrepreneurs, we first need to understand the cycle that most entrepreneurs go through and the challenges encountered at each stage of the process. The entrepreneurial process or cycle starts with identifying an opportunity for a new business/product/service. Opportunity identification is one of the most important steps in the entrepreneurial process. Cognitively, it consists of a search process for new opportunities for a market, industry, or customers. The search process can be either active or passive. In the active case, one seeks out information from a variety of sources (personal contacts, specialized publications, etc.). In the passive mode, also called alertness, one recognizes opportunities on-the-fly, from daily encounters and happenings. In both cases, a very important characteristic for the identification of novel entrepreneurial opportunities is the ability to connect apparently unrelated concepts in a novel and useful way. This process requires the same skills as creative or divergent thinking. Indeed, many relationships between creativity and entrepreneurship have been found.

The second phase of the entrepreneurial process is opportunity evaluation. An idea must be evaluated for its potential to be implemented and to lead to a successful enterprise. Typical characteristics of a good idea are: technologically feasible, novel, it satisfies the need of a large enough market, and is financially sound. A business plan and a vision are usually generated in this phase. The vision is a description of what the entrepreneur wants to achieve with the new idea over the long haul. Opportunity identification and evaluation are the shortest stages in the entrepreneurial process, but also the most important ones. A good idea needs a solid business plan as a foundation for the short-term goals of starting up and a clear vision describing the long-term goals and dreams.

The third phase is the implementation in which necessary resources are gathered and a new organization/product/service is created. The last stage is the growth stage, when the new enterprise is expanded and the original vision is realized. These last two stages involve uncertainty, high-risk, scarcity of resources and unexpected changes. Most of these variables are external, depending on social and economic factors outside the control of the entrepreneur. But some of them are internal and depend on the ability of the entrepreneur to attract resources/customers, to manage an ever-growing organization and to continue to innovate and stay ahead of the competition. While creativity is necessary in the opportunity identification stage and for continuous innovation in the implementation

and growth stages, other characteristics such as tenacity, perseverance, self-efficacy, risk-propensity, stress tolerance and the ability to make rapid decisions in an uncertain and constrained environment become essential in later stages.

The characteristics of successful entrepreneurs have implications for understanding the role of entrepreneurship education on future entrepreneurial intentions and behavior. Before the 1990s, research on the effect of general personality traits on business success and business creation found little or no relationship. More recently, specific traits have been related to various aspects of the entrepreneurial process. For example, need for achievement and risk-propensity have been among the most studied characteristics of entrepreneurs, and these do relate to economic outcome and business performance. Also, entrepreneurs have a higher need for achievement and risk-propensity than managers. Self-efficacy (i.e., task-specific self-confidence) seems to have a particularly significant role. High levels of self-efficacy in entrepreneurs relate to business creation and business success and growth and in students to entrepreneurial intentions. Innovativeness, stress tolerance, need for autonomy, proactivity (i.e., initiating actions to change one's environment) are all moderately related to business creation or business success. Other relationships between traits and venture growth have been found for the ability to communicate the vision of an organization and high goals for the venture. More interestingly, some traits cannot be related directly to an entrepreneurial outcome such as business success or growth but are related to other traits that in turn affect entrepreneurial success. For example, passion, tenacity and the ability to manage new resources and skills affect vision, goals and self-efficacy, which in turn affect business success and growth. Perceived learning experiences from formal entrepreneurial education, previous entrepreneurial experience, risk-propensity and entrepreneurial intentions are related to self-efficacy, with the strongest correlation coming from perceived entrepreneurial training. Highly proactive and creative students manifest high entrepreneurial desire and intention. The picture revealed by research on entrepreneurial traits is that of many direct and indirect relationships between traits and the entrepreneurial process, traits and business outcomes, traits and entrepreneurial intentions, and among traits themselves. Models of entrepreneurial intentions imply that there is a direct relation between entrepreneurial intentions and future entrepreneurial behavior such as business venture formation. Some of these traits, such as entrepreneurial self-efficacy, can be affected by entrepreneurial education.

Creativity and Innovation in Entrepreneurship

Entrepreneurship, creativity, and innovation have a natural affinity. Innovative entrepreneurs are able to identify new business opportunities and are motivated to pursue them to their completion. To start a new venture, entrepreneurs need a good idea that is technologically feasible, novel, satisfies the need of a large enough market, and is financially sound. The idea or the vision of the new business is what drives entrepreneurs and what can potentially determine its success. It is the most important part of an entrepreneurial cycle and the most creative one. For example, Google's idea of creating a new way of

implementing web searching by extracting information from the structure of web links was novel, it was technologically feasible by implementing a new algorithm for indexing and ranking of web pages on a large computer and storage network, it satisfied the needs of practically everyone with a computer connected to the internet or a business with a web-presence, it was financially sound because of its novel advertising scheme. Similarly, the idea by Jeff Bezos of using the internet as a means to sell books in 1994 practically started the e-commerce field. It was a new idea providing an improved experience of searching and buying books, technologically feasible (the internet usage was increasing 2300 per cent a year), it had a large supply (publishing industry) and market demand.

In contrast, a good idea that was not technologically feasible and/or did not have a large demand until two decades later was that of a mobile phone. It could have been implemented in the 1960s because radiotelephony was widely used in marine and military communication since the 1930s, and cellular technology was invented in the 1960s. But the market demand and the implementation of the large infrastructure were realized only in the 1980–1990s.

Discovering new business opportunities or ideas requires the ability to synthesize information from different sources, to identify gaps in existing products and services and the ability to envision new concepts in the form of new products/services. The cognitive process underlying the identification of a novel business opportunity has the same characteristics as creative thinking (problem identification and construction, gathering of relevant information, idea generation, idea evaluation, and selection). Creativity is defined as the production of novel and useful ideas and products, which uses exactly the same cognitive process underlying the opportunity identification phase.

A cognitive model of opportunity recognition based on pattern recognition proposes that business opportunities are emergent patterns that form dynamically by discovering new links between apparently unrelated concepts. Many visionary entrepreneurs developed their ideas by connecting different concepts. For example, Niklas Zennstrom and Janus Friis, co-founders of Skype, envisioned the internet as a provider of a free global phone communication service. They made the connection or analogy between internet and the phone. Research in Motion, founded by Mike Lazaridis, developed the BlackBerry, a smart phone that could send/receive e-mails by accessing internet using wireless cellular networks. This idea connected the cell phone industry with the internet.

Cognitive factors likely to have critical roles in opportunity identification are active search or alertness and a rich prior experience and knowledge. Comparisons between novice and experienced entrepreneurs show that they might use different search modes. They may focus on distinct factors: novices put more weight on the novelty of an idea whereas experts emphasize business success factors such as cash flow and markets. This framework suggests that education in opportunity identification should train students to focus on factors that are likely to have a role in the success of a new venture such as searching for apparently unrelated links and exposure to a range of business experiences and opportunities (e.g., case studies and internships). Ideation and divergent thinking is higher in successful entrepreneurs. Entrepreneurs who started more than one business have higher ideation fluency (i.e., generate

more ideas) than those who only started one company. Creativity has been linked to entrepreneurial intentions in students. A higher level of self-perceived creativity is associated with increased entrepreneurial intent (e.g., desire to own a business). These findings suggest that entrepreneurial education should address students' entrepreneurial desirability and creativity, not only the technical and business aspects of entrepreneurship.

Entrepreneurs' creativity is associated with firm-level innovation, and the strength of the relationship is higher in a highly dynamic environment. There is a positive relationship between creativity and radicalness of innovations, not the sheer quantity of innovations. Moreover, the relationship between creativity and firm-level innovation is stronger in a more dynamic environment. The role of innovation in entrepreneurship and business success has been researched extensively. It is generally assumed that innovation creates a competitive advantage that positively impacts business success, but empirical research is somewhat mixed. Studies have shown there is a small but significant effect of innovation on business performance.

Innovative entrepreneurs like to challenge the status quo, defined as a desire to change the way things are done or to create something entirely new. They recognize opportunities. For example, Michael Dell of Dell Corporation had a vision to offer affordable personal computers, unavailable at that time. Sergey Brin and Larry Page wanted to change the way web searching was done. Innovative entrepreneurs often engage in activities that allow them to come up with such transformative ideas. They use what-if and why questions to challenge the status quo. Michael Dell asked why a computer cost six times more than its parts. Dean Kamen, the inventor of Segway, asked what if a wheelchair could climb stairs and invented one that did just that. Entrepreneurs observe everything that happens around them in day-to-day experiences (i.e., passive search for opportunities). For example, Howard Shultz, the founder of Starbucks, observed coffee bars in Italy for weeks and noted what people enjoyed about them. Entrepreneurs like to experiment, learn and explore new things. They often engage in idea networking with people of diverse backgrounds. Innovative entrepreneurs engage in these type of activities more often than managers.

Creativity in Entrepreneurial Teams

Although the image of the lone entrepreneur is a popular one, most entrepreneurial activities involve small teams. Teams are typically small groups of individuals with differing but complementary skill sets who depend on each other for the successful attainment of the team goal. These may be the team of founding members or teams formed for specific aspects of entrepreneurship such as marketing. Some researchers claim that such teamwork enhances the success of entrepreneurial activities. This is consistent with the other research on the positive effects of teamwork and other forms of group interaction on innovation (see groups, teams). Teams can benefit from the multiple perspectives and skills of their members to achieve the complex goal of taking an idea through the various stages required for entrepreneurial success. These include idea development, modification, and feedback and the development of a talent pool for the production and marketing of

the product. Teams also need to be creative in recognition of opportunities in markets and technology. Although there is a growing literature on innovative and entrepreneurial teams, much of this literature relies on surveys of team members and managers. Some studies suggest that such reports may not always be accurate indicators of the processes and outcome related to innovation. However, there is considerable consistency among various studies in findings and among the survey studies and studies in more controlled settings with objective measures of process and performance. Hopefully, future research will confirm this consistency and the validity of the prevalent generalizations.

Most entrepreneurial teams are likely to be co-located, especially during the early stages of the process when frequent face-to-face collaborations are required. However, sometimes the diverse skills and interests required involve geographically distributed or virtual teams. These teams have to rely on the various media such as email, teleconferencing, and video conferencing to facilitate their collaborations. Such teams can be effective, but they tend to be more difficult than conventional teams to manage effectively. It is difficult to build the cohesion, trust, and the transactive memory (knowledge of who knows what in the group) required when group members are not co-located, especially during the early stages of the entrepreneurial process. Some degree of training for the team members and the leader on the key principles for effective functioning of such teams is likely to be helpful. It also appears to be important to supplement the virtual team interaction with periodic face-to-face meetings.

Creativity in entrepreneurial teams is a complex and multifaceted phenomenon. It involves creative thinking in many different phases. Unfortunately research on groups and teams has not provided much insight into the unique processes related to the different stages. Research on ad hoc groups, often in laboratory settings, has focused mostly on the process of generating ideas while research on work teams has emphasized the actual implementation of ideas. Very few studies have examined how the outcome of one process affects the subsequent ones. Often there is a distinction made between exploration and exploitation processes. The exploration processes are the creative/divergent thinking ones involved in the development of new ideas or initiatives. Often these may be incremental in that they involve modifications of existing ideas, products or processes. However, sometimes they can involve radical changes in approach or paradigm. This requires that the team members are strongly oriented to risk taking, experimentation, and innovative thinking. Exploitation involves the subsequent evaluation, selection and development, and marketing of the innovations. It is often difficult to balance the exploration and exploitation processes in an organization. These may require different types of people and processes. Apparently some of the most successful companies use an ambidextrous organization in which the exploration and exploitation are separate units but are integrated at the senior executive level. This way the organization can effectively maintain a culture in which rapid and disruptive innovations can be developed without distracting from the incremental processes required to maintain operational success for products already developed. Others have emphasized the importance of originators of ideas staying with the development of products related to their idea given

their unique perspective and background relevant to this idea. However, such an approach can probably be accommodated in an ambidextrous organization.

Effective Entrepreneurial Teamwork

Since entrepreneurial teamwork requires much complex coordination, it is important that team members have the necessary social skills in addition to creativity and task relevant skills. One important skill for teams is the ability to adapt to changing circumstances. Since the exploration process involves much uncertainty and numerous potential dead-ends, it is important that team members evaluate their activities and adjust them in accord with changes required for maintaining positive momentum in the team toward innovative outcomes. This type of team skill is sometimes referred to as team reflexivity.

Many entrepreneurial founding teams are composed of individuals who are rather similar in values and background. This enables them to maintain the social cohesion required during the difficult early stages of development. However, to maintain their innovative edge, especially for radical innovations, it will be important for such teams to incorporate team members with diverse skills and perspectives. This can be accomplished by a gradual turnover of membership in the team. Such teams can help maintain some level of cohesion while continually bringing fresh perspectives into the team. One such team that started with individuals who had similar values and later incorporated team members from different backgrounds to maintain a creative and technical edge were the founders of *Fast Company* magazine. This was launched by a team of two ambitious entrepreneurs Alan Webber and Bill Taylor, former *Harvard Business Review* editors. With the help of its diverse work force, the company created a social network online called the 'Company of Friends.' This soon became a business support group where people with diverse skills and backgrounds met together, discussed challenges in their businesses, brainstormed together and found exceptional solutions. Hewlett-Packard (HP), one of the world's largest information technology companies was also formed by two individuals from very similar backgrounds. Hewlett and Packard were electrical engineers from Stanford University. Over the years HP collaborated with various other companies such as Sony and Yokogawa Electric to develop several high quality and innovative electrical products. Working with other companies and merging with Compaq Computer enabled HP to develop successful lines of scanners, cameras, and computers and develop sales of over 100 billion dollars a year.

Innovation requires effective communication among team members and with others outside the team. Communication with individuals outside the team can help supplement gaps in knowledge and skill in the team as well as providing a means of assessing the validity of the ideas expressed by team members with unique expertise. However, one has to be careful to balance the amount of time one spends in communication with outsiders and the amount of time spent on actual development of innovations. There is some evidence that being too centrally involved in communication networks may detract from innovation. At some point the group members have to make a best decision and move forward or the opportunities that exist for the application of the innovation may disappear.

Leading Entrepreneurial Teams

Ideally entrepreneurial teams have a considerable degree of autonomy in carrying out their goals. Such feelings of autonomy are important for maintaining the intrinsic motivation that underlies much creative and entrepreneurial behavior. However, groups do require a degree of monitoring and structure in order to be effective. This function typically resides in a team leader. This person can be part of the team (potentially the founding member) or can be someone external to the team (as in larger organizations). The role of the leader should be to help provide the vision for the team and to provide financial, emotional, and structural support for the innovation process. One type of leader that has been associated with enhanced innovation is a transformational leader. This leader inspires group members through high expectations and a shared vision, provides individual consideration and support, and encourages team members to take new approaches. However, there is also evidence that the type of leader should vary with the stages of the entrepreneurial process and the degree of diversity of the team. At the startup phase of the entrepreneurial process, a team with diverse members may need a directive type of leader who makes sure the team focuses on its common goals and does not become distracted by conflicting perspectives. Later on in the development process, a more empowering or transformational style may be best to maintain a high degree of motivation and an effective sharing of diverse perspectives. This would require either a change in leadership style over time or the ability of the leader to modify his or her style as the needs of the team change.

The Role of Creativity Training in Entrepreneurship

Many entrepreneurs attend a university before delving into new ventures. However, research indicates that the ability of university students to identify entrepreneurial opportunities is suboptimal. This suggests the importance of training students in creative problem solving and enhancing their ability in identifying entrepreneurial opportunities.

Creativity training occurs in disciplines such as art, architecture, and design. All these areas share a common required outcome of their work – novelty. Additionally, design disciplines add attributes such as usefulness, feasibility, elegance, and simplicity to their work. Creativity is commonly taught to students in design, architecture, and mechanical/manufacturing engineering but very rarely in computer science.

In engineering, creativity has been introduced as exercises/training to promote divergent thinking or idea generation techniques (e.g., brainstorming). In the former case, manufacturing engineers have increased their tendency to generate new solutions, while in the latter case the training has improved scores on creativity tests. Positive effects of creativity training have been attributed to enhancements in the following areas: good thinking skills (e.g., divergent thinking), positive attitude, confidence, motivation to be creative, and reduction of anxiety about creativity. The effects of short-term training on creativity do not persist over time and do not transfer to situations significantly different from those experiences in training. However, it appears to be possible to train students to seek new ideas and to

try novel approaches. Past studies have shown that students who receive lectures on creativity and counseling about their creative styles design more elegant and creative projects than those who attend the lectures only.

In computer education, students do not learn creativity and innovation explicitly; they are not essential requirements of computer products (software or hardware). Creativity emerges mostly in the process of producing novel and useful computer applications. Information and communication technology experts and students perceive their work as highly creative because of the opportunity offered by programming to create new artifacts. Some researchers have examined the cognitive processes that underlie creative innovations in computer science. They see creativity as arising in the process of coming up with a new problem – by frustration with repetitive, dull tasks and by identification of a need for a new product, technology, or application (i.e., frustration-based creativity). Computer scientists use local or distant analogies in coming up with solutions to their problems.

Training in entrepreneurship commonly occurs in business schools and in engineering schools. In business schools, the focus is on acquiring the right business skills needed to start a new business. In engineering schools, the objectives are a balance among innovation, technology, and business skills. Interdisciplinary programs between business and design students that stress entrepreneurial thought and action with design thinking and team building have also been introduced.

Cultural Diversity in Entrepreneurial Teams

Diversity in teams helps foster the creative expansion of ideas. Many studies suggest that creativity in teams may be influenced by the type of diversity present among team members.

Diversity refers to individual differences on any attribute that causes us to view another person as different from self. There are many types of diversity that group members bring into their work groups. Demographic diversity or social categorization diversity refers to differences in group members in terms of characteristics such as age, gender, or ethnicity. Informational diversity refers to differences in knowledge bases that are more job-related, such as educational and functional background. Value diversity refers to differences in values, beliefs, and attitudes.

Informational or functional diversity in a founding entrepreneurial team is associated with high quality strategic planning and product innovativeness. This may be because interdisciplinary entrepreneurial teams can integrate the wide range of technical, marketing, and financial knowledge that is available at their disposal. There is evidence for the positive impact of interdisciplinary teams on openness and propensity for strategic change. These characteristics enhance innovative and strategic planning on new ventures. Informational or educational diversity in entrepreneurial teams also gives rise to cognitive diversity. Multiple perspectives among team members facilitate insightful discoveries and innovative products. Furthermore, entrepreneurial founders from various disciplines have a greater ability to identify and interpret relevant information in various areas. They consider a larger set of information that is relevant to decision-making. This results

in monitoring, retrieving, and evaluating the technological and financial market at a larger scale and enhances opportunities for product innovations.

Environmental scanning is one of the many important ingredients in successful innovation. It requires entrepreneurs to recognize and adapt to changing demands of the society. Team members need to perceive and process external information to gain insight into the needs of customers. Thus, when team members have diverse informational backgrounds such as technology, sales, or marketing they can conduct a comprehensive search of external information along various dimensions. There is a general notion that extensive environment scanning may lead to identifying potential competitive opportunities and producing innovative products.

Heterogeneous perspectives in new ventures in entrepreneurial teams may occur not only as a result of informational diversity but also as a result of demographic diversity. Diversity in terms of age, gender, and cultural background may increase creativity, innovativeness, and success. In cross-cultural entrepreneurial teams, there is a greater exposure to multicultural experiences as a result of visiting various countries. These experiences cause team members to tap into unconventional knowledge by incorporating ideas from various cultures, thereby facilitating creative problem-solving. Other findings indicate an increase in creativity in societies that embrace outside influences and are both politically and demographically diverse.

In diverse entrepreneurial teams, interpersonal and inter-organizational relationships among team members may also influence performance. A considerable amount of team cohesion is important for both effective and efficient use of available resources especially in cross-cultural teams. Recent literature on networking teams suggests that the impact of functional diversity drops drastically when more teams network together since greater network range results in lower internal cohesion. Further, networking among culturally diverse teams is associated with more communication errors, distrust of outgroup members, negative stereotypes, intragroup rivalries, poor cohesion, and a decrease in overall performance. This suggests that lack of cohesion stemming from cultural diversity may impact performance negatively in cross-cultural as well as non-cross-cultural diverse entrepreneurial teams.

Although dissimilarity of perspectives in entrepreneurial teams facilitates creativity, dissimilarity in terms of cultural dimensions is associated with poor communication, more conflict, less social integration, and more departure from such groups. However, these negative effects can be offset by enhanced communication among team members. In other cases, greater similarity in terms of skills, functional background, and attitudes in entrepreneurial teams may lead to minimizing cognitive conflict and reaching consensus in pursuit of group cohesiveness. This phenomenon is called groupthink. In small teams, people may avoid promoting conflicting viewpoints which is a key in the development of multiple perspectives and innovative solutions. Groupthink in entrepreneurial teams may hinder creativity by discouraging the merger of conflicting ideas that are important to developing novel and innovative new ventures. Several researchers suggest that novelty of an entrepreneurial idea is a prerequisite for successful ventures. Further, the amount of time members in an entrepreneurial team have spent working with each other may also

influence performance. During the initial stages of group development, there is evidence that ethnically homogenous groups perform better than the ethnically heterogeneous groups. However, in the long run heterogeneous groups outperform the homogeneous groups on some measures.

Although some knowledge gaps still exist in regard to the impact of diversity on entrepreneurial teams, there is also relevant research on the effect of diversity on the performance in brainstorming teams. This research involving demographic diversity has found that there is value-in-diversity. Many studies indicate that demographic diversity such as gender, ethnicity, and nationality can increase the number of perspectives and alternatives in group decision-making. When people from varying knowledge, gender, and ethnic backgrounds bring insights to the group, it increases flexibility and generation of higher quality ideas. However, these studies also found negative effects of demographic diversity on interpersonal relationships among team members.

In ethnically diverse settings, team members tend to categorize themselves and others on the basis of social categories, such as race, gender, or ethnicity, which leads to the perceptions of similarities and differences in the work group. People isolate themselves from those different from themselves and are attracted to similar others. The perceptions of differences among group members may lead to conflicts, lack of trust, and lower group commitment. Team members tend to favor ideas and opinions of similar others over dissimilar others, which in turn leads to potential conflict in groups. It has been found that similarity to in-group members increases in-group cooperation, trust, social attraction, higher member commitment, group cohesion, and fewer relational conflicts. In some situations, racial or national diversity appears to interfere more with group processes than gender or personality diversity. On the contrary, information diversity in brainstorming teams is associated with increased generation of ideas as well as higher quality (novelty) of ideas.

The literature on brainstorming teams suggests that diversity seems to act as a double-edged sword. Diversity can increase performance, provide broader perspectives, more innovative ideas, and a greater pool of potential solutions, but it can also cause problematic intragroup relations through increased conflicts and decreased group cohesion stemming from the lack of similarity.

There are several factors that appear to be important in determining the impact of diversity on creativity. First, the diversity has to be relevant to the task. If the variation in team characteristics does not enhance the diversity of task relevant perspectives, skills, or approaches, it is unlikely to enhance the creative potential of the entrepreneurial team. In this case, the effects of diversity may actually be negative because of the interpersonal differences. If the diversity is relevant to the team task, then positive effects are most likely observed in team members who are highly motivated to take advantage of this diversity. This usually occurs if the group members have positive interpersonal bonds based on some shared identity, team cohesion, or shared positive attitudes about diversity. Under those conditions team members appear to effectively build on the ideas and contributions of fellow team members.

Conclusion

Most entrepreneurial ventures involve the process of identifying opportunities, evaluating opportunities, and successful implementation of innovative ideas. Creativity is an important ingredient in opportunity identification and implementation stages. Tenacity, perseverance, self-efficacy, proactivity, and risk-propensity are other important qualities that contribute toward successful innovation. Over the years, several training programs have been developed to enhance entrepreneurial orientation.

Many entrepreneurial endeavors are started by teams of individuals. Entrepreneurial teams may enhance success in ventures because of the multiple perspectives and skills that team members bring to the table. However, in order for teams to be innovative, effective communication among team members is necessary. The composition of entrepreneurial teams may also influence innovativeness and creativity. Our review suggests that in the absence of groupthink, informational diversity is associated with quality planning and innovative products. Further, demographic diversity among team members may hinder innovativeness when cohesion and efficient communication are lacking. Entrepreneurial teams that have strong interpersonal bonds and shared goals should be able to take advantage of both the demographic and informational diversity in their team.

Everyday Creativity

Glossary

Eminent-level creativity This regards creative persons or their creative products where recognition has been awarded by society at large, or by relevant organizations, and may involve awards, honors, prizes, publication, performances, or other forms of distinction. Criteria may vary, and may be implicit or explicit – the common factor here is social recognition. Such creators and their works are often thought to have exceptional qualities (although later generations might not agree). The term may also be applied to the underlying creative process.

Everyday creativity This regards the creative outcome (products, ideas, or behaviors) that involve day-to-day activities at work and during leisure time, or the person or process involved. Everyday creativity is characterized both by originality (involving new or unusual aspects) and meaningfulness to others. Beyond this, many manifestations of everyday creativity are possible, be this in office management, raising children, repairing a home, cooking a meal, or doing community service. Indeed, everyday creativity, viewed as a survival capacity, or motive for ongoing growth and human development, would necessarily have this universal applicability. Studies of creative *process* and *person* underline the many healthy aspects of living openly in the present moment.

Mood disorders Families of mood disorders, or affective disorders, in milder forms sometimes linked with everyday creativity, defined by multiple criteria in the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*. Disorders are characterized particularly by lowered or depressed mood (unipolar depressions – most significant also if there is a bipolar family history), or by alternating mood elevations and depressions (bipolar disorders); Bipolar I and II disorders each involve

major depressions; they differ in nature and degree of mood elevation, very dysfunctional in the first case, relatively more functional, even creative and productive, in the second case. Such moods may alternate with significant periods of normalcy – particularly with adequate treatment. Genetic factors have been shown by twin and adoption studies to contribute, although environment has a major (and so far incompletely understood) role.

Self-actualizing creativity Everyday creativity may help pave the way toward higher forms of creativity, and human development, involving what Abraham Maslow called *self-actualizing creativity*. As with everyday creativity, self-actualizing creativity can manifest throughout all of everyday life, more a way of life than special skills, drawing on diverse qualities of the person – here generally toward Maslow's self-actualizing way of life, and becoming one's potentialities, a high goal in Maslow's hierarchy of needs. Self-actualizing creativity draws from the personality and from higher 'being' values. Included are qualities like courage, spontaneity, perspicuity, freedom, and integrity.

States of consciousness Clearly distinct from ordinary waking consciousness are states such as sleeping, dreaming and meditation. More generally, altered states of consciousness can be said to involve "stable patterns of physiological, cognitive, and experiential events different from those of the ordinary waking state . . ." Creativity may involve some such alterations. Altered states may include ". . . changes in the registration of information and acting on it in a goal-directed manner (consciousness); the explicit knowledge of one's situation, mental states, and actions (behavioral consciousness); the stream of thoughts, feelings, and sensations that one has for oneself (subjective consciousness); and the sense of existence of the subject of mental acts (consciousness)" (Baruss, 2003, p. 8).

What Is Everyday Creativity?

One still hears it, "I can't draw a picture – I'm not creative!" As if all that creativity is about is artistic activity. Thus, the person decides, creativity is not for him or her. Meanwhile, what we call everyday creativity is not only universally available, but is essential to our very survival as humans, to our flexible accommodations to changing life conditions. Further, it can enrich our lives, and help us to further unfold our human potential.

Defined only by criteria of *originality* and *meaningfulness*, as below, everyday creativity can apply to anything from drawing that picture to raising a child, organizing the office, fixing the car, planning a family vacation, or counseling a friend. In process

terms, everyday creativity offers a way of meeting life that can enrich the moment, bringing us greater awareness, openness, and vivid appreciation of the world and ourselves. One finds that here are ways of integrating parts of our experience and mind–body continuum, and flexibly orchestrating mind states toward results that, all else being equal, seem healthy for us as individuals and cultures. Below four areas are considered:

1. What is everyday creativity?
2. Healthy effects, including some mental health paradoxes;
3. Creative mind states; and
4. Creative normalcy, why it's needed, and how we can enhance it.

It is also important, to begin, to consider what *everyday creativity* is not. For some people, creativity and Eminent Creativity are the same thing.

Eminent-Level Creativity

This subtype of creativity, which we are apt to most read about in the newspapers, may be called eminent-level versus everyday creativity. Here is the prize-winning playwright, the best-selling novelist, the distinguished artist, the groundbreaking scientist, or the Internet innovator with software that ties the world more closely together. Often these are accomplishments in the 'traditionally creative' areas of the arts and sciences. Most often, these have also received some significant form of social recognition. The criteria aren't so much about originality as how it is received in a culture.

Such creativity can be amazing. Yet, for too many people this is where creativity also ends. If they themselves don't have stellar levels of recognized accomplishment, then it doesn't count. Such people may also be equating creativity with the arts – or perhaps sciences – rather than as a way of life, which can be applied everywhere.

Everyday Creativity – Identification

Only two criteria are required for everyday creativity, after creativity researcher Frank Barron: *Originality* (the product or outcome needs to be relatively new or unusual) and *meaningfulness* (the creation is not random or idiosyncratic). Everyday creativity is less about *what one does* than *how one does it*. At best these approaches, tendencies, or cognitive styles can even become a way of life. Examples of everyday creative *product* or outcome include a sympathetic coworker saving her friend from a breakdown, an at home mother developing a thriving cottage industry to keep her family fed, a high school teacher who inspires new involvement in social studies, and social change, in an inner city school. Yet these creators also take their innovative approaches home with them. As Barron said, originality is 'habitual' with highly creative persons. Scientists do not turn their originality off when they leave the laboratory, nor artists when they leave the studio. And do note that Eminent Creativity, as defined, is not different than, but is a *subset of, everyday creativity, where the work has also received extraordinary social recognition*.

Through the lens of chaos theory, creativity may be viewed as a distinctly human hallmark of life's emergent systems (here using a term from nonlinear dynamical systems theory, or chaos theory) – of systems found everywhere from the working of our brains, to the weather, economic systems, and the rise and fall of governments. What is called creativity may involve a profound working out of a fundamental life force toward change, complexity, and benefit in our manifest reality, by human beings with intentionality, inspiration, and vision.

Everyday Creativity – Is It Real?

Is 'creativity' a 'real' quality or a fabricated human construct? This is a critical question. Here, creativity broadly defined,

must be the everyday creativity that fuels our flexible improvisations and adaptations to changing environments, for all humans. As our 'phenotypic plasticity,' it is seen as fundamental. (Other forms of creativity may be viewed as subsets of this broader category.) One thus turns from creative *product*, as above, to other of Rhodes' Four Ps of Creativity, namely creative *process, person, and press* of the environment. 'Phenotypic plasticity,' according to evolutionary biologists, involves our human capacity to manifest in different ways within our genetic endowment and environmental conditions. Unlike birds and other creatures who are more instinct bound – consider birds building a nest – human beings have flourished all around the world, building a remarkable diversity of homes, lives, and cultures, across varied conditions and climes. Some do this more routinely than others. Here one speaks to both creative *process* and to the more creative *person*. Indeed we could all further develop our creative potential. And this is not just about a special ability or two, but about attitudes, values and an approach to life.

Later we shall also address everyday creativity as a genetic *compensatory advantage*, in special situations. Any such evolutionary value must occur at the level of everyday creativity, to have any survival value, and not be selected against down through the generations. Authors such as Fred Abraham, Liane Gabora, and Scott Barry Kaufman have written about models and possibilities. Drawing on evolutionary biology and chaos theory, Richards has, in an open systems context, suggested that individuals find, in conjunction with others, a 'cognitive niche.' This includes a need within human society for certain persons who *seed change* and *live closer to the metaphorical edge of chaos*. They are the initiators, and others respond. (Most everyone knows people like this.) This leavening effect may happen at the everyday or the eminent levels of creativity.

In this regard, everyday creativity may seed spurts of *eminent creativity* in a culture. It may also produce broader cultural appreciation of novelty and change, as for instance among Ray and Anderson's so-called *cultural creatives*, said to include about one-quarter of the population of this country, who are more able to accept, appreciate, and incorporate innovations of others, and style changes, into their own lives. Hence one is also concerned here with the Fourth P, the *press* of the creative environment. In an open systems sense, we refer not just to what spurs creativity, but the matrix in an interconnected culture that will accept and use it. Perhaps one person discovered how to create fire. How quickly every home had a fire burning. (Plus, consider the relative survival of the group that was more hesitant and did not embrace this new discovery.)

Beyond Survival – Self-Actualizing Creativity

Creative process can also be viewed as a humanistic force in ongoing growth and development – in actualizing one's potentialities. New research on creativity and health further underlines its value as a force in human wellbeing and development. Abraham Maslow, who spoke of self-actualizing persons, viewed self-actualization as a peak in his hierarchy of needs, and *self-actualizing creativity* (vs. special talent creativity) as linked to this. Maslow (1968) said:

SA creativity stresses first the personality rather than its achievements, considering these achievements to be epiphenomena . . . It stresses characterological qualities liked boldness, courage, freedom, spontaneity, perspicuity, integrity, self-acceptance . . . the expressive or Being quality . . . rather than its problem-solving or problem-making quality. (p. 145)

Hence *self-actualizing creativity* is almost a byproduct of a way of life that is healthy, open, more evolved, and attuned to what he called Being Values (e.g., truth, justice, beauty) rather than Deficiency Needs of the self-concerned individual. Maslow proposed that we are motivated to actualize our potentials and talents “toward fuller knowledge and acceptance of (our) own intrinsic nature” (p. 25). Celeste Rhodes extended Maslow’s hierarchy to speak specifically of *deficiency creativity* – spurred by lower personal needs and wants – and beyond this, *being creativity*, that transcended more self-serving motives, toward universal themes, values, and altruistic motives. The first can indeed morph into the second, as in the author who writes of childhood traumas, first to heal, but later to connect with universal strands of pain, growth, and humanity

Self-actualizing creativity is often practiced, in more humble ways, “in the ordinary affairs of life . . . like a tendency to do *anything* creatively: housekeeping, teaching, etc. (p. 137) Under the right conditions, one can imagine everyday creativity providing spur to a higher path of development. For some people it could even contribute to a spiritual path, through the rich simplicity of deeper knowing, beyond ego, in the present moment, manifesting in one’s life in a way more consistent with Eastern models of creativity, as Zen Master Loori and others have described.

One Creativity or Many?

J. P. Guilford postulated 120 different structure of intellect abilities; a subset of these, called ‘divergent production’ abilities, 24 in number, were particularly linked with creativity, across verbal, visual, and other modalities. Howard Gardner has written about seven multiple ‘intelligences,’ including linguistic, musical, mathematical, spatial, kinesthetic, personal, and interpersonal capacities. Some people can be good at painting, some at mathematical problems, and some at modern dance. Whence comes ‘everyday creativity’?

The notion of everyday creativity is not in conflict with the idea of discrete abilities or talents. Everyday creativity is not necessarily an ability, or *only* an ability. For one thing, it appears to relate to personality factors found in highly creative people across fields. Originality is ‘habitual’ with highly creative persons. Scientists do not turn their originality off when they leave the laboratory, nor artists when they leave the studio. They tend to encounter the world in more transforming ways than another person might do. In fact, in a recent edited book, bringing together some celebrated and visionary authors, called *Everyday Creativity and New Views of Human Nature*, 12 integrating themes for the volume included many stylistic and characterological features. Themes included qualities such as Dynamic, Open, Conscious, Nondefensive, and Brave.

Everyday creativity, as a disposition or style, may potentially lead to the ‘self-actualizing creativity’ of humanistic psychologist Abraham Maslow, as above. Along different

lines, research on everyday creativity and bipolar affective disorders indicates that higher creativity appears in connection with somewhat milder forms of bipolar disorders – as dealt with further below. This may yet be in the service of health, not appearing in the most severely ill. The pattern appears despite subjects’ areas of endeavor. There is higher familial creativity in many cases, but it does not ‘run true’ to a particular modality or interest, such as the Bach family of musicians. Hence the creative impulse might emerge for one person in art, one in schoolteaching, and one in business.

In the area of cognitive style (modes of thinking reflective of underlying personality trends), greater ‘overinclusive thinking’ has been found among creative persons in general. *Behavioral overinclusion* involves the number of elements in a category. *Conceptual overinclusion* regards the range of classification rules involved, which may be more vague, developmentally primitive, or distant. Overinclusion has also appeared among people with bipolar mood disorders, especially when hypomanic, consistent with tendencies toward ‘loose associations.’ Overinclusion has also been a consistent finding both with eminent creators, and with everyday creators.

Studies have additionally found greater overinclusion among people in general who were in a mildly good (vs. neutral) mood. This finding helps explain one way in which mild mood elevation may be relevant to creativity. Another primary feature is Openness to Experience, now one of the factors in the Five Factor Theory of Personality. Here one finds, indeed, generality across life activities.

Summary

Hence, everyday creativity, as defined, appears universal and applicable to all of life, and all of us. It is a style more than a special ability, one which, unlike specialized abilities, crosses domains. It appears relevant to survival itself and can be linked to our human ‘phenotypical plasticity.’ It draws on stylistic qualities such as Openness to Experience. At higher levels of personal development it may transform into self-actualizing creativity. However it is probably not well developed in most people.

Can Everyday Creativity Be Good for Us?

Is creativity healthy? This may sound odd to people who are concerned about the likes of ‘creativity and madness.’ However, all else being equal, the effects of creativity tend to be good for us physically and psychologically. The discussion concerns more direct and obvious benefits, as well as the issue of creativity emerging from illness or pain, with potential for resilient coping.

Arts, Creativity, and Health

Here one’s mind–body connection can be seen in bold relief. Although much research on expressive arts is anecdotal and not well controlled, the work on expressive writing in particular is abundant and often rigorous. The writing paradigm of James Pennebaker and colleagues, and related work on the ‘writing cure’ can surprise even the nonbeliever.

Imagine you are asked to write about absolutely the most traumatic thing you ever experienced, and in rich emotional color – something so traumatic you had never told anyone about it. Meanwhile a control group writes about something more neutral. In the classic paradigm, two groups of college students did this writing, remarkably, for 4 days at only 20 min apiece. The results were startling. Although the experimental group was initial more upset (understandably), 6 weeks later they scored higher, and significantly so, compared to the control group, on measures of psychological well-being. And not only had they made fewer visits to the college health center, they were actually higher, compared to controls, on two measures of T-cell function. *That is, the expressive writers were higher on two biological measures of immune function. They were more resistant to disease.*

What were they writing about? Stress of college, loneliness, conflicts with potential partners, with parents, divorce, trauma, death. Is it possible they had not even fully confessed some of this to themselves – or at least integrated it more into their conscious experience? Among multiple replications and expansions upon this basic design, one finds support for integration of fragmented mental structures and freeing of working memory. The working through of the conflict seems particularly important. Art therapists such as Shaun McNiff profess something similar about benefits of art therapy. One doesn't just draw; one processes.

Yet can one say that going out and painting a landscape or doing bird watching is any less therapeutic? Or taking long and demanding hikes and enjoying the beauty of the outdoors, which can indeed be creative? These are questions that need answering. In addition, a growing literature on guided imagery and health is exciting indeed. Using attention and intention, guided imagery can even produce physiological changes. It has been used with breast cancer, diabetes, and eczema among others. It has been said that such imagery is "the very foundation of all mind-body interactions and effect . . . (and) plays a critical role in all health care. . ." And what allows the best access? Our everyday creative minds.

Opening Pandora's Box

The therapeutic benefits of inner processing are of clear interest. In a sense, one opens Pandora's Box, and sees the unconscious, the Shadow, the rejected past – the hidden parts we need to accept consciously for greater balance and integration. One moves ahead resiliently to cope with them, to integrate them into conscious experience. Among descriptors for high everyday creative *process* are qualities of openness and non-defensiveness, along with the 'ego-strength' to make adaptive use of such buried yet rich material.

Accessing such material is not unlike what Ernst Kris meant by 'regression in the service of the ego,' or what Frank Barron addressed when he said "The creative person is both more primitive and more cultivated, more destructive and more constructive, occasionally crazier and yet adamantly saner, than the average person" (Barron, in Richards, p. 33).

Ever greater attention is being given to many forms of arts medicine for healthy confrontation of difficult issues – with indications including grief, shock, depression, cancer, HIV, and more, as recent mind-body medicine books attest. Creative

activity of many types also seems linked to successful aging, to greater acceptance of one's circumstances, to finding purpose and meaning in life. One can also apply this to many everyday endeavors such as mental health effects of journaling, blogging, and perhaps in some contexts, social networking. Can these forms of communication qualify as everyday creativity? They can.

When Illness Yields Creativity

However sunny the picture, there is a connection between creativity and certain illnesses or problems. Yet, the mistake is to think that the creativity is a problem too, when it may actually be the best medicine.

Creativity may be found in a disproportionate amount, for instance in people at risk for bipolar mood disorders – perhaps one of the most common associations one hears about. See the glossary for typical classifications, which include major mood swings, elevation and depression, and more minor variants. They are common, and serious, but can be very treatable. The picture may be healthier for everyday than eminent creativity – and certain cognitive, affective, and motivational advantages for creativity have been posited, as a potential *compensatory advantage*. These have been linked especially to mild (not extreme) mood elevation. This topic is covered more fully in the article on *Bipolar Mood Disorders* within this encyclopedia. But it is important to stress here as well that *creativity tends to be healthy, even and perhaps especially with certain illnesses*.

One can make some general statements. Consider the simpler genetic model of sickle cell anemia, where a genetically homozygous person with the full-blown syndrome may suffer and die young, but where the heterozygote may have a mild anemia at best, but still manifest the compensatory advantage: Resistance to malaria. Everyday creativity has been suggested as a *compensatory advantage* for certain better-functioning individuals at risk for bipolar disorders, and for some mild schizophrenia spectrum conditions as well. Some potential generalizations:

- *'Creative benefit' fits an inverted-U pattern of Compensatory Advantage.* Evidence supports higher everyday creativity in the presence versus absence of risk for bipolar disorders. Yet, contrary to the stereotype, it is not the sicker people who benefit most. Higher creativity is found in better functioning individuals (e.g., cyclothymes not manic-depressives), or people in better functioning mood states (mild mood elevation especially, and not mania.) Beyond that, affective, cognitive, and motivational advantages have all been suggested. One key implication is that *treatment* should tend to help, not hurt, creativity.
- *Both personal and family history need consideration.* Surprisingly, a creative advantage even has been suggested in the psychiatrically normal relatives of bipolar individuals. Subtle and subclinical factors may be operating – perhaps in mild mood elevation – even factors which are not about illness at all. In addition, creativity emerged higher in people with unipolar depression who had, rather than lacked, a family bipolar history. Personal *and* family history are both important.

- *Everyday creativity may work toward health not illness.* Heightened *everyday creativity* in the more mildly affected people at risk, and even in normals, support this, although more work is needed. Perhaps creativity can even be protective for certain children at risk for mood disorders.

Findings may pertain not just to a handful of eminent people, but literally to millions in the population. Akiskal and colleagues estimate that as much as 5% of the population may have a bipolar spectrum disorder. Plus there are more unipolar than bipolar offspring of bipolar parents; finally many more people carry the risk. How important it is if this risk has a silver lining, especially if it can boost health and resilience. Notably, early conflict and difficulty is frequent among eminent creators. How have they overcome, and what were their unusual strengths, resources, models, and supports? Why did they prevail when others did not? Studies of *compensatory advantage* in everyday creative individuals may provide further perspective on creative coping and resilience

Summary

One finds many healthy consequences of everyday creative activity, perhaps seen most clearly in expressive arts therapies and healing imagery. Further study is needed of creativity in other contexts. Further, the link of everyday creativity with bipolar mood disorders – especially with milder conditions – raises new questions about resilience and a *compensatory advantage*.

Does Creativity Involve Diverse States of Consciousness?

One rarely hears about altered states of consciousness in creativity – at least beyond discussion of Mihaly Csikszentmihalyi's *flow*, where a person becomes totally involved in an activity. In sports, the term 'in the zone' is also used for this special state. Interestingly, Baruss in his text, *Alterations of Consciousness*, describes *flow* and its eight features, in the same chapter as Maslow's Peak Experiences (related to self-actualizing persons), and also aspects of meditation.

Surely we have all had at least a few moments of such *flow*. We become so involved that every detail sparkles with intensity, time fades, the world dims around us, and only the effort, only our task, remains – and our work may in fact proceed with a naturalness far beyond the usual meaning of the word 'effort.' Within this harmonious whole, a lot is getting done.

Receptive and Diffuse Mind States

Why not more attention to this and other altered states in creativity? Creativity is often treated as another form of conventional problem solving, using ordinary consciousness. Could one reason be to separate creativity from allusions to the 1960s, to psychedelics and to induced 'altered states of consciousness'? Do 'altered states' to some people seem only about exogenous substances or countercultures? For creativity, this is not at all so!

Flow states may relate to only one part of the multistage creative process. Other possibilities should be studied too.

Flow appears most relevant to the seeing through of a creative work once the main goal is clear – be this a canvas, a script, or perhaps a game of basketball, or creating a party game with children. The challenge is on. Taking Wallas's four stages of creativity, *preparation, incubation, illumination, and verification*, the *flow* experience may involve the illumination and post-illumination working through of a creative idea.

Consider other crucial mind states in creativity, notably involving the *incubation* stage or opening of one's mind to new insights. Rather than intense and one-pointed, this state may be diffuse. The two styles have been loosely compared to *shamatha and vipassana* approaches in meditation, as well as to aspects of Eastern models of creativity.

Psychologist Colin Martindale did key work here a decade ago, now being built upon. He found, on EEG, in the more diffuse and receptive creative stage features including (a) low cortical activation, (b) right hemispheric dominance, (c) theta waves and low frontal activity. The subjective experience of the participants involved associative thinking, defocused attention, and multiple simultaneous representations. Here is a creative stew out of which a bright creative idea could emerge.

Intuition, Stylistic Features, and Relaxed Mental Control

To many, intuition and insight are the heart of creative functioning. Intuition concerns finding the solution to a problem without explicit reasoning toward it. It may involve tacit and vague knowledge; it may be vague and suggestive, and contrasts with insight which is sudden, sharp, and definite. There are varied theories of intuition involving special processes and multiple processes. Intuition may draw on right hemispheric specialization – as Martindale suggested – and on unconscious knowledge, experiential, holistic, procedural, and body wisdom, on affect as well as cognition.

There may be stylistic and preferential aspects, such as being open to one's 'gut' feelings. Adaptive use of 'latent inhibition' is relevant, involving the ability to lower a gating mechanism that screens from attention stimuli previously found irrelevant. S.B. Kaufman has shown this is linked to 'faith in intuition.' It has also been related (in creators) to openness to experience. By contrast it has been linked (in schizophrenics) with thought disorder. Here, indeed may be further evidence of a *compensatory advantage* linked to intermediate levels of key characteristics, where there is mental control to use it, perhaps relevant, again, to what Kris called 'regression in the service of the ego.' There is also apparent fit with creative personality traits such as 'tolerance of ambiguity' and 'preference for complexity.' And with the notion, related to chaos theory or nonlinear dynamical systems, as suggested by Richards, Schulberg, Zausner, and others that the creative person may live intentionally closer to a metaphorical 'edge of chaos.'

Neuropsychological Findings

A range of ingenious laboratory studies by Kounios, Jung-Beeman, Subramaniam, and others have used EEG and fMRI to compare a rapid and more unconscious strategy of problem solving called the *insight* approach to a contrasting and more conscious *analytic* strategy. Note one cannot rule out the action

of *intuition* prior to the creative *insight*; hence with the *insight* strategy, both types of phenomena may be involved.

Tasks could use either the *insight* or *analytic* strategy, such as Mednick's Remote Associates Task, or anagram problems. Participants reported, after solving each problem, what strategies they had used. Of interest, corresponding brain changes were found for *insight*, actually occurring *before* the problem solutions were discovered. The Aha! Moment therefore appeared to be the end of a stylistic preparatory sequence that raised the odds of solution.

In other work, remarkably, EEG changes and distinct brain states were found even *before* the activity was begun, at all. In some sense, participants were anticipating the task and changing mental set. What mental set was this? Similar to what Martindale found earlier, participants using insight strategies showed attentional diffusion and right hemispheric dominance. Beyond this, such strategies have correlated with embedded figures tasks and identifying out of focus pictures, both right-hemispheric and holistic tasks.

Certain results are relevant to creativity as *compensatory advantage*, as reported above, for persons at risk for bipolar disorder showing creativity with mild mood elevation. In addition, Isen and colleagues have shown a mild positive mood appears to augment creative thinking. In general. Here, participants solving Mednick Remote Associates tasks in a *positive mood state* both solved (a) more problems than controls, and (b) more using an *insight* versus *analytic* strategy.

Clearly, there is much more to be learned about brain states and creative inspiration, using neurobiology, behavior, and subjective experience. Research may even open new doors to understanding healthy and integrative effects of creativity in our mind-body continuum, as well as help explain some findings of *compensatory creative advantage*, related to certain personal or familial psychiatric disorders.

Summary

Diverse states of consciousness may be involved, both in the receptive state of everyday creative inspiration and in the more active flow state of realization. New EEG and fMRI evidence is showing that special mind states not only occur during, but actually in preparation for, creative activity. The mysteries of incubation and creative insight are yielding increasingly to scientific inquiry.

Seeking 'Creative Normalcy'

The creative person is not currently the typical, or average, person. Yet what is 'normalcy'? The norm, the average, the usual case. That doesn't necessarily mean the norm is good, or beneficial to us individually or to society. In fact, many scholars and visionaries, for example, in edited books by Richards, or Montuori and Purser, referenced here, posit that being and living more creatively can lead to healthier individuals and a sounder more participative culture. This requires modifying our sometimes conformist and mindless societal norms toward modes that are more aware and alive, diverse and growing – a more creative way of being, and toward a more 'creative normalcy.'

New Views of Central Tendency and Variation in Society

In addition to the 'norm' or central tendency, we can also talk about 'variation' that goes along with it, for example, the standard deviation that accompanies the mean, the range that complements the median. Nurturing creativity means valuing 'a broader acceptable range of normality.' We, in a shrinking and multicultural world, have a wide range of ways to manifest, and many varied gifts to bring each other across lifestyles and across cultures. We need to go farther to appreciate that diversity, that creative variety, rather than push for a normative conformity.

The prices of mindless conformity can be strikingly evident. Consider the famed Stanford Prison Experiment of Phillip Zimbardo (2008) and collaborators from the 1970s. College students who role played guards and prisoners became so involved, so believing of, and so conforming to, their roles, so cruel on the one hand, or so traumatized on the other, that the study was terminated early. Some had to seek clinical help. If one thinks this level of distress and abuse unlikely in our day to day lives, let us just remember Abu Ghraib. We humans have a dangerous potential to go along with the crowd.

Who is most apt to resist such pressures? Surely our everyday creative person, open to experience, nondefensive, non-conforming, courageously questioning. This person, who is alert and aware, mindful not mindless, who will not take things at face value. Here is someone who has developed the skills to create change, to question the *status quo*. And who, nearing higher levels of self-actualizing creativity, may also manifest higher values that benefit all humanity.

Factors that Can Inhibit Our Creativity

There are many factors – as healthy as our creativity can be – that can oppose it. It's worth thinking how some of these may affect us, singly or in combination and estrange us from our own creative birthright.

1. *Idealization of the eminent creator* – our tendency to glorify certain people – heroes, geniuses, and the like – who seem qualitatively different from us and can do (we think, or hope) what we cannot; thus we may disenfranchise our own creative selves.
2. *Fear of as well as mystique of creativity*, coming from irrational places in our minds we may prefer not to access. We may shy from creativity or project our own unconscious material onto others (e.g., the so-called ill creator).
3. *False dichotomies that keep us from our whole creative selves* – as promoted by our culture, for example, thought versus feeling, mind versus body, science versus art, objective versus subjective, male versus female – rather than embracing the whole-person mind-body integration and freedom from stereotypes that frees our fullest creativity.
4. *Resistance to the nonconformist and the new*. Sources of resistance can be grouped into four categories, involving inner and outer, and both conscious and unconscious, factors. These allow us to reject the innovative, either individually or together with others. Particularly fearsome are unconscious self-organizing forces that can subtly squeeze out certain views.

Changing Our Classrooms, Changing Cultures

Studies suggest that too often, some teachers do not greatly value – and even those teachers who think they value creativity sometimes poorly tolerate certain behaviors going along with it. This pattern might sometimes be true in our families, and workplaces as well. This complex situation requires a change in our institutions, with a greater societal valuing of creativity, and of attitudes and values needed to nurture it.

This advocates for a more participatory, less hierarchical structure. In the schools, for instance, there could be greater valuing of the new, of the dissident person, of alternative perspectives, rather than one universal truth, of the teacher more as resource and guide than universal expert. Of the young person or child as a new and valuable resource in the world. Of the value of exploration, and the ability to be wrong, as well as right. Or the use of conflict resolution skills to facilitate creative syntheses between independent thinkers, to smooth the way among diverse perspectives. Finally, greater honor could be accorded to qualities of bravery, challenge, nondefensiveness, and ongoing openness to new possibilities. On top of everything is the joy of creative living that can make this all worthwhile. My recent review in *Creativity in The Classroom* (2010) included the following seven areas for enhancement:

1. *Outer space* – Greater attention to a rich, safe, and accepting environment. Creativity requires an openness and attitude that ‘anything goes,’ at least until later evaluation. It also requires the potential to make – and to value – mistakes, without which we cannot learn. Creativity also thrives in a resource rich environment. Our schools could go far to furnish these conditions.
2. *Inner space* – This is about development and acceptance of inner mental processes, including irrational or unconscious content, and varied mental states, including more right and left-hemisphere dominant modes of processing.
3. *Bravery within* – This alludes to the healthy effects of creativity, which are not won without a cost. As per the previous section III, healthy effects involve challenging oneself, hurdling over mental blocks, valuing this creative *process* more than defending certain fixed views of self. Being non-defensive, and open. Thus one moves beyond ego and more into the present moment.
4. *Bravery without* – This means in one’s environment and in the world. It can mean taking a stand, and challenging the *status quo*. Do we not want our young people to develop this possibility? Consider our frightening potential for conformity in the Stanford Prison Experiment above, and dangers that erupt in so many smaller ways. The creator is able not only to see farther, but to share this, even when difficult, to create a healthier environment, even a healthier world.
5. *Cherishing our creativity* – Not as simple as it seems, this means living with the disruption of multiple views and challenges to one’s opinions and even worldview. It touches on valuing *change* and the process of evolution above fixed views and outcomes. It means, when creating in groups, to value the unique contributions of all, but also the group product, using skills of conflict resolution and compromise to make and honor the mix.
6. *Relating to each other creatively* – Here is our too often overlooked interpersonal creativity, the *relational creativity* we bring

to our awareness and interactions in the moment. We are present, aware, empathetic, flexible, and can manifest mutuality in a give-and-take that is characterized by the hallmarks of everyday creativity, *originality* and *meaningfulness*. The context is one of intimacy and of enhanced group creativity. The outcome can often be, appropriately, a surprise.

7. *Knowing the Joy* – This shining reward can occur at any time, as one goes beyond preconceptions, fears, fixed views of self, to be present, take chances, enter the flow of life, and learn something new. There are also moments of frustration to be sure. Individually, creativity can enhance our further development, our potential for self-actualization. There are advantages for resilient coping, self-healing, seeing multiple options. Interpersonal creativity can also bring us more together and enhance our potential for caring and collaboration. For some people, creativity can further a spiritual path. Creativity is as diverse as we are. Whatever it be for you and me, this delight in being creative appears another sign that this way of life is, overall, *good for us*.

Summary

Making everyday creativity a central part of our life, in schools, in jobs, at home, will require dealing with obstacles, in ourselves and others, and social structures that are not set up for this, along with needed changes in attitudes and values. This could, however, be well worth it.

Conclusions

Everyday creativity is universal, necessary, key even to survival itself. It also holds promise of greater life meaning and even personal development. It seems an intrinsic quality related to ‘phenotypic plasticity,’ our ability to flexibly adapt and change as a function of conditions (or adapt conditions to us). Although we all have it, we could develop our creativity more than we do.

Creativity, viewed as a process, gives us new insight into healthy ways of living. One is more open, less defensive, more richly aware, with implications for physical and psychological health and even immune function. We can use arts, imagery, and more to these ends. There is even evidence supporting a *compensatory advantage* for certain people at psychiatric risk. This too is not about illness but about health.

One sees, in creative incubation and insight functions particularly, signs of innovation in terms of characteristic creative mind states. This draws on hemispheric specialization, unconscious knowledge, affect and cognition, mind–body integration, and other factors including procedural memory, experiential and holistic impressions, and more, which bear further study.

Making creative processing more normative in our culture, and honoring a wider range of ways to be, could diminish some of our mindless conformity and rejection of the new. The creator is especially immune to significant group pressures, while more aware of needed change. Our schools among others could lead in furthering a new valuing of creativity and the diversity we all can bring, toward a healthier population and world.

Glossary

Authenticity A characteristic of a person who demonstrates creativity – ‘authenticity’ literally means ‘author of values.’ The person who demonstrates creativity must form new principles, new heuristics, make new connections, and open new worlds.

Constructionism The belief that the person who creates participates in choosing and shaping the surroundings within which the work proceeds, the skills needed for the work, and the definition of the ensemble of tasks – the person must take possession of whatever is needed for the work.

Constructive repetition An important organizing principle proposed by Gruber – the central theme is that creativity, mastery, and meaningful repetition have an important connection. For example, da Vinci sketched over one thousand hands before selecting the version he used for the ‘Mona Lisa.’

Facet Any aspect of a creative case that can be made sufficiently distinct to permit intensive study of it, whether regarding process, product, content, or context.

Initial sketch The creative person frequently begins work on a project by making a quick and crude sketch of the work to follow.

Intrinsic and extrinsic motivation When the considerations impelling a person to do a certain project are inherent in the nature of the work, either as a process or as

product, we speak of intrinsic motivation. When the motivating considerations are different in kind from the nature of the work we speak of extrinsic motivation. The two kinds, although usually contrasted with each other, are not necessarily incompatible.

Network of enterprise Creative work can be viewed as organized so that enduring enterprises are composed of several projects, and to carry out a project requires engaging in several tasks. The whole assembly of a creator’s enterprises is a network of enterprise.

Pluralism An attitude guiding the investigator, welcoming and looking for the many rather than the one or two essentials. Thus: many metaphors, many insights, many mentors, many motives.

Purpose An essential system of the ‘evolving systems approach’ – the creating person requires the ability to see vividly into the future, to have a sense of mission, and to designate a network of viable strategies to ferry one’s self to the desired goal.

System The way in which the elements comprising an entity are interrelated or organized into a functional whole. It is usually intended that the elements do not completely lose their identity when participating in such an arrangement.

Introduction

The evolving systems approach (ESA) is both a method and a theory created by Howard E. Gruber. Its foundation consists of three pillars: purpose, affect, and knowledge. ESA is designed to study and understand creativity. The focus of ESA is for understanding the uniqueness of the individual creative person at work. It involves no commitment to discovering generalizations one can make about all creative people. Its primary aim is to construct an account, both analytical and developmental, of each creative person considered and to arrive at what may be called a ‘theory of the individual.’ By ‘developmental’ we do not mean an account starting with infancy, but one that starts wherever it is feasible. Fortunately, productive creators usually leave ample traces of their work. The evolving system comprising the creative person includes three major subsystems: knowledge, purpose, and affect. Creative acts are taken to be outcomes of the functioning of this system, and every episode and every facet of the process of creative work engages all three subsystems.

ESA has the following points of emphasis:

1. The approach is developmental and systematic. ESA views creativity as the result of protracted, hard work over long periods of time.
2. The approach is pluralistic. The person who creates exploits many insights, projects, social relations, and educational sources. ESA identifies three essential, wedded systems that give rise to creative production: purpose, affect, and knowledge.
3. The approach is interactive. The person’s work is always conducted in relation to the work of others.
4. The approach is constructionist. The person who creates must reconstruct the elements of a medium to bring a vision to fruition.
5. The approach is existentially, experientially, and phenomenologically sensitive. The person who creates is not considered simply as the maker of the product, but additionally as an active person in a world. He or she is literally living in a medium.
6. ESA proposes that an understanding of creative work requires a conception of the person as an evolving system in an evolving milieu. Each person-as-system is comprised of three subsystems: organization and application of knowledge, a sense of mission and purpose, and a rich affective domain. Each of these subsystems has a dual aspect; in one way it has an integrated life of its own, in another way it contributes to the internal structure of the person’s other systems.

7. The preferred methodology of ESA is the case study. The case study method has a venerable tradition in psychology. It was employed with great effectiveness by such luminaries as Rudolf Arnheim, Sigmund Freud, Jean Piaget, Gordon Allport, Erik Erikson, Jean-Marc Gaspard Itard, Hermann Ebbinghaus, and Alexander Luria. Each made their groundbreaking discoveries through the in-depth exploration of relevant case studies.

One of the important facets of the case study is the initial sketch, which seems to occur in many if not all instances of creative work. For example, when Picasso began the month long effort that produced the great mural *Guernica*, his first move was a small, rather primitive sketch to which he referred repeatedly in the month that followed. Later, we will come to other facets of the creative case study. For the moment suffice it to say that each new starting point serves as a searchlight that reveals new configurations and as a gyroscope that keeps the creator pointed toward remote goals. In this way, selecting a new starting point permits the creator to maintain a freshness of his or her work. In practice, history and evolution guarantee that such new starts will recur incessantly.

If we do no more than vary the starting point of each study, other changes follow so that each new starting point reveals new facets of the creative process. Consider two contrasting points of view: the psychobiographer approaches the case with the primary aim of understanding the historical and personal factors that set the stage for the creative process, without actually examining in any detail the creative work itself. On the other hand, the experimental psychologist interested in creativity, in order to have a manageable experimental design, narrows the focus of attention drastically and increases the number of subjects. The psychobiographer typically pays little attention to the process of creative work; the experimenter relaxes the criteria used in selecting creative subjects (e.g., the more creative half of an ordinary high school class) in order to have enough subjects to complete the experimental design. Taken to an extreme, the assumption underlying much of this experimental research is that everyone or almost everyone is creative to some degree, and we can consequently study the process in the less than great even if our aim is to understand the higher levels of creative endeavor.

By a system we mean a set of distinct components in specified relationships. A simple list of traits is a kind of theory because it proposes to say what is important, but it is not a systemic theory. Only when we examine interrelationships of these members of the system can we begin to speak of systems. Systemic analysis is possible at many different levels, for example, the organism is composed of organs and society is composed of organisms. To choose as one focus of attention a particular level of analysis, or set of levels, need imply no denigration of other levels of their students.

Organization

In the present context, the idea that organization and adaptation are twin aspects of creative evolution could also be expressed by describing them as forces making for stability and forces making for novelty. In the study of creativity, as in all other living processes, there must be continuity and stability.

There is a confederation of scholars interested in creativity, such as genetic epistemologists, Gestalt psychologists, and system theorists. Some researchers in each camp claim superiority for their brand. Each of these approaches can be considered as highlighting some important aspects of the whole process, their totality providing the context for any one of them.

One of the cardinal concepts of ESA is 'pluralism.' At any given historical moment there are several schematizations available to the person, and they can be selected, composed, and arranged in different ways. The principle of pluralism proposes several schematizations, multiple metaphors, and many enterprises are examined, explored, exploited, redefined, fused, and synthesized with the person's current and evolving vision and body of knowledge.

At times, the discipline of psychology seems to present a puzzling spectacle. The same controversies seem to crop up in every generation, such as the conflict between holism and atomism, or that between evolution and stasis, or that between sudden intuitive leaps and incremental change. In 1937, the prominent personality psychologist Gordon Allport wrote, "It is not upon the cell nor upon the single organ, nor upon the group, nor upon the species that nature has centered her most lavish concern, but rather upon the integral organization of life processes into the amazing stable and self-contained system of the individual living creature." (1937: p. 3)

It may be that these repeated controversies stem not from blind commitment to one or another ideology, but from the legitimate necessity to rework fundamental concepts as circumstances change. Allport argued emphatically and at length for the necessity of studying the single case and to point out the various tendencies, in the psychology of that period, to escape from the trap of atomistic, individualistic positivism.

Facets

It is common in psychological research to distinguish between 'how' questions and 'why' questions. 'How' addresses itself to the processes of creative work; 'why' asks, what are the underlying reasons for doing it? To a large extent the failure to separate the two kinds of questions has led to profound neglect of 'how' questions. An important movement in the study of creativity has been psychobiography, which is the application of personality theory, especially Freud's, to understanding creative people. A related effort, psychohistory, applies the same range of theories, not to understanding the individual creator, but rather to historical events for which a psychological theory is proposed. Insofar as these approaches delve deeply into the life of a creative person, they are of very great interest. Unfortunately, to a large extent psychobiography and psychohistory have been the occasion for neglecting 'how' questions. Insofar as these approaches draw upon the early years of the creator they are forced into undocumented speculations. A third category of creativity research is the psychometric approach, in which tests are administered to large enough numbers of subjects to permit statistical analysis. For different reasons these three methods all avoid studying the creative person at work. On the contemporary American scene this has meant a shifting focus on:

- Birth order effects, in which the person becomes creative because of his or her special place in the developing family.

- Bipolar disorder, where the anguish of private life provides the stimulus for creative expression.
- Metaphor, where the ability to see and express commonalities between unlike things is the central ingredient of creativity.
- Great powers of visualization.
- Divergent thinking, the ability or propensity for thinking of unusual responses.

All of these and many more have been singled out as the essence of creativity.

Paradoxically, in the ESA we avoid a singular focus by welcoming all such proposals into our tool shed. However, the uses to which the tools will be put vary from project to project and different creators may accomplish similar ends with different collections of tools. For example, the physicist Richard Feynman solved an important class of physical problems with theoretical tools quite different from those used by others in solving the same problem. Feynman's method was geometric and the others' was algebraic. While in this instance Feynman's method eventually prevailed, the work of the others was also creative. Moreover, the creator does not use one pre-fabricated tool but a collection of them, including some that are invented in the course of work on each project.

Looked at from the creator's point of view, a given facet or facets may be foremost in attention, the vast remainder being the background. The distinction between figure and ground is well known in the psychology of perception. A change in attention may be thought of as a figure-ground reversal. If the figures in question are cherished projects, the creator may experience mixed feelings at the new engagement together with regret at what is left behind. The ground, or context, is so complex and dynamic that new facets are continually appearing. For example, after Charles Darwin published the *Origin of Species* he took up with great vigor questions of physiological botany that had long lain fallow in his network of enterprise. This move brought a certain closure to his work: nearly a century before, his grandfather Erasmus Darwin had written much on botany. Of particular relevance was his long scientific poem, "The Love of the Plants," which the young Charles Darwin greatly admired but never emulated.

For a second example, many scientists who are completely engrossed in their work are nevertheless aware of severe and chronic social disorders in the world around them. Even if they manage to shut that world out it may still cast a dark shadow on their lives.

Insight and Problem Solving

Prior to the introduction of the Evolving Systems Approach, researchers studying creativity tended to ignore processes and emphasized states, such as the sudden epiphany. There was a widespread belief in the prevalence of sudden insights arrived at intuitively, such insights constituting the genuine article, a creative product. An often retold and celebrated story is August Kekulé's account of his discovery of the benzene ring, which he made while half asleep on a London bus. However, if his account is read carefully in light of the Evolving Systems Approach, one can see that he had been moving in that direction for well over a decade, and the dance of the molecules that

he described was not a unique event, but a mode of thought that he employed in his chemical thinking.

The reverie on the bus must be seen in its larger context, the general nature of Kekulé's thinking. Moreover, his thinking must be seen in the still larger context of the history of chemistry in the nineteenth century. Viewed in these lights, Kekulé's epiphany was not a miracle of intuition, but the product of protracted and directed work by a network interested in structural chemistry.

If insight is not the cause or the embodiment of creative work, what is its role in the creative process? First it should be said that insight, when it does occur, takes a variety of forms. As the culmination of a protracted process it may be a sudden change in awareness or it may be a gradual shifting in point of view. With this in mind, there is no great need to define insight *a priori*: researchers employing the evolving systems approach simply study the record, note changes, and describe them (sudden or gradual, aware or unconscious, pursued immediately or bracketed for later attention).

Purposes and Motives

A sharp distinction widely agreed upon is made between intrinsic and extrinsic motivation. The former refers to the self-satisfaction sought in actually engaging in creative work. The latter refers to the satisfaction arising out of recognition, prizes, monetary awards, and the power that comes with fame. With regard to intrinsic motivation we ought to distinguish between the satisfaction deriving from engaging in the work and that derived from completing it. On the surface it might appear as though extrinsic motives correspond to 'why' questions and intrinsic motivations to 'how' questions. But if we take the creator's network of enterprise as a whole as reflecting the totality of his or her intentions, absorption in this set of tasks becomes a powerful motive.

Beginning work on a task sets up a kind of drive for completing it. The question remains open whether this drive is the same as the pleasure in actually engaging in the work. It may well be that in real creative work, both kinds of satisfaction are at work under the broad heading of intrinsic motivation. Meanwhile, it is reasonably clear that extrinsic motivation is also important. Nobel prizes and other blandishments are ever present and highly visible. A plausible hypothesis is that, for whatever reason, at moments when one is not engrossed in the work, extrinsic motivation drives the creator back into it; when he or she is engrossed, the very same extrinsic motives may be a distraction, even a pollutant: intrinsic motivation takes over. In Darwin's notebooks there are few passages indicating extrinsic motivation, but there are some. And it should be remembered that writing the notebooks was itself part of the work process, a record of activity governed by the task, not of activity governed by other considerations. On the cognitive side belief systems evolve throughout the life history, and on the intentional side motives evolve.

Tasks are not undertaken singly. Each task becomes a member of one or more enterprises. These, taken together, form a network of enterprises, and this network can be thought of as the individual's evolving organization of purpose. This network of enterprise, once formed, serves to locate any

given project within it; at the same time, it represents a large portion of the individual creator's self-concept. Every task may be said to have a history. A gap, disequilibrium, or unsatisfactory situation is observed; this leads to the undertaking of a task. Some subset of such tasks forms an enterprise. Seen in this light, an insight need not be the solution to a problem; it may be the initial recognition that one exists. Often, the recognition of a problem unsolved, a voyage not yet taken, can produce the thrill of discovery that we usually associate with solution.

Skill

Studies of persons who demonstrate creativity indicate convincingly that it is important to develop a level of expertise for a domain as a necessary foundation for subsequent creativeness. Astonishingly high levels of skill account for high levels of creativity. But we certainly can find examples of individuals with great skills who are not very creative. For example, among artists there are greatly skilled copyists and plagiarists who can successfully imitate at least one artist and sometimes many. Such individuals become the plague of museum curators, who for all their expertise sometimes fall victim to artistic fraud. So skill alone is not sufficient for creative work. On the other hand skill is certainly a virtue and it is attainable through practice.

Collaboration

Growing out of the extreme individualism of modern Western society, the picture of the creator as a lonely genius is very widespread. But we are coming to see that various kinds of collaborative processes are also important. For example, there is the well-known case of Albert Einstein and the Olympia circle, three young men who met every week over coffee to share ideas. Thus Albert Einstein, during his years working in the Swiss patent office, was not, as is sometimes suggested, alone in his theoretical quest. He had important collaborative opportunities. Another example is the case of Pablo Picasso and Georges Braque, who together invented and initiated the important movement in art of cubism. We have Vincent van Gogh and Paul Gauguin, Dudley Warner and Mark Twain, Orville and Wilbur Wright, Marie and Pierre Curie, and on and on. All persons who demonstrate creativity have significant collaborations during some phase in their creative development, whether it be with teachers, peers, or heroes.

Even in the case of the project that is conducted alone, one almost invariably finds that the individual creator is in some kind of fruitful relation with others. Van Gogh, for example, sent his canvases to fellow artists all over Europe and received theirs, providing a rich language for aesthetic discourse, the work itself. Gauguin and van Gogh lived together in Arles, France, working side by side and simultaneously dreaming of a utopian artists' community. Mythically isolated creators such as Isaac Newton, Albert Einstein, Emily Dickinson, and van Gogh profited from collaborative relationships. To these examples should be added informal groupings such as the Salon des Refuses – artists who were rejected by the French artistic establishment, but nevertheless managed to construct relationships of mutual defense and support.

Conclusion

We need enough case studies to get from the unique creative person at work to whatever generalizations may follow. Post-Grubarians are approaching a position to present a well-founded, well-integrated theory of creativity that is both descriptive and prescriptive. We currently know that creativeness rises and reaches fruition from the viable pluralism of five evolving systems: (1) a rich store of domain-relevant knowledge; (2) the cognitive ability to rearrange and recombine the elements of a domain in service of a synthesis and insight; (3) high levels of motivation to work hard over long periods of time; (4) a sense of purpose; and (5) ability to benefit from collaboration and to benefit from exposure to the ideas of others. It is possible to study an individual in detail without raising individualism itself to cult status. Unique people, which we all are, can work together. Creative work always takes place in a multiplex environment. There is no necessary conflict between respect for the individual and sensitivity to the social nature of all creative thought.

Glossary

Broadening Building skills and knowledge well outside of your current areas of expertise.

Capturing Preserving new ideas as they occur, without judging or editing them.

Challenging Seeking challenges and managing failure constructively.

Core competencies of creative expression Skills that are important for the expression of creativity in individuals. The four core competencies are: Capturing, Challenging, Broadening, and Surrounding (see separate definitions).

Creative problem solving A structured system for solving problems creativity, involving visionizing, attribute listing, problem finding, and other techniques.

Generativity Theory A formal, predictive theory of the creative process that asserts that new behaviors result from an orderly competition among previously established behaviors.

Hypnagogic state The semisleep state people experience when just falling asleep or waking up.

Managerial competencies for enhancing creativity Skills that help managers, teachers, and supervisors elicit creative

expression in other people. Eight important managerial competencies include: Encouraging the Preservation of New Ideas, Challenging Others, Encouraging the Broadening of Skills and Knowledge, Providing Diverse and Changing Physical and Social Environments, Managing Teams Appropriately, Providing Adequate and Appropriate Resources, Providing Positive Feedback, and Modeling Creativity Competencies.

Open-ended problems Problems that have an endless number of solutions. Almost all tasks and goals can be made open-ended by adding a phrase such as 'at least' to the description, as in: 'Please generate at least three names for this new product.'

Resurgence The reappearance of previously reinforced behaviors that occurs when a current behavior is no longer effective.

Shifting Allowing people to leave group or team meetings for short periods in order to work privately on idea generation.

Surrounding Surrounding oneself with diverse and changing physical and social stimuli.

Background

Exercises intended to enhance creative expression have been around since at least the 1940s, when Alex Osborn and Robert Crawford formed the first creativity development programs. In the 1950s, Osborn founded the Creative Education Foundation and the annual Creative Problem Solving Institute, and William Gordon and George Prince founded Synectics, precursors to dozens of training programs and consulting firms dedicated to enhancing creativity in both individuals and organizations. Today, many business schools have also incorporated courses on creativity and innovation into their curriculums, and thousands of companies and organizations, including the US military, feature creativity training in their training programs. Dozens of popular books, such as Julia Cameron's *The Artist's Way* and Michael Michalko's *Thinkertoys*, also promise to increase creativity. Exercises and games of various sorts play an important role in many of these efforts.

Osborn's 1953 book, *Applied Imagination*, described both the Creative Problem Solving technique, later updated by Sidney Parnes, and the now-ubiquitous practice called 'brainstorming.' Both were taught in part through exercises. In brainstorming, people work as a group to generate ideas following guidelines that increase creative output, the most important of which is to withhold judgment when someone voices an idea. Brainstorming groups strive for quantity of creative output,

deferring judgment until a later time. One can teach brainstorming by assigning tasks and problems to a group and then having them follow the guidelines. One can also show the power of the brainstorming rules by comparing the output of groups that follow the rules to groups that do not.

Although particular exercises are usually not evaluated, programs that employ exercises have been evaluated in a number of studies. In a paper published in 1972, E. Paul Torrance reviewed 142 studies that evaluated various creativity-enhancing techniques programs for children and students, many using the Osborn-Parnes Creative Problem Solving technique, concluding that 72% of them had produced positive results. In a review of additional studies published in 1987, Torrance found a success rate of 68%. More recently, Ginamarie Scott and her colleagues at the University of Oklahoma looked at 70 carefully selected training studies with both adults and children and concluded, unambiguously, that 'creativity training works.' This was confirmed in a similar study published by Hsen-Hsing Ma in 2006.

Creativity training studies tend to focus on problem solving abilities *per se*, but creative expression can also be enhanced in other ways: through play, incentive systems, altering the work environment, broadening people's knowledge, providing new resources, changing the feedback that people are given, forming and guiding teams in certain ways, and so on. Exercises can be used to teach all of these concepts.

A Scientific Framework for Understanding Creativity Exercises

Games and exercises for enhancing creativity can be organized into 12 categories suggested by Generativity Theory, a formal, predictive theory of the creative process first proposed by Robert Epstein in the 1980s.

According to this theory, which has been validated in both laboratory and applied settings, the behavior we call creative occurs as previously established behaviors (which also includes thoughts and ideas) become interconnected in various ways to produce blends and new sequences. The process of interconnection is both orderly and predictable; instantiated as a series of equations called 'transformation functions,' Generativity Theory can predict the emergence of novel performances in the laboratory moment-to-moment in time in both animals and people. According to the theory, creative behavior or ideas are especially likely to occur under circumstances that cause multiple behaviors to compete. Two situations invariably cause such competition: when behavior is ineffective and when organisms are exposed to multiple or novel stimuli.

In the laboratory setting, ineffectiveness is studied by first reinforcing behavior (say, with food if an animal is hungry, or with money if humans are being studied) and later by withholding reinforcement, a process called 'extinction.' All situations involving 'problems' are, by definition, extinction situations. Laboratory research shows that extinction affects both behavior and emotions in ways that are consistent with what typically happens when people solve problems. The primary effect of extinction is to weaken behavior: if a problem is sufficiently difficult, initial attempts to solve it fail, and ideas are rejected; in other words, behavior weakens. (If you can solve a problem quickly and easily, it's unlikely that much 'creativity' has occurred; previously established behaviors were apparently adequate for the task.) As behavior weakens, 'resurgence' takes place: other behaviors that were successful in similar situations in the past rapidly increase in probability. Now multiple behaviors (ideas, thoughts, images) are competing, setting the stage for interconnections. This dynamic process is typically felt as 'confusion'; if it continues long enough, more negative emotions are experienced, such as 'frustration.'

From this competition, both new sequences and new forms of behavior (blends) emerge in an orderly way; interconnection is the fuel of solutions to problems and the basis for all novel behavior, some of which is sometimes labeled 'creative.' (That label is applied by a community when it values the novel behavior; one can't label one's own behavior creative.)

Generativity Theory and related research suggest: (a) that virtually everyone has enormous creative potential; (b) that most people tend to express little creativity because of inhibitions created by socialization; and (c) that creative expression can be enhanced both through various environmental manipulations and by teaching people special skills (called 'creativity competencies').

Four core competencies of creativity expression flow directly from the theory: Capturing (preserving novel ideas as they occur, without first judging or editing them), Challenging (seeking challenges and managing failure constructively), Broadening (acquiring knowledge and skill well outside of

one's current areas of expertise), and Surrounding (surrounding oneself with diverse and novel physical and social stimuli). Because novel behavior occurs naturally and frequently, simply teaching people to preserve their new ideas (by jotting things down, keeping a notebook or recorder by one's bed, finding quiet places where one can listen to one's thoughts, etc.) often has a dramatic effect on creative output. Teaching people to seek challenges and to manage the negative emotions that often are produced in challenging situations sets the stage for resurgence to occur and for new ideas to emerge at a high rate. When people broaden their knowledge and skills, more diverse material is available for interconnection, and new ideas tends to be more interesting and unusual. And when people surround themselves with interesting and diverse stimuli, both social and physical, again, multiple repertoires of behavior compete with each other, increasing creative output.

The four core competencies are helpful for individuals. Eight competencies that allow managers and supervisors to enhance creativity in other people also flow from Generativity Theory and research:

1. Encouraging Capturing (encouraging people to preserve novel ideas, and providing resources that make it easy for people to capture such ideas);
2. Challenging Others (giving people difficult problems to solve and ambitious goals to reach);
3. Encouraging Broadening (providing training in areas well outside current areas of expertise);
4. Providing Diverse and Changing Physical and Social Environments (changing the work environment frequently, assembling diverse teams, and in other respects creating an interesting and stimulating environment);
5. Managing Teams Appropriately (assembling diverse teams, e.g., or 'shifting' team members out of the group periodically to work on problems on their own);
6. Providing Appropriate Feedback and Recognition (rewarding people for contributing new and valuable ideas);
7. Providing Adequate and Appropriate Resources (providing tools and supplies adequate to solving problems or generating new products or methods); and
8. Modeling the Core Competencies of Creative Expression (showing others that you, as a supervisor, practice what you preach).

Shifting people out of a team meeting to work on a problem on their own, even for a few minutes, can increase team creativity dramatically. While in the group, the presence of other people, although stimulating, also inhibits creative expression. When people shift out of a group, inhibitions are reduced, and people typically record many new ideas. When the group reassembles, people have a much larger pool of ideas with which to work. With even one brief shift (about five minutes), groups that shift tend to produce 50% more ideas than nonshifting groups.

Managers can challenge employees in many ways. One of the simplest and most effective ways is to make sure that all tasks, goals, and assignments are stated in an 'open-ended' fashion, meaning that what is requested has no set limit. Instead of asking for three new names for a product, for example, a manager can ask for *at least* three new names. Challenge can also be added to deadlines by adding phrases such as 'at the latest.'

All competencies for enhancing creative expression can be taught through games and exercises. Here, organized by competency area, are examples of such exercises.

Exercises that Boost Individual Creativity

Exercises can enhance four types of competencies that are important for creative expression in individuals, which Epstein calls the Core Competencies of Creative Expression: Capturing, Challenging, Broadening, and Surrounding.

Capturing

Exercises can quickly show people the value of capturing new ideas without judging them. Exercises can also help people learn to use a variety of materials to help them capture ideas on the fly and to identify places and times that facilitate capturing – to make use of the ‘Three Bs’ of creativity, for example: the Bed, Bath, and Bus. Some capturing exercises, such as simple daydreaming exercises, do little more than remind people that they have creative potential which they may currently not be exploiting. Studies of people who are famous for expressing creativity virtually always show that they have excellent capturing skills; they obsessively record new ideas on pads, memo recorders, napkins, or whatever is at hand.

Both Salvador Dali, the great Surrealist artist, and Thomas Edison, the most prolific inventor in history, got ideas by making deliberate use of the hypnagogic state – the semi-sleep state that everyone experiences at least twice a day. Dali would lay on a sofa, extending a spoon outward over the edge. On the floor beneath the spoon, he placed a glass plate. As he began to doze off, his hand released the spoon, and it fell to the plate and made a noise, which brought him back to full consciousness. If he had experienced interesting images during his brief hypnagogic experience, he would grab a pad and sketch. Edison got ideas for inventions by relaxing in a chair, holding steel spheres in each hand, beneath which were metal plates.

Although other competencies are important for enhancing creative expression, when people learn and practice capturing skills alone, their creative output sometimes increases by a factor of ten or more. No other competency increases creative output to such an extent.

Here are examples of relevant exercises.

Morning pages

Poet and artist Julia Cameron, author of *The Artist's Way*, teaches people to enhance their creative output by doing stream-of-consciousness writing every morning: so-called ‘Morning Pages.’ Says Cameron, “Every morning, set your clock one-half hour early; get up and write three pages of longhand, stream-of-consciousness morning writing. Do not reread these pages or allow anyone else to read them. Ideally stick these pages in a large manila envelope, or hide them somewhere. Welcome to the morning pages. They will change you.”

Capturing a daydream

In *The Big Book of Creativity Games*, Epstein describes a simple daydreaming exercise: he instructs people to close their eyes, relax, and let their minds wander for a few minutes – in other

words, to have a daydream deliberately. When done in a group setting, almost everyone reports having a daydream, and some are quite bizarre. The exercise quickly demonstrates that daydreaming can be used intentionally for creative purposes. It also empowers; that is, it reminds people that even if they don't normally express much creativity, the generative mechanisms that underlie creative expression are operating inside their heads every day.

The memory game

Another of Epstein's exercises, ‘The Memory Game,’ shows what happens when people fail to capture. Some groups work on a simple problem – say, generating names for a new running shoe – without the aid of paper or recording devices. Other groups work on the same problem and have access to paper and pencils. After 15 minutes, both groups report on their best ideas. The groups that had access to paper will often report three times as many ideas as the groups without paper. The longer the work sessions, the greater the difference in creative output between the two types of groups.

Challenging

Most programs that promise to enhance creative expression do so by improving problem-solving strategies, and all of these programs incorporate exercises of some sort. Dozens of exercises used in the venerable Creative Problem Solving training program are collected in books such as Sidney Parnes' *The Magic of the Mind* and its sequel, *Optimize the Magic of the Mind*. Popular creativity-enhancing books such as Edward de Bono's *Lateral Thinking*, Tom Wujec's *Five Star Mind*, and Roger von Oech's *A Whack on the Side of the Head* are also filled with intriguing problems, as are thousands of books of puzzles, riddles, and mathematical challenges, some of which have been around for centuries.

As noted above, the ‘problem’ is a special case of a larger class of situations in which behavior (which includes thinking) is ineffective. The only way to be effective in such situations is to do something new, or at least to do old things in a new order; hence the connection between problem solving and creativity. Thus, any tough situation in which we don't know exactly what to do is good for creativity, and so are exercises which (a) teach us to value and seek such situations, (b) teach us how to be more effective in such situations, and (c) teach us how to manage the unpleasant emotions we often feel in such situations, some of which can ‘block’ creative expression. Here are some representative examples:

The nine dots problem

Perhaps the most famous problem-solving exercise of all time, this is the exercise that gives rise to notion of ‘thinking outside the box.’ The problem solver is shown nine dots arranged in a square, three-by-three array and instructed to connect all of the dots by drawing four lines or less – without lifting his or her pen from the paper. Initially, people try to draw lines within the square, but they eventually discover (sometimes after experiencing considerable frustration) that the problem can't be solved this way. The solution involves extending lines *outside* the square. The problem appears in a puzzle book published in 1914 and may have even earlier origins.

Half of eight

This is one of dozens of exercises used in the Osborn–Parnes Creative Problem Solving program. It appears in Parnes' book, *The Magic of the Mind*, and elsewhere. When asked, "What Is Half of Eight?" most people immediately reply, "Four." An instructor then asks for more creative replies, and people soon become aware of interesting possibilities: splitting the number 8 into two zeros (with a horizontal cut), for example, or into two threes (with a vertical cut). Employing problems of this sort, a Creative Problem Solving workshop teaches people new strategies for solving problems: visionizing (focusing on dreams and visions), forcing relationships among ideas or objects, listing attributes of a situation, and so on.

Wrestling with your voice of judgment

Negative emotions associated with solving problems or expressing new ideas can be debilitating. In this exercise, from *The Creative Spirit*, by Daniel Goleman, Michael L. Ray, and Paul Kaufman, one is instructed to close one's eyes and imagine hearing a negative statement, such as "You've never had an original idea." Then one amplifies and enlarges it "using laser lights, screaming rockets, full symphony orchestras, and choruses of disapproval," until the message is so big that it looks ridiculous. The exercise derives from a powerful technique used by clinical psychologists called 'flooding.' Michalko teaches a simpler exercise called 'Tick-Tock' that also aims to eliminate harmful thinking: on the tick of an imaginary clock, one writes one's fear; on the tock, one writes a positive thought that overcomes the fear.

Steel pipe

This is from former Stanford University professor James L. Adams' book, *Conceptual Blockbusting*: "Assume that a [4-inch-long] steel pipe is imbedded in the concrete floor of a bare room as shown below. The inside diameter is 0.06" larger than the diameter of a ping-pong ball (1.50") that is resting gently at the bottom of the pipe. You are one of a group of six people in the room, along with the following objects: 100' of clothesline, a carpenter's hammer, a chisel, a box of Wheaties, a file, a wire coat hanger, a monkey wrench, and a light bulb. List as many ways you can think of (in five minutes) to get the ball out of the pipe without damaging the ball, tube, or floor."

Stone soup

This is from creativity consultant Michael Michalko's book *Thinkertoys*: After you learn about an old fable in which a beggar asks villagers to imagine that the stone in his pot can make a delicious soup, you are challenged as follows: "List as many 'what if' scenarios as you can" and then "answer the questions posed by your scenarios." This is an example of an open-ended task with virtually no boundaries. Edward de Bono describes a similar game, called "The 'Why' Technique," in *Lateral Thinking*.

Egg drop soup

Web designer Stefan Mumaw and graphic designer Wendy Lee Oldfield's book *Caffeine for the Creative Mind* includes a classic design problem, sometimes given as a challenge to school children: "Create a container for an egg that will safely keep the egg from breaking when dropped from a two-story window.

The container can be made of whatever materials you deem appropriate. Draw a sketch of the container as if you were going to show a craftsman what your idea is and how to make it. Use a dotted line to signify where the egg would be, inside of the container, and callouts to describe what the materials are and what their functions would be."

Broadening

Exercises can also be used to teach people the value of broadening their knowledge and skills. Generally speaking, the more diverse a person's knowledge, the more interesting the behavioral interconnections – and, ultimately, the creativity.

Reading archaeologically

Choreographer Twyla Tharp recommends a unique way of broadening one's knowledge in her book, *The Creative Habit*. When you read a book that refers to an earlier book – maybe even one written long, long ago – read that one next. Then repeat. She calls this a 'reading dig.' A variation on this, called 'reading fat,' involves reading books related to the one you just read, and then, in turn, books related to those.

Imaginary lives

In *The Artist's Way*, renowned poet/artist/playwright Julia Cameron recommends that you generate a list of professions you might have led in other lives. Then, each week, she suggests *living* one of them to some extent. If you imagined yourself as a bus driver, you could read a pertinent training manual, for example – or even sign up for some *real* training.

Surrounding

Exercises can also help people learn the value of surrounding themselves with interesting objects and people, as well as the value of modifying one's environment regularly.

Artist date

In *The Artist's Way*, Cameron recommends that people go out on adventurous little dates every week. One possibility: "Take five dollars and go to your local five-and-dime. Buy silly things like gold stick-'em stars, tiny dinosaurs, some postcards, sparkly sequins, glue, a kid's scissors, crayons. . . . Just for fun." Fresh environments stimulate thinking and lead to fresh ideas. Michalko recommends nature walks in his book, *Cracking Creativity*, for the same reason. An early trash compactor was invented when engineers got curious about how different animals handled their waste. Goats, it seems, compact it.

Create your own oracle

In his book, *A Whack on the Side of the Head*, creativity consultant Roger von Oech reminds us that in ancient times people consulted oracles or wise men to get new ideas or solve problems. You can create your own oracle, he says, by asking yourself a question, then generating some random information, and then interpreting that information as the answer to the question. For example, you might ask, "How can I become more creative?" and then open a book to a random page and point. I just did this and found the word 'Mexico.' Then interpret: Yes, visiting Tijuana for a few hours (I live fairly near the border) would definitely free up my thinking.

The Srtcdjgklerden Game

It's difficult to pronounce, and that's the point. In this game, from Epstein's *Big Book of Creativity Games*, people are asked to generate sentences as quickly as possible in reaction to random streams of alphabet letters called 'word ticklers.' Stick a dagger in a juggler? Sort your CDs from black to red? The possibilities are endless.

Selling a zork

In this exercise, Epstein also teaches the value of surrounding oneself, and especially one's work area, with unusual stimuli. A trainer first asks for a volunteer 'salesperson' to come to the front of the room. That person, the trainer explains, will soon have to try to sell a very unusual object to the audience for a large sum of money, explaining in detail why it's worth so much. Then the object – something absolutely bizarre that has no obvious function – is uncovered or displayed on a screen, and the fun begins. What's especially interesting in this exercise is that the salesperson virtually always has no trouble at all generating outlandish ideas almost immediately. Unusual stimuli generate unusual ideas.

Exercises That Help Managers to Enhance Creativity in Others

Exercises can also enhance eight types of competencies that help managers, teachers, and supervisors to elicit creative expression in other people, whether in small groups or large organizations.

Encouraging the Preservation of New Ideas

Just as individuals can learn the value of Capturing, managers can learn many ways to promote Capturing in an organization. They can use exercises, for example, to train people to capture their ideas. They can also create an environment in which people are simply more *likely* to capture their ideas; the employees themselves usually don't have such power. For example, a manager can equip everyone's computer with capturing software: 'new idea' boxes or icons that encourage people to record their new ideas on the fly. Managers can also provide free time for people to listen to their own thoughts and explore their ideas. Both 3M and Google are famous for allowing employees to spend part of their time every week exploring pet projects. Managers can also create physical spaces that promote capturing. At the famous Lockheed 'Skunk Works' where stealth fighters were invented, people could write on the walls, for example – a superb way both to promote capturing and to surround people with idea-generating stimuli.

Here are two pertinent exercises.

Brown paper caper

A stunning photograph in Hanley Norins' book, *Young & Rubicam Traveling Creative Workshop*, shows thousands of words and designs written on wide brown paper lining a 30-foot-long wall. To generate new ideas for a project, he often has people capture all of their thoughts on a 'problem-solving mural' of this sort. You can show people the benefit of wall writing by creating a large writing surface on a wall, giving

them a difficult problem to solve, and then having people use markers to record their ideas one at a time on the surface. With each new contribution, the group will be able to see how the ideas grow and develop over time. In some companies, erasable white boards are permanent fixtures on a great deal of wall space.

The anonymous suggestion game

This exercise, from *The Big Book of Creativity Games*, demonstrates a way of dramatically increasing the number of contributions people make to suggestion boxes in an organization. People are asked to suggest ways of solving a sensitive problem, such as how to reduce street crime. Some are given forms on which they must reveal detailed information about themselves; others are given forms that allow them to remain anonymous. The latter group will typically produce twice as many suggestions as the former. Given this outcome, people are asked to redesign their organization's present suggestion system. In an ideal system, people can submit suggestions anonymously, but the suggestions are coded in a way that allows people to claim them (and perhaps be rewarded for them) if they're later adopted by the organization.

Challenging Others

Managers can increase the creative output of employees by giving them difficult assignments, and all assignments, including easy ones, will produce more creativity if they are open-ended. When managers (or teachers or supervisors of any sort) are being trained or retrained, exercises can be used to teach these concepts. Perhaps equally important, managers also need to help employees deal with the frustration that often accompanies challenge. They can do this by teaching stress-management skills and by providing resources that help people manage stress. These concepts can also be taught with the help of exercises.

The lola cola game

This exercise, from *The Big Book of Creativity Games*, teaches the value of open-ended assignments. Teams are divided into two types, those who receive traditional closed instructions and those who receive open-ended instructions. Written instructions are distributed. The closed instruction is to invent three names for a new cola product; the open-ended instruction is to invent *at least* three new cola names. After ten minutes or so, the groups report on their creations. Typically, the open-ended groups will have devised at least twice as many names as the closed instruction groups. The difference in the instructions is then revealed, and a discussion follows. The critical question is: What if *all* assignments were always open ended? How much more would people produce and create?

Building bridges

Bridge-building exercises of various sorts are commonly used for team building and management training. In a typical scenario, teams are given equal quantities of newspaper and instructed to build a bridge between two tables. Sometimes, each team is divided in half, and each subgroup must build only half a bridge; the two halves must ultimately connect to each other. The first team to build a successful bridge wins the

exercise, or bridges can be judged according to how much weight they can support or other criteria. The exercise can then be repeated with the tables moved much farther apart, increasing the difficulty of the task. This kind of exercise not only builds teamwork, it also shows the power that challenge has to boost creativity.

The ultimate challenge game

In this exercise, also from Epstein's *Big Book of Creativity Games*, people are asked to propose solutions to extreme challenges, such as, "Give me at least three ways of flying people from here to the moon for the price of a New York subway token" or "Give me at least three methods for making birds swim and fish fly." No matter how difficult the problem, people generate solutions, and if the challenge is made open-ended, they will generate many solutions. The game can easily be adapted for the business environment: people can be asked to spend a few minutes each day generating solutions to ultimate challenges related to a particular business or industry.

The beastly boss game

In this exercise, from Epstein's *The Big Book of Stress Relief Games*, people learn the value of performing relaxation exercises when they're under stress. People divide into pairs and role play situations in which a Beastly Boss makes unreasonable demands of an Exemplary Employee. In some role plays, the employee subtly performs simple breathing exercises in order to stay relaxed. Without such exercises, the conversations often escalate; with the exercises, they do not. Exercises of this sort can be used to teach both managers and employees the value of stress-management training.

Encouraging the Broadening of Knowledge and Skills

Managers can teach people the value of broadening, and they can also use an organization's resources to make sure that people acquire new knowledge and skills. Some companies groom people for high management positions by having them work in different departments in the organization; the broad knowledge they acquire not only gives them a more informed picture of the organization, it also gives them the raw material they need to be more creative.

The experts game

Used in a group setting, this exercise, from Epstein's *Big Book of Creativity Games*, teaches the value of broadening. People from the audience who are experts on something very obscure (and there are always such people in every audience) are asked to give five minute, impromptu lectures about their unique knowledge – about hooking rugs, perhaps, or color-balancing a picture using Photoshop, or designing a nuclear reactor. Then everyone is asked to invent at least three new products based on the three kinds of new knowledge they just acquired. A colorful carpet with molecular designs, perhaps?

The amazing magazine game

Also from *The Big Book of Creativity Games*, in this exercise, individuals or teams are supplied with small stacks of widely different kinds of magazines. They're given time to read articles from each of the magazines and then asked to solve a

challenging problem using the new knowledge they've acquired. They can also be asked to design new products or services, or even to write a poem or story based on their new knowledge. A discussion about the value of broad training follows.

Providing Diverse and Stimulating Physical and Social Environments

Managers have enormous power to enhance creative expression through manipulation of the physical and social work environments. Diverse teams typically produce more and fresher ideas than homogenous teams. Interesting workspaces produce more and better ideas than dull ones. Most important of all, changing environments produce more and better ideas than static ones. Moving people or desks or posters around is unsettling to people, and that's the whole idea. In team meetings, people can temporarily become quite different people through role playing.

Here are exercises that demonstrate such concepts.

Six thinking hats

Creativity consultant Edward de Bono's exercise, 'Six Thinking Hats,' described in his book by that title, is a widely used role-playing technique that helps teams solve problems and generate ideas. It involves having people imagine wearing, and sometimes removing, each of six different hats that signal that one is to play a specific role in the discussion: the white hat signals that one is neutral and objective, the red hat that one is angry, the black hat that one is negative and gloomy, the yellow hat that one is positive and sunny, the green hat that one is creative, and the blue hat that one is cool and concerned with control issues. As a discussion proceeds, the team leader can ask people to remove a hat or to switch hats. The technique allows people to examine an issue from many angles, and it also brings out different sides and capabilities of people that otherwise might never appear. The value of the Six Hats technique can be demonstrated by having two sets of teams work on the same problem; one set uses the technique and the other does not. The work product of the two teams can then be compared. If time allows, the two sets of teams can then swap methods and take on a new problem.

Picture portfolios

This is an exercise from Michalko's *Cracking Creativity* which uses both pictures and other people's ideas as stimuli to help improve creative expression: "1. Read a problem statement aloud and ask the group to verbally brainstorm solutions. 2. Give each group member a folder containing eight to ten pictures that are not related to the problem area. 3. Instruct them to examine each picture and silently write down any new ideas or modifications of previous ideas suggested by the pictures. 4. After a designated time period, ask the group members to read their ideas aloud. 5. As each idea is read, ask the group to discuss it and try to develop more new ideas or modifications."

Airplanes

Also from *Cracking Creativity*, this exercise gives people a fun way to build on other people's ideas: "Have each participant

construct a paper airplane. Each participant writes down an idea on the airplane and sends it flying to another participant. Upon reading what's been written on the airplane, he or she writes down a modification or improvement of that idea, or an entirely fresh possibility, and then sends it flying to someone else. Continue the exercise for twenty minutes and then collect and categorize the ideas."

Managing Teams Appropriately

As noted above, one of the best ways to enhance team creativity is to ensure from the outset that the team membership is diverse. Michael Michalko suggests a dramatic way of assembling diverse teams: occasionally announcing 'open meetings' that anyone in an organization can attend, from custodians to accountants to CEOs. Once a team has been assembled, surrounding techniques such as Six Thinking Hats can improve process and output. Other rule systems, such as brainstorming, can also be helpful. Finally, since group settings will tend to inhibit creative expression in many people, team output can be greatly increased by having people shift out of a group one or more times to generate ideas on their own. Here are exercises that teach such concepts.

Brainstorming

First proposed by advertising executive Alex Osborn in 1938, brainstorming is the most widely used technique for generating new ideas in teams. Team members are instructed to follow simple rules to keep ideas flowing: express ideas freely; withhold making any kind of judgment, especially a negative one, about people's ideas; the team is seeking to generate a large *quantity* of ideas; quality concerns will come later. The power of this technique can be demonstrated by dividing people into teams that brainstorm and teams that do not. Then all of the teams work on the same problem for the same amount of time, after which results are compared. Typically, brainstorming groups will produce far more ideas than non-brainstorming groups.

The shifting game

Two sets of teams, Shifters and Togethers, are given the same naming task or a problem to solve. Over the next 15 minutes, the Togethers remain together to work on the task. Shifters team members spend five minutes together, then split up and work on the problem on their own for five minutes, and then reassemble for the remainder of the 15 minutes. Even though time has been wasted moving around, the Shifters will typically produce 50–100% more names or solutions than the Togethers. Although groups are stimulating, they also inhibit creative expression in many people, in part because people are afraid of receiving negative feedback in the group, but also because of criticism people have received throughout their lives. The shift makes it more likely that people will capture their own ideas. When the group reassembles, people usually pool their many ideas.

Providing Adequate and Appropriate Resources

It's difficult – sometimes even impossible – to express creativity unless you have access to adequate and appropriate resources.

If your job is to develop a new glue or medication, you'll only get so far without a well-equipped chemistry lab. Simple exercises can help managers and teachers see how this concept works in action. Here is an example:

Sticky business

In this exercise from *The Big Book of Creativity Games*, two sets of teams are supplied with equal amounts of wooden sticks or pieces of colored construction paper. One set of teams is also supplied with a full bottle of glue. The other set of teams are given glue bottles that are nearly empty. The task for all teams is to create at least one beautiful work of art. After 15 minutes, participants who have been appointed judges rate the creativeness of the artistic creations and also count the number that each team has produced. Teams lacking glue generally fare poorly in this exercise.

Providing Positive Feedback

Scientists sometimes debate about the value that positive feedback has for creative expression. Under some conditions with children, if creative expression is rewarded and then later rewards are no longer available for expressing creativity, the rate of creative expression may drop. That said, there is strong evidence that rewards, properly used as incentives, can greatly increase creative output. Adults routinely make discoveries or produce new books, works of art, musical compositions, products, or services in order to win awards, get praise, or earn money. What's more, even the slightest negative reaction to a new idea – say, a raised eyebrow – can have a devastating effect on creative expression, in some cases leading to blocks that can last for years.

In an organization, incentive and evaluation systems that recognize and reward creative contributions can help keep creativity flowing. Managers also need to use care when giving people feedback on their ideas. Here is a pertinent exercise from *The Big Book of Creativity Games*.

The tiny little nod game

This game shows that even very subtle feedback can have a big effect on behavior. People are divided into pairs in which one person chooses to be a speaker and the other a listener. The listener then writes down a target sentence that he or she wants the speaker to say. Listeners are told that they can't communicate with speakers in any way except to nod their heads very slightly up and down (in other words, signifying 'yes' but never 'no'). Participants are told that they have five minutes in which to try to reach the target sentence. Then speakers are told to start talking. Listeners are instructed to raise their hands when they hear the target sentence or something close to it. Remarkably, within the allotted time, at least a third of the pairs will reach the goal. If additional time is allotted, more pairs will reach the target. The speaker and listener can then switch roles.

Modeling Creativity Competencies

One of the best ways for a manager to stimulate creative expression in other people is to model the core competencies. People tend to imitate the behavior of others, especially the behavior or authority figures. Here is an exercise from *The Big Book of Creativity Games* that makes the point:

The green-and-yellow game

The instructor asks an audience to suggest names for two new soft drinks, one green and one yellow. As people raise their hands and make their suggestions, the instructor makes two lists on a blackboard or flipchart and also asks people to take notes. When suggestions for green drinks are made, the instructor records them accurately, but he or she records suggestions for yellow drinks less accurately, in abbreviated form, or not at all. After a fairly large number of suggestions have been made, the instructor erases the board or flips the page and then gets a rough count of how many green and yellow names people recorded. These numbers are compared to an accurate count that a designated person has made secretly. Because people tend to imitate authority figures, participants' notes will under-report names for the yellow drink. In this instance, people were imitating the instructor's uneven capturing skills. A discussion about the importance of being a good role model follows.

Glossary

Deliberate practice Structured activity, often designed by teachers or coaches, with the explicit goal of increasing an individual's current level of performance. In contrast to other activities such as work and play, it requires the generation of specific goals for improvement and the monitoring of various aspects of performance. Furthermore, deliberate practice involves trying to exceed one's previous limit which requires full concentration and effort.

Consequently, it is only possible to engage in these activities for a limited amount of time until rest and recuperation are needed.

Domain Area of behavior with an organized set of activities where experts and an accumulated body of shared (teachable) knowledge are recognized. The most well-known disciplines or domains are those of the Arts and Sciences, Medicine, Sports, and Games.

Expert performer An individual who, by objective standards and over time, shows a superior and reproducible performance in representative (typical) activities of a domain. In contrast to the everyday usage of the term expert, which is applied freely to any specialized individual, expert performers must display consistent superior performance in their respective domains.

Innate talent Innate capacities that many believe are necessary for attaining the highest levels of performance in a specific domain. It is well known that most necessary component skills and attributes of expert performers require extended training for their acquisition – with the exception of talent. Talent is thought to be directly determined by genes, and it cannot be modified or improved through training. The associated abilities develop naturally without the need for any specific practice. Consequently, society tries to identify talented individuals during early phases of training and provide them with the best education and encouragement for the extended road to expert performance. The terms 'talent' or 'giftedness' are used in the text, despite the lack of firm scientific evidence supporting these constructs.

Novice A person who has received all the necessary knowledge and instruction to be able to perform independently in a domain. Novices represent the lowest level of attained skill for individuals who can still perform the basic tasks of the domain. They are therefore often used as a reference group for comparisons with the highest level performers in studies of expert–novice differences.

Expertise refers to the cognitive, perceptual-motor and physiological mechanisms that allow experts to consistently attain superior levels of performance in routine and new challenging situations and/or produce new products valued in the domain of expertise. Webster's dictionary defines an expert as "one who has acquired special skill in or knowledge of a particular subject through professional training and practical experience." Accordingly, typical experts are individuals such as medical doctors, accountants, teachers and scientists, who have been certified as professionals after extended training and have then accumulated experience in their specialty. More recently, the term expert has been expanded to describe any highly skilled performer who exhibits superior achievement after instruction and extended experience in a field. Among those fields, which are called domains, are the arts (e.g., music, painting, and writing), sports (e.g., swimming, running, and golf), games (e.g., chess, Scrabble, crossword puzzles, Othello, and bridge), and professional activities (e.g., medicine, nursing, and business). Because we assume that the mechanisms mediating performance of experts in different domains share certain characteristics, we use a single concept, namely that of expertise, for different domains. Also, we expect expertise to require domain-related experience and thus develop in a similar manner across

domains. As the level of performance and achievements increase we expect that the quality and value of products and the adaptation to situational demands will increase and reflect higher levels of creativity.

Overview: Expertise and Expert Performance

The main task for researchers of expertise is to explain how some individuals attain the highest levels of achievement in a domain, and why there are only so few who reach these superior levels. In order to be able to attain very high (expert) levels of performance in domains of expertise, both nature and nurture must be involved. Experts' performances often look effortless, and their most refined and insightful behavior is generated rapidly and naturally rather than being the result of prolonged deliberation. One is thus led to believe that experts excel based on general basic characteristics, such as intelligence, memory, speed and flexibility. It has traditionally been assumed that those general characteristics are impossible to train and thus are determined to a large degree by genetic factors (nature). Everyone agrees, however, that experts must acquire at least some necessary domain-specific knowledge and

skill (nurture). The relative importance of nature versus nurture for expert achievement has been discussed and argued since the origin of our civilization. A couple of questions have been the primary focus. First, how does expert achievement develop and what is the role of instruction and training? Second, are people born with certain characteristics to attain expert performance or are those characteristics acquired as a consequence of training? We will briefly review the most important conceptions of expertise spanning the last centuries, then turn to a summary of our current knowledge, and finally outline the implications and connections of expert performance for genius and major creative innovations.

The Traditional Account for Expertise, Expert Performance, and Exceptional Achievement: Innate Talent

Beginnings in the Nineteenth Century: Sir Francis Galton

In his pioneering studies of excellence in nineteenth century England, Sir Francis Galton found that a very large number of the most valued achievements were made by members of a small number of eminent families. Galton found that as the genetic similarity between relatives decreased, the likelihood that individuals had outstanding reputations also was reduced. To explain how individuals from these eminent families could succeed in such diverse professions as politics, literature and science, Galton claimed that instruction and training were beneficial, and associated with large initial improvements of performance. However, with further experience the associated improvements in performance became increasingly smaller and eventually a rather fixed upper bound for performance was attained. Galton thought that the upper bound on individuals' performance was limited by their respective basic capacities which could not be modified through training and experience. The rare occurrence of expert performance could thus be explained by the small number of individuals engaged in the domain who were genetically endowed with superior basic capacities critical to the domain of expertise. Consequently, Galton and many other contemporary psychologists and educators developed psychometric tests to measure basic capacities of memory, perception and thinking. In those tests the influence of knowledge and prior experience was minimized. Through extensive testing of children and adolescents, investigators hoped to identify innately talented individuals who, given the necessary resources of training and support, were most likely to achieve high levels of performance.

Importance of Innate Basic Capacities Overrated?

Today, over a century later, we can safely say that past efforts to measure individual differences in basic capacities did not succeed in predicting future expert performance or even identifying adult experts. For example, when athletes or other experts are tested in the laboratory on how fast they can respond to the onset of a light (simple reaction time), they are not systematically faster than other subjects. The superior speed of a tennis player in returning a fast tennis serve must thus reflect an acquired ability to respond rapidly in representative situations rather than a general superiority of speed of neural impulses.

Similarly, chess experts can recall nearly all the 24 chess pieces in a typical chess arrangement after a brief exposure, whereas beginners in chess can only recall around four pieces. Yet, if the chess pieces have been randomly arranged, then the advantage of the experts over beginners is dramatically reduced to a few pieces. Both the chess experts' and athletes' superior abilities are primarily limited to their domain of expertise and therefore do not reflect basic capacities measured in the laboratory.

In recent reviews, the major differences between experts and less proficient individuals were found to nearly always reflect specific adaptations acquired by the experts during their lengthy training. This holds true for many anatomical and physiological characteristics of athletes such as the size of their muscles and bones and the flexibility of joints; and for the increased range of mobility of the limbs in ballet dancers and musicians. Some of these attributes, such as structural changes in the brains of musicians are correlated with the length or early onset of training. Other adaptations – for example the increased thickness of the bones of the playing arm (but not the other arm) of tennis players, or the optimization of oxygen absorption of runners only at certain levels of running intensity – are so specific that (self) selection of individuals in those domains appears highly unlikely. Finally, most physiological adaptations have been shown to revert back to normal values once training was stopped or dramatically reduced at the end of athletes' active career, which is clearly an indication of their acquired nature. However, at least in one instance, namely height, we know for certain that genetic factors independent of experience and training can play an important role for the attainment of expert performance in domains, where more height constitutes either an advantage (e.g., basketball) or a disadvantage (e.g., gymnastics).

The incidence of expert achievement in some famous families, such as the Bach family with many famous musicians, is frequently cited as proof for the high heritability of special talents. However, recent reviews of this evidence have questioned such claims. Instead, the early start of instruction of children initiated by domain-competent parents and access to networks and specialized training seem to offer sensible alternative accounts. Because expert performers are so rare, it is very difficult to conduct rigorous studies of heritability. So far, the small number of published studies on experts (i.e., Olympic athletes and musicians) has been unable to document any significant heritability of expert levels of performance. Heritability studies rely mainly on data from individuals who have shared the same environment during upbringing (adopted children), and from those who share genetic material (identical twins, fraternal twins, or siblings). Unfortunately, those individuals are surprisingly underrepresented in the expert population, making estimation of heritability of expert performance extremely difficult.

The Alternative Account: Expertise as Acquired Knowledge and Skill

Acquiring and Organizing Knowledge for Use in a Given Domain

One of the most significant advances in our understanding of expert performance resulted from a direct comparison of the thought processes of experts and less accomplished

individuals. In the 1940s researcher Adrian de Groot gave a pioneering account of the thought processes that allowed world-class chess players to consistently find better chess moves than less skilled players. He instructed chess players of each group to think aloud while they selected their next move for a given chess position. The transcriptions of these reports, so called think-aloud protocols, revealed that all chess players were quickly retrieving promising moves from memory while examining the organization and structure of the presented chess position. Then, during the process of evaluating these potential moves by searching and planning, even better moves were often discovered. Neither de Groot nor other researchers found evidence that elite players were more intelligent or that their speed of processing tasks unrelated to chess differed from those of less skilled chess players. The primary difference between the chess players was that the world-class players were superior in evaluating and reasoning about possible chess moves and generating corresponding moves.

According to authors Herbert Simon and William Chase, who extended de Groot's work, expertise is an extreme case of acquired skill. Their view is thus in agreement with general theories of skill acquisition in which knowledge is first acquired and then organized into adequate procedures and actions. With continued practice, individuals become increasingly able to access more appropriate chess moves automatically and speedily through pattern-based retrieval. By recognizing complex configurations of chess pieces, Simon and Chase argued that an expert can retrieve good moves from his memory of related chess games. Their theory was also able to explain the chess experts' superior memory for briefly presented chess positions. Also, the availability of stored complex chess patterns could explain why experts recalled much more pieces from presented positions for chess games than less skilled chess players. However, randomly rearranged configurations reduced the advantage of the experts over the less skilled players to a few pieces, because the random configurations would not match the experts' body of already stored patterns.

Highly organized knowledge was also proposed to be a key factor in expertise involving more traditional, academic activities, such as solving textbook problems in physics. When physics experts (professors) read through a physics problem, they immediately retrieve a solution plan as part of their normal comprehension. In contrast, nonexperts (novices such as beginning college students) typically look for the question at the end of the problem first and then retrieve formulas – one by one – and compute intermediate results by working 'backwards' from the requested answer. As one would expect, physics experts not only had more knowledge than novices, but as researchers Micheline Chi and her colleagues found, they also had organized it around relevant theoretical principles of physics. This allowed the experts to retrieve plans for solving the problem directly as part of their understanding of it. In contrast, the physics knowledge of the novices was poorly integrated and based on superficial appearance rather than deeper concepts. More generally, the superior ability of experts to reason and solve problems appears to be specific to material related to their domain of expertise. For example, studies have shown that experts in chemistry and social science lacked the special knowledge and strategies to successfully analyze a problem in political science; experts in experimental research were

found to be able to design experiments of superior quality only within their particular area of research specialty.

All these results support the general notion that experts' superiority is closely linked to their superior accumulation of knowledge. Could one use this knowledge to build computer programs, so-called expert systems, which almost behave like a human expert? A number of researchers have indeed taken this knowledge-based approach to expertise by designing methods to elicit the knowledge of experts, and then describing the structure and organization of their knowledge in specific domains. However, the massive amount of relevant knowledge and methodological problems of extracting knowledge and implementing it in computer models present major obstacles to the expert-systems approach to expertise.

Recent Challenges to the Knowledge-Based View of Expertise

Once psychologists had become interested in expertise, they went out and searched for domain experts. To their amazement, some experts with lengthy education and extended experience did not exhibit a performance superior to that of less experienced individuals or even novices. For example, professional stockbrokers were not found to be consistently superior in selecting investments when compared to random selection of stocks from investment indexes. Similarly, psychological therapists with a Ph.D. and many years of clinical experience were not more successful at helping clients than less experienced therapists with much less advanced training. The most consistent dissociation between level of expertise (indicated by the amount of schooling and experience) and performance has been demonstrated in many types of expert judgment, especially in medicine and nursing.

With experience, individuals generally increase their performance for a limited time until they have reached an acceptable level of performance. Further improvements beyond this point are unpredictable. For domains such as medicine, nursing, computer programming, auditing and sports, the number of years of work experience has been repeatedly shown to be a poor predictor of attained performance. Thus, it cannot be taken for granted that all highly experienced and knowledgeable individuals (experts) will actually exhibit superior performance. For scientific purposes, objective evidence for their superior performance is therefore indispensable.

Identifying Experts' Superior Performance

How do we establish superior performance, if mere social recognition does not always yield scientifically reliable evidence for a person's expertise? If we assume that expertise consists of reliable superior performance in a domain, then the first step is to ensure objectively that all the studied experts actually exhibit this performance under controlled conditions. By defining expertise as a reproducible performance which is superior to that of most other individuals in the domain, it becomes an observable empirical phenomenon that can be measured independent of any theoretical framework. It now becomes possible to analyze the phenomenon experimentally and compare alternative theories of its structure and acquisition. For example, we can try to find out whether or to what degree the performance requires innate talent or if it can be

explained with skills acquired through extended experience and training.

Objectively measuring performance of individuals is difficult, and most domains have developed and refined relatively standardized methods for assessing the level of achievement. Virtually every domain focuses on independent and reproducible performance of participants in the domain. In the simplest case, different performers perform the same task, such as athletes running 100 yards during a competition, and the performer with best performance for an event wins. In other domains, such as chess and tennis, the outcomes of many pair-wise competitions allow to compute a ranking of all the advanced performers in the domain. In the arts, sciences, and some sport events, a panel of experts or judges evaluates and agrees on the quality of individual performances or specific achievements. Those achievements can be artifacts, such as paintings, compositions, recordings, books or articles that are ultimately recognized as major creative contributions and innovations. In sum, the evidence from the measurement of expert performance shows a general superiority of experts that can be consistently reproduced under different conditions. Next we will discuss findings regarding the importance of experience and practice for attaining consistently superior levels of performance.

Need for Extended Domain-Specific Experience to Reach High Levels of Performance

Recent reviews show that long-term engagement in activities of the domain is absolutely necessary to attain expert performance. When the skill development is studied over longer periods of time as in longitudinal studies (see Figure 1), we find that there are no sudden increases in performance from one point of time to the next. For example, even child prodigies in chess show a gradual yet steady increase of their performance in adult chess tournaments over time. Also, expert performers continue to improve their performance long into adulthood. They typically reach the highest (peak) performance of their career at ages from the mid to late 1920s for many vigorous sports and from the mid to late 1930s and 1940s for the arts and sciences. The extended development

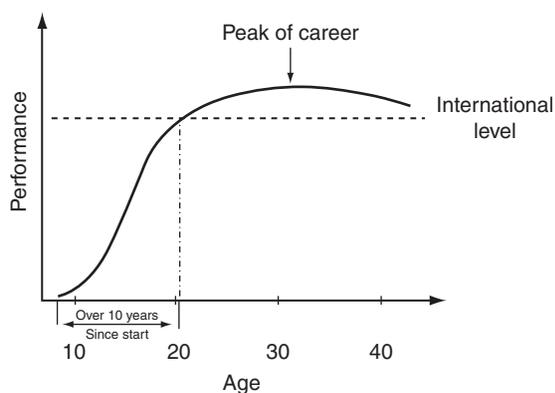

Figure 1 An illustration of the general performance trajectory of elite chess players as a function of age. The international level, which is attained at around ten years of involvement in the domain, is indicated by the horizontal dashed line.

past physical maturity, illustrated in Figure 1, shows that experience is necessary for improving performance.

Finally, the most compelling evidence for the necessity of extended experience is how long it takes even the most talented individuals to reach an international level after their start of engagement in the domain (see Figure 1). In their influential theory of chess expertise mentioned earlier Simon and Chase proposed the 'ten-year rule,' because they observed that no modern chess master had ever reached the international level in less than around ten years of playing. Although there are now several recent exceptions to that rule for young chess players, the fact remains that everyone needs well over five years and nearly everyone more than ten years of concentrated training before reaching the international level in chess. Results from domains of expertise other than chess, such as music composition and a wide range of sports, science and arts, are consistent with this modified ten year rule. However, the vast majority of individuals who reach such high levels take considerably longer. For example, winners of piano competitions have typically spent over 20 years of concentrated training. In sum, the necessity of active engagement in domain-related activities in order to improve performance in a domain of expertise is well established.

Mere Experience is Not Enough: The Role of Deliberate Practice and Teachers

When individuals start to engage regularly in a leisure activity, such as playing tennis or golf, or begin to work in a job/profession after finishing school, they initially go through a limited period of relatively rapid improvements. During this time obvious mistakes are corrected. Once they reach a satisfactory level of performance further increases are usually not noticeable. Most of us have experienced this phenomenon of a stable level of performance in spite of long-term active engagement in a domain. Consistent with this cessation of improvement, the length of experience in the domain has been found to be, at best, a weak predictor of current level of performance in a wide range of domains, such as sports, medical diagnosis, psychotherapy, and accounting. If additional experience does not automatically change individuals' behavior, what does?

When our actions and activities run smoothly, the structure of performance becomes habitual and thus remains essentially unchanged. Even if mistakes occur, such as when a tennis player misses a back-hand volley during a game, the other players are not willing to stop the game and give the player chances to train on similar shots. Moreover, this shot is so rare, that the next encounter with a similar shot may well occur unexpectedly and only after hours of subsequent play. Yet, the same performance could easily be improved by specially designed activities. For example, a tennis player could hit many consecutive back-hand volleys under the supervision of a tennis coach, who could create back-hand volleys of suitable difficulty. When first learning to master the basic stroke, the student would benefit from simple training situations. Later, the trainer could challenge the tennis player with less predictable and more difficult shots that are embedded in a representative game context. Optimal training involves exactly this design and presentation of situations that challenge the trainee. But at the same time, the trainee has to be able to master the

challenge with full concentration and/or repetitions. 'Deliberate practice' is the term that Anders Ericsson and colleagues have coined for such training activities that are designed by a teacher (or even the skilled learner) solely for the purpose of improving an individual's performance. Contrary to what one might think, active participants in domains rarely engage in deliberate practice. Although they recognize that engaging in this type of training would improve their performance, they also find it so much more effortful and less enjoyable than regular recreation – that its costs outweigh its benefits. Engaging in a domain activity is usually motivated by its inherent enjoyment (play) or external rewards (work). Yet these activities lack essential prerequisites for efficient improvement which deliberate practice offers, including training goals, feedback and opportunities for gradual improvement through repetition. Active engagement in a domain does not invariably lead to improvement of performance once some initial acceptable level has been attained.

It is well established that mere engagement in activities of the domain is necessary but by itself not sufficient for attainment of very high (expert) levels of performance. In many domains, promising individuals are supervised by a teacher who instructs them and designs their practice from a very young age. Benjamin Bloom and his colleagues found out through interviews with international level performers in mathematics, bio-chemistry, music, sculpture, swimming, and tennis that they had studied with excellent (master) teachers. In fact, many of these performers or their families had even relocated to be close to a desired teacher or an excellent training environment. Virtually all of them had chosen teachers who either were international level experts themselves or had successfully trained students to reach that level.

Why is it nearly impossible for individuals to guide themselves to expert levels of performance without the help of teachers? Moreover, why does the level of excellence of teachers appear to be so important? Whereas the general cognitive development in children is surprisingly invariant across very different environments and cultures, the development of expertise in domains of expertise, such as music, sports and science, shows large differences across varying cultures and historical times. One of the primary reasons is that domains of expertise have over time extracted and accumulated a body of organized experience in the form of knowledge and produced artifacts. This body of externalized, written-down, and codified experience can be shared with subsequent generations through teachers, books, and other media. It is no longer necessary for each individual to rediscover pieces of knowledge and methods for doing things, and individuals are thereby able not simply to match but to surpass the level attained by pioneering predecessors. In the thirteenth century, for example, Roger Bacon argued that it would be impossible to master mathematics in less than 30 to 40 years by the contemporary method of learning through self-study; Bacon was talking about a material roughly equivalent to the mathematics which is today taught in well-organized and accessible form in high schools everywhere.

The necessary role of teachers in mastering any of the arts and sciences becomes apparent when one considers that the accumulation of knowledge and achievements is based on specific shared concepts, symbolic systems, technology (in a

very broad sense, e.g., instruments, equipment, materials), and theories with efficiently organized knowledge. Generally, we take the increases in level of expert performance over historical time in science and sports for granted. Given the large changes in technology in these domains, it is difficult to make inferences about the actual changes in skill. Yet, in domains with less changing technology such as music performance on the piano or the violin, today's performers readily master music that was, by the best musicians in the eighteenth and nineteenth centuries, initially considered unplayable. Similarly, in many sports with minimal equipment, such as running or swimming, the highest level of performance attained early in this century is now common place and matched by serious amateurs.

In all major domains there has also been an accumulation of effective methods for teaching the growing body of knowledge and skills. By going through the sequences of training tasks that teachers and coaches have developed over the last centuries, students eventually perform more complex tasks than they thought they would be able to master. Unlike the beginners themselves, the teacher can foresee future skill demands. They know with what method and to what degree of mastery the simpler tasks have to be learned to serve as a solid foundation for more complex future skills. If the simpler skills are not acquired properly, the student might have to completely relearn the fundamental skills. The core assumption of deliberate practice is that expert performance is acquired gradually and that effective improvement of students' performance depends on the teachers' ability to isolate a sequence of simple training tasks that the student can successfully master by repetition with feedback and instruction. As mentioned earlier, the individual training tasks have to be difficult enough to lie slightly outside the students' current range of skills, so that the students concentrate on critical aspects and gradually refine their performance through repetition in response to feedback. This requirement of focused attention to individual task components differentiates deliberate practice from both mindless drill and playful engagement. In the best of cases these latter two activities would strengthen the current structure of the performance but not change it.

In many domains, promising children start training with teachers at very young ages. Because of the requirement of sustained concentration, the duration of training is initially quite short – typically no more than around 15 to 20 minutes per day. This leaves enough time for many other more playful but still domain-related activities. Many parents supervise their children's practice by helping them to concentrate during practice, by establishing regular practice patterns, and by encouraging them. With increasing age, domain-related activities, especially deliberate practice, occupy more and more room in the daily lives of future expert performers; by the end of adolescence the commitment to the domain is essentially full time.

Using diaries and other methods to study how expert musicians spent their daily lives, Ericsson and colleagues demonstrated the importance of deliberate practice for attaining expert performance. They investigated three groups of experts differing in their level of music performance. Although all experts from the three groups spent about the same overall amount of time with music-related activities each day, the

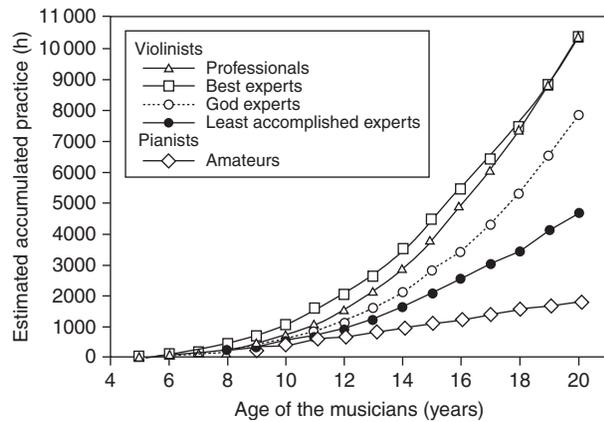

Figure 2 Estimated amount of time for solitary practice as a function of age for the middle-aged *professional* violinists (triangles), the *best expert* violinists (squares), the *good expert* violinists (empty circles), the *least accomplished expert* violinists (filled circles) and *amateur* pianists (diamonds). Adapted from Ericsson KA, Krampe RTh, and Tesch-Römer C (1993) The role of deliberate practice in the acquisition of expert performance. *Psychological Review* 100(3): 379 and 384. Copyright 1993 by American Psychological Association.

better musicians spent more time in deliberate practice; the top two groups spent around 4 hours every day, including weekends, in solitary practice. Based on retrospective estimates of past practice times, the researchers calculated the number of hours of deliberate practice accumulated by the different groups of musicians (see Figure 2). By age 20, the best musicians had spent over 10 000 hours of practice, which was 2500 and 5000 hours more than the two less accomplished groups of expert musicians; and 8000 hours more than typical amateur pianists of the same age. A number of studies in chess, sports, and music have confirmed the relationship between performance and amount/quality of deliberate practice. The broad range of known evidence suggests that individual differences in giftedness or talent can be attributed to differences in practice history, rather than innate differences in talent, especially among children. For example, John Sloboda and his colleagues found that higher achieving music students who showed faster improvements spent more time practicing each week than lower achieving students.

Some critics of the benefits of practice incorrectly equate practice with mere drilling to attain rapid and effortless automaticity. However, the next section will show that developing expert performance results in acquisition of complex mental mechanisms. Experts rely on these mechanisms to evaluate, reason, and improve planning, and also to continue learning without a teacher, essentially becoming their own teachers.

The Structure of Expert Performance

The development of performance of most active individuals in the domain is often arrested once an acceptable level of performance has been reached. These individuals want to achieve effortless performance, similar to how they master most everyday activities, such as driving a car or typing. In contrast, aspiring expert performers want to improve important aspects of their

performance with deliberate practice and continue to do so for years and decades. The key challenge for these performers is thus to avoid a stagnation in their development and instead acquire mental mechanisms that can support continued learning and improvement. What these cognitive mechanisms are and how they mediate performance will be explained in the next two sections.

Cognitive Mechanisms that Mediate Superior Performance

By giving experts representative tasks that capture the essence of the expertise in their domains, it is possible to reproduce their superior performance in the laboratory. Figure 3 gives some examples of tasks for which experts' performance in the laboratory would correspond closely to real-life measures of performance used in their domain. In laboratory experiments we can instruct the experts to think aloud while they perform a certain task or give a retrospective report immediately afterwards. Reviews by Ericsson and Walter Kintsch show that in a wide range of domains experts' think-aloud protocols reveal precisely how their superior performance is mediated by preparation, planning, reasoning, and evaluation. The first example in Figure 3 illustrates de Groot's procedure where different chess players are asked to select the best move to a set of unfamiliar positions from published games of elite players. By presenting medical doctors with descriptions of a patient's symptoms and asking for a diagnosis, one can similarly study medical doctors' expertise. In both above examples the correct solutions are known to the researcher: We know what move the best chess computer programs would make (these programs are far better than any human player), and we know what disease the patient was eventually diagnosed to have, sometimes from autopsies or advanced tests. The second example in Figure 3 illustrates how to reproduce superior typing performance in a controlled situation by instructing every typist to copy the same material. The final example shows how musicians can be asked to give multiple renditions of the same piece of music. All three types of expert performance are mediated by different types of acquired cognitive mechanisms. The mechanisms mediating chess and medical diagnosis have many similarities, but the mechanisms underlying expert typing and performing music differ and will be considered separately.

When highly skilled chess players select the best move for an unfamiliar position, they rapidly identify potential moves which are retrieved from among the many moves they have previously stored in memory. To select the best move the players then examine the retrieved moves by planning out their consequences mentally. During this evaluation even world-class players can discover better moves than those they retrieved at first glance. Although chess experts can retrieve acceptable moves soon after being confronted with a new chess position, their move selection is further improved by planning, reasoning, and evaluation. This indicates that performance of experts is not completely automated but remains controlled by increasingly complex processes. The ability to anticipate what consequences a particular chess move would have after several move exchanges increases slowly as a function of chess skill. Chess masters have perfected this type of planning to a point where they are able to play chess

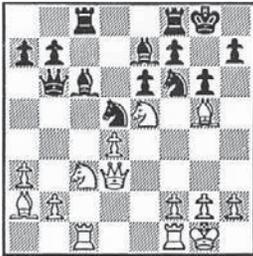

Domain	Presented information	Task
Chess		Select the best chess move for this position
Typing	<p>Overview—nature and nurture of expertise</p> <p>The central challenge for any account of expertise is to explain how some individuals attain the highest levels of achievement in a domain and why so few reach that level. However, given the continuing struggle in Psychology to explain every day (lower) levels of achievement, it many appear presumptuous to attempt to explain even more advanced levels. Consequently, the accounts of expertise have been focusing on the general characteristics of the mechanisms. In order to be able to achieve at very high (expert) levels in domains of expertise both nature and nurture are necessary. Hence, everyone agrees that experts need to have acquired the necessary domain-specific knowledge and skills (nurture). Furthermore, the expert's performance often looks effortless and their most refined and insightful behavior is generated rapidly and naturally rather than the result of prolonged deliberation. It would thus appear that experts must excel in general basic characteristics, such as intelligence, memory, speed and flexibility, which have been assumed to be impossible to train and thus must be determined to a large degree by genetic factors (nature). Over the last couple of centuries, the arguments of the relative importance of nature versus nurture for expert achievement have been intricately linked to the theories of the actual processes that mediate the achievement of experts and to the conceptions of which aspects of human characteristics could be modified through development and training. Hence, this entry will briefly review the most important conceptions during the last century and then turn to a summary of our current knowledge and in conclusion the implications and connections of expert performance for creativity and genius will be outlined.</p>	Type as much of the presented text as possible within 1 minute

Figure 3 Three examples of laboratory tasks that capture the consistently superior performance of domain experts in chess, typing and music.

blindfolded, that is without seeing a chessboard, and relying entirely on their mental image of the chess positions. Experts from other domains reveal similar characteristics. The processes that mediate the performance of medical experts allow them to extract the relevant information about a patient better than less accomplished doctors. Also, they can entertain and reason through alternative diagnoses until they have found the correct one. Thus, at higher levels of performance, individuals have acquired the ability to mentally represent relevant information. This information is made accessible in a fashion suitable for supporting more extensive and flexible reasoning about an encountered task or situation. In most domains, better performers have acquired complex memory skills that allow them to rapidly encode and store relevant information during representative tasks. However, as mentioned earlier, their superior memory skills are developed to encode information related only to executing superior performance in their domain of expertise.

Even the rapid typing speed of expert typists appears to depend on acquired representations rather than mere speed of their nervous system or finger movements. High-speed films of typing show that expert typists look ahead in the text beyond the words that they are currently typing and move their fingers in position for anticipating upcoming keystrokes. In fact, the best predictor of individuals' typing speed is how far they look ahead. Accordingly, in experiments where typists were

restricted from looking ahead in the text, their typing speed was dramatically reduced. During the mastery of typewriting the expert typist has acquired the skill to look ahead in the text in order to prepare future keystrokes. Similarly, the rapid reaction times of athletes such as hockey goalies, baseball hitters, and tennis players, have also been found to reflect the ability to anticipate future events.

In many instances, the relevant information that performers extract and encode changes as a function of attained level of performance. For example, the primary reason that expert tennis players can so rapidly intercept and return a fast serve is the following: rather than looking at the actual trajectory of the ball once it is hit, they anticipate the ball's path from the preparatory body movements of the server, they are even able to make rough predictions before the server's racquet makes contact with the ball. Hence, the resulting shorter reaction times of experts (as compared to less accomplished individuals) in a domain of expertise are not explained by an innate basic speed advantage but by superior anticipation, preparation, and improved perceptual skills.

Finally, expert musicians are well known for their ability to vary their performance of a given piece of music to convey a different musical interpretation. This ability would be difficult to study if the performance changed every time the musicians performed. Laboratory studies have shown however, that if expert musicians are instructed to play the same piece several

times in as similar a manner as possible, they are able to reproduce their own performance very accurately from one rendition to the next. Expert artists have a high level of control along with a precise image of their own performance, allowing them to reproduce or vary a performance at their will or to satisfy external requests or their own aesthetic decisions.

In sum, expert performance is not simply characterized by reduced cognitive processing and automatization. In fact, in order to reason about, anticipate, and plan alternative future actions, experts increase the control over their performance and their ability to internally represent it. This control is essential for experts in order to select appropriate behavior. In the case of athletes this could mean capitalizing on an opponent's weakness or taking into account the weather conditions; for the performing artists it may imply adapting to unfavorable room acoustics or synchronizing with other members of the ensemble. Imagine competitive domains, where newly discovered techniques or knowledge constantly change the *status quo* of a domain, or where each tournament takes place with different opponents and in unfamiliar locals. If experts were not able to adapt rapidly to those conditions, the emerging weak points would be exploited by others. Thus, in order to maintain high levels of performance despite any changes in the environment, experts need to possess a flexible, generalizable skill.

Cognitive Mechanisms that Mediate Learning

Attaining expert performance in a domain appears to depend on the acquisition of mental representations that permit control and monitoring of the gradual improvements. Only when the expert performers themselves can image and plan their desired performance, and monitor and evaluate their own ongoing performance, are they able to become independence of their teachers and coaches, and reach their highest levels. Developmental studies show that the improvement in representations goes hand in hand with increases in observable performance. Thus, a similar development of representations appears to be the key mechanism that prepares students for adult independence.

Bloom showed that the training of expert performers can be roughly broken down into three phases illustrated in Figure 4. After a brief period of playful engagement in a domain (Phase I) some children are introduced to systematic practice in the domain (Phase II). The teachers will present the beginners with simple training tasks and often explicitly guide their students to focus their attention on critical aspects and to make specific changes and corrections. Parents or teachers normally help the children, at least initially, to monitor their performance and to give feedback on how well the training goal was attained. As the complexity of the acquired level of performance increases, so does the complexity of the practice tasks and goals. With further increases in performance, some individuals reach a point where they decide to commit full-time to the domain and make it their professional career (Phase III). Along with the improvement of observable performance, students acquire improved representations to image the desired performance and to monitor their own performance, and they learn how to reduce discrepancies between the two. For example, musicians must be able to internally represent many different aspects of their music performance,

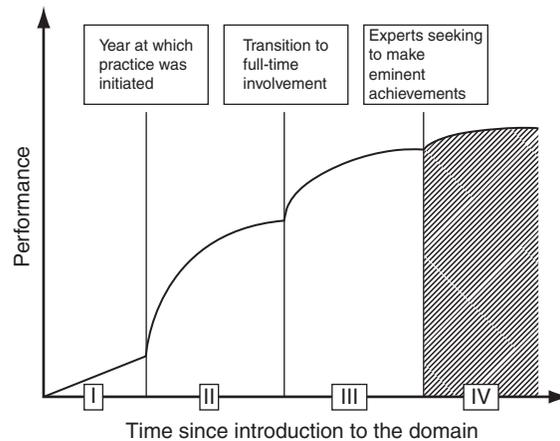

Figure 4 Three phases of acquisition of expert performance, followed by a qualitatively different fourth phase when experts attempt to go beyond the available knowledge in the domain in order to make a creative contribution. Adapted from Ericsson KA, Krampe RT, and Heizmann S (1993) Can we create gifted people? *The Origins and Development of High Ability*, pp. 222–249. Chichester, UK: Wiley. Copyright 1993 by CIBA Foundation.

such as how a given music performance should sound to an audience, and how to play their instruments to achieve this goal. In this context, it does not matter whether the musician is in the practice room or performing in public. It seems unlikely that a musician who fails to acquire any of these representations would be able to perfect their music performance through solitary practice.

When the expert performers have finally assimilated most of the available knowledge and skills in the domain, they start their professional career. During this fourth phase that Ericsson and colleagues added to Bloom's three phases, the primary goal is to make a personal creative contribution to the domain. By making those major innovations that permanently change the conception of performance or training in the domain, some expert performers will be able to reach a new level of achievement in the domain.

With the help of their highly developed representations skilled performers can organize their own training to further improve their performance. Studying and analyzing performances and achievements of masters in the field is one important way of doing this. For example, expert chess players collect books and magazines with published games of chess masters. Similar to the laboratory task mentioned earlier, they play through those games move by move and try to predict the next best move the master could have chosen. Any inconsistency between their own prediction and the chess master's actual move would imply that they overlooked some aspect of the configuration during their planning and evaluation. According to Neil Charness and collaborators, serious chess players spend up to 4 hours every day with this type of solitary study. In general, this form of self study is theoretically interesting because attempting to copy the model behavior of established masters allows the performers to gradually refine their own independent representations and expand their body of knowledge.

Expert Performance and Creative Achievements

Within the framework of expert performance, the first three phases of training leads to increases in the quality and generality of the aspiring experts' performance by learning from teachers and experts, thus benefiting from already codified knowledge and insights about performance and deliberate practice in a given domain. During the Phase IV a small number experts go beyond and thus redefine the current boundaries of a domain of expertise and generate creative innovation. This view contrasts sharply with the popular view that creativity is reflected in children's spontaneous behavior and that education and extensive training tend to confine and suppress it rather than enable it. In fact, the expert performance view maintains that without training students do not acquire the necessary representations for imaging and generating their products and achievements. To even have a chance to make a genuinely new innovation it is necessary to have assimilated the previously accumulated knowledge and be familiar with earlier, similar achievements. Only extended education will allow an individual to recognize a purposefully generated innovation as being uniquely new and different from prior achievements by others.

As far as we know, the empirical evidence on creative achievement shows that individuals have not been able to make major creative contributions to a domain unless they had mastered the relevant knowledge and skills during a long preparatory period of study and training. Even prodigious children seem to need extensive experience and training, and their creative achievements do not always compare well when judged by adult standards. Not even in the cases of revolutionary innovations by individuals such as Einstein and Picasso, did Howard Gardner find that the key creative innovations were generated until the creative individuals had completed their study and mastery of the existing knowledge and techniques. Furthermore, careful analyses of extraordinarily gifted children have shown that the trajectory of development they follow is similar to that of normal children engaged in the same domains. The difference appear to be that gifted children progress through the stages faster than less gifted children, attaining higher levels of proficiency at younger ages. Detailed analysis of the mechanisms mediating the very high level of performance of children in tennis and chess suggests the same types of acquired mechanisms as those of adults with comparable level of performance. These findings do not support

claims of qualitatively different mechanisms in talented children. In music, and also in other artistic domains, researchers have found that the higher achieving children tended to practice more on a daily basis than the lower achievers. This higher involvement along with motivational differences, for which Ellen Winner has argued convincingly, may account for the faster progress of some children over others.

In conclusion, the training of expert performers should not stifle creativity but rather provide the tools to empower the experts to be more successful and effective in their daily work and their search for innovative ideas, especially those few that go beyond what is currently known and done. Equipped with the rich knowledge of other experts' creative achievements through extensive education, the artists, scientists, athletes, or other expert performers can explore possibilities, and perhaps generate major innovations, thus making lasting contributions to their domain.

Expressive Arts Therapy

K T Donohue, California Institute of Integral Studies, San Francisco, CA, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Aesthetic response Our felt-sense response to works of art.

Aesthetic responsibility The commitment the expressive arts therapist has to the emergent in the creative process.

Affect regulation Management of one's emotions or in response to stress and daily living.

Approach Multiarts or integrative arts processes.

Archetype Existence of universal forms that channel experiences and emotions, resulting in recognizable and typical patterns of behavior with certain probable outcomes.

Creativity Mental and social process involving the discovery of new ideas or concepts, or new associations of the creative mind between existing ideas or concepts.

Decentering The process of play in which one does not focus on the issue at hand, but instead uses imaginative processes to explore in an unfocused manner.

Imagery Productions from the imagination that can appeal to any of the senses, and not just the standard five.

Imagination The ability to form mental images, sensations, and concepts.

Intermodal Multiarts approach.

Modality Refers to one singular creative arts therapy.

Play space An imagined free and protected space between therapist and client where there is room for the imagination to create.

Potential space A term coined by D. W. Winnicott as a space shared between mother and child in which creativity can occur.

Temenos A Greek word meaning the sacred space surrounding a temple or an altar. Used by C. G. Jung to name the relationship, frame, and vessel the analyst creates with his/her client.

Definition

Expressive arts therapy (EXA) connects the creative arts, the imagination, arts rituals, and the creative process into a therapeutic approach. This arts tapestry weaves forms of creative expression into integrative arts processes for therapeutic healing, self awareness, understanding the psyche/soul, accessing alternative states of consciousness, individual and collective creative growth, community building, and political action. The thrust of expressive arts therapy is to ignite the creative process in each person or group through the use of creative expressive techniques to facilitate healing and growth. This approach is also referred to as expressive therapies, integrative arts therapies, intermodal therapy, multiarts therapy, multimodal arts therapy, and creative expression therapy.

While there is diversity of orientation in the field of expressive arts therapy, 12 dimensions have united this approach. These define the essential parameters and expand the definition of expressive arts therapy.

1. *Multiarts imagination*: The imagination is not limited to any singular arts form, and the human experience is revealed not only through words, but through images, symbols, and the body.
2. *The creative process*: Stimulating the creative process is central in this approach.
3. *Temenos and play space*: Creating a safe relationship and a free play space is critical for the creative process to unfold.
4. *Imagery*: Imagery is holistic and nonlinear and helps us hold many ideas simultaneously. It allows us to create, innovate, and plan for the future.
5. *Power of each art discipline or modality*: Each art modality has its own experience, language, and therapeutic application.
6. *Direct action-oriented experience*: Direct experience of art making is essential to this action-oriented approach.

This focus on direct experience guides the practitioner to emphasize the process more than the product.

7. *Phenomena of the image*: Staying focused on the phenomena of the image and first exploring it artistically is very important in the creative process.
8. *Potentials of image*: Each image has vast unending potentials for meaning on personal, relational, cultural, and archetypal levels.
9. *Intermodal theory*: Understanding intermodal or multiarts theory can aid in blending the arts into processes that are healing and increase creative potential.
10. *Therapy as art*: With these healing multiarts processes, the creative spirit is aroused and the therapeutic process itself is experienced as art.
11. *Approaches to intermodal processes*: There are many styles of integrating the arts. They range from structured predesigned processes to a flow process; allowing the unfolding of the arts intuitively. This choice is determined by the goals of the practitioner.
12. *The power of play*: Play, improvisation, and decentering increase the freedom and imagination in the Temenos play space.

These 12 agreements form the foundation of the discipline upon which practitioners differ only in their application. This is explored in the methods and applications sections.

The Development of the Expressive Arts Therapy Approach

The pioneers in the field of expressive arts therapy came from diverse disciplines. As the field was cultivated, the inspirational seeds of thoughts were transformed into a distinct expressive arts therapy voice and theory. The trailblazers were from the

arts, psychology, philosophy, science, arts education and community action professions, and also from various locations: the east and west coasts of the United States, Europe, and Israel as well as South Africa. The zeitgeist of the 1960–1970s encouraged interdisciplinary endeavors and the interdisciplinary aspects of expressive arts flourished. The dimensions of the definition trace the development of this approach.

Multi-Arts-Multimodal Imagination

The 1960s atmosphere of open exploration supported a shift in perspective about the arts and psychology. Shaun McNiff, one of the first East Coast trailblazers, used the image of the Enduring Shaman as inspiration. In many people's minds, Shamanism often refers to indigenous traditional beliefs and practices concerned with communication with the spirit world in order to heal illness and address the problems of the community.

The Shaman used all artistic forms of expression to transit into the spirit world. McNiff emphasized group and community arts approaches as a defining element in expressive arts. Similar to ancient Shamanistic practices, McNiff relied on the group's multimodal imagination and cohesion to heal, change, and creatively solve problems.

Paolo Knill, a physicist and musician, incorporated his European and more scientific background to define his interdisciplinary approach. One of his chief mentors was Wolfgang Roscher. Roscher's interdisciplinary approach, called polyaesthetics, observed that all arts disciplines engage in all sensory and communication modalities in the perception and production of art. This was similar to traditional Chinese models of arts education where all arts are part of one harmonic body. To truly educate the artist there must be a synthesis that engages all the sensory modalities. Roscher had a profound influence on Knill, who was one of the pioneers of EXA, in the development of intermodal theory, which emphasized the sensory and somatic ways each art discipline communicates to the psyche. Knill blended in broad interpretation of the neurological concept of synaesthesia to his intermodal approach. Synaesthesia is a neurologically-based experience in which the stimulation of one sensory pathway stimulates a different sensory pathway. At times, these multisensory experiences are involuntary and automatic, and can occur naturally in children and adults. A central concept for Knill was the idea that one art/sensory channel would stimulate another, thus creating an intuitive flow of arts.

The Creative Process

Otto Rank was a major influence on the importance of the creative process in healing. A poet, playwright, novelist, and therapist, he understood the creative process and the creative personality. He argued that the artist delves not only into personal creativity, but into collective creativity, thus adding to the continuity of life. Rank felt the artist's creativity solves personal and collective problems and that art becomes a universal symbol. His thoughts gave expressive arts therapy a foundation in understanding the importance of the creative urge and process in societal as well as individual growth.

Natalie Rogers, who led the expressive arts therapy vanguard on the West Coast, was tremendously influenced by

her father, Carl Rogers' humanistic psychology orientation. This model emphasized growth through the creative process as well as holistic and somatic understanding, self actualization, consciousness, relationship in the emotional here and now, and creativity as the life-fulfilling expressions of the healthy personality. Natalie expanded her father's approach, creating an expressive arts approach called the creative connection or person centered expressive arts therapy, in which the creative process was fundamental. She emphasized that finding one's creative connection ignites this process of change and transformation.

Temenos and the Play Space

Creating a free and protected relational space is crucial in any therapeutic relationship. The expressive arts therapists took these ideas into the play space. Ellen Levine, from the East Coast of Canada, was one of the first expressive arts trainers to highlight that safety and freedom were requirements for creativity and the creation of the play space. She was greatly influenced by D. W. Winnicott and the idea of play or potential space. He emphasized that play develops the creative potential and is essential to development. He saw creativity as a basic human experience. This creation of potential space in which inner and outer are blurred permits the creative process to unfold.

Daria Halprin, an early West Coast California expressive arts instructor, was greatly influenced by the work of Jacob Moreno, the originator of psychodrama, and his idea of the protected frame of the stage for creativity and healing. Many other California pioneers were inspired by the work of C. G. Jung, the founder of analytical or archetypal psychology in terms of creativity and safety. Jung borrowed the Greek word Temenos, meaning a sacred circle where one can be himself without fear, to illustrate this image of safety and freedom. These ideas reaffirmed the concept of the importance of Temenos and a safe, clearly defined play space as essential for creative healing and growth.

The Phenomena of the Image

Images are the chief language in expressive arts processes. They have their own intelligence and communicate sensory and somatic experiences. These add to the repertoire of tools in the field. Staying close to the image initially is essential in the expressive arts process. Many expressive arts processes originated from the idea of active imagination, conceived of by C. G. Jung. He proposed that the psyche could be best understood through symbols. Active imagination uses the power of the imagination and creates images that guide associations, out of which a distinct dramatic character is created. Jung used visual arts, drama, and movement to aid his patient's in accessing their multilayered imaginations, and creative expression. Each image becomes a symbol of the psyche and consequently can be more fully understood.

The Potentials of the Image

Here again, the founders of expressive arts therapy were inspired by C. G. Jung and his keen understanding of the

potential of images. He called images *affect images*, as they contain an emotional response, one of our first sources of discovering meaning in the world and in ourselves. Images also become associated with perceptions of other experiences. As the symbolic meaning of an image takes shape, it accesses a never-ending reservoir of meaning. A singular image can offer associations on personal, relational, cultural, and archetypal domains. Archetypes are primordial universal motifs that exist for all people, in all cultures throughout history and they compose the collective unconscious, a reservoir of unconscious imagery that is shared by humanity. These Jungian concepts create a link through imagery, imagination, creativity, and spirituality to earlier Shamanistic practices.

Play, Improvisation, and Decentering in the Play Space

As noted earlier, Winnicott, Jung, and Moreno informed the early expressive arts therapy founders of the importance of play and improvisation. Knill and his colleague, Steve Levine, a prolific author in the early and current expressive arts therapy literature, consider postmodern philosophy to be part of the foundational structure of expressive arts therapy, and use many of related concepts such as deconstruction and decentering. Decentering, a change in perspective or approach, such as improvisation, expands the play space so that unexpected new ideas may emerge. These concepts celebrate the imagination and increase the potential for creativity in the play space of the Temenos.

The Power of Each Art Modality

The trailblazers in expressive arts therapy were artists, musicians, dancers, poets, writers, actors, and creative arts therapists representing each of these disciplines. Each pioneer studied their respective discipline and knew its power thoroughly. These cocreators wanted to emphasize the power of each art modality with its own experience and language. Both the experience and language of the arts may offer great therapeutic value. Knill delineated a paradigm to explain what each modality may offer in terms of sensory-based expression, communication mode, therapeutic, and transpersonal application. Each art modality stimulates a particular set of sensory channels. This permits a particular mode of communication about the imagery and set of therapeutic applications.

Intermodal Theory

As the field developed, expressive arts therapists realized their specialty focused on understanding what happens in the junctures between modalities, with the goal of intensifying or containing emotional and imaginal energy. Understanding these junctures added an additional level of expertise for the expressive arts therapist, and offered them the ability to work with specificity with each person or group in creating these healing multiarts tapestries.

This specialization in intermodality gave rise to unifying concepts and differences in approach and application. There are certain concepts about the arts, imagery, arts modalities, intermodal weaving, and symbolic meaning that define how expressive arts work therapeutically. Over the last 40 years,

expressive arts therapy has grown and deepened its knowledge of the psyche through the use of creative expression and symbolic meaning of one's images. This depth of knowledge and theory gave rise to specialized methods of working with the arts.

Expressive Arts Therapy Methods

This section will highlight those methods that define expressive arts therapy and differentiate them from other traditional verbal therapy and creative arts therapies.

Methods with the Creative Process

In 1928, Graham Wallas defined four stages of the creative process: preparation, incubation, illumination, and verification. These stages are vital to all growth and healing. The expressive arts therapist's understanding of the stages of the creative process can aid in supporting the client when negative feelings arise. C. G. Jung hypothesized there can be negative emotional experiences that are part of the creative process: the void, the abyss, chaos, and alienation. Understanding these negative affects can prevent a premature cessation of the creative process. The incubation stage, which is a quiet stage of consciously turning away from the task at hand and allowing the unconscious to lead, can be enhanced by use of other modalities or de-centered play.

The creative process is universal and underlines all change. Otto Rank espoused that therapy is a process of revitalizing one's artistry, and bringing a creative attitude back into life. Expressive arts therapists accentuate the surprise experience, which is the illumination stage. Focusing on the surprise can invite creative energy back into one's life, and balance the suffering of life with one's creative potential.

Methods with the Image: Phenomena of the Image

Working the image artistically is foundational to expressive arts therapies. This direct experience with the art image, the actual phenomena of the image, separates expressive arts from many other approaches and keeps the focus on the art itself. The body and the senses, and the medium of the art, are used to explore the image artistically, not through cognition. The practitioner might stay with the same modality or transfer into another modality. In a movement sequence, a particular series of movements may have a great noetic or inner energy for the person. In exploring this, the practitioner might suggest that the movement sequence be repeated in larger movements and/or smaller movements, or could suggest drawing the movement or combining sound with the movement. These explorations can unfold into deeper levels of knowing what may be contained in the image, and may lead to revealing its meaning to the client.

Method with Decentering Play

Focusing, or centering on an issue, can narrow the play space and limit and block innovative ideas or images. The method of decentering, however, shifts the person's orientation from

what is known to what can be imagined. It relies on the incubation of the creative process to allow a shift from right to left brain, to create more potential space, and to allow what is new to emerge. Examples of this are free association, or transferring into another art modality.

Methods with Singular Arts Modalities

When working with singular art modalities, expressive arts therapists employ such modalities collaboratively to enhance a person's repertoire of creative possibilities and perspectives. Each modality aids in addressing what is needed at a given therapeutic moment or for a particular issue. Use of the various arts modalities also can open different aspects of the psychic experience that could not be experienced through words or with other modalities.

This approach, created by Paolo Knill, helps the practitioner more fully utilize these potentials, as described here. With visual arts, we have a full visual-motor experience that permits us to obtain a full picture or map of an internal terrain, as well as giving great detail about the experience. It is a modality that lends itself to individual, introverted processes, and then serves to therapeutically contain emotional expression as compared with other arts. Imaginal language arts, such as poetry, prose, or creative writing, permit a subtle opening of many sensory channels through the metaphoric word. Similar to visual arts, it tends to be a more individualized and introverted process and consequently creates more of a container for emotional expression. This creation of a container for emotions is reinforced in that the process of creating and the product of production are separated by time and can be encountered again, permitting more reflective distance.

Music, dance, and drama can be used in an individualized fashion as well as in a group manner to promote more socialization. Each has a more extroverted quality in the production of art and is often expressed in an act of collaboration. This increases the intensity of expression and is helpful when the full power of an experience is essential. Neurologically, dance and music without words can access preverbal experiences, have less reflective distance, and hence can connect to dissociated aspects of consciousness more easily. The multisensory experience of drama often can access these preverbal experiences as it utilizes sound and movement.

With knowledge of the therapeutic qualities found in each modality, the therapist can suggest the modality that may best meet the need for intensification or containment of emotional issues. This is particularly helpful in affect engagement and regulation. Since expressive arts therapy is a body-based approach that invites action and direct art-making, it enhances the relationship of the link between the body's experience and emotional understanding.

Methods of Integrating the Arts

Layered on the foundation of understanding the creative process, imagery, and the nature and language of each modality is intermodal theory developed by Knill. Its main concept, of integration of the arts, is called intermodal transfer, the sensitive, intuitively trained skill of integrating arts modalities. Its goals are multiple:

1. to focus the process;
2. to provide emotional clarity, containment, or intensification;
3. to enhance the play space or imaginative range;
4. to enhance the crystallization of emotional material that may emerge in the arts process.

An alternative concept is intermodal superimposition, in which the client is asked to stay with the original intention of the image, and add on another art to amplify the imagination around the original image. McNiff utilized this a great deal in his image dialogues, in which a visual image would be asked to speak or be asked questions. This is very similar to Jung's active imagination.

Low skill and high sensitivity is another idea, coined by Knill. It means the arts are available to all, so no artistic skill is necessary. However, the expressive arts therapist must be highly sensitive to the client's process by being fully present, and able to hold an understanding of the art and psyche in order to aid the client in their artistic expression. McNiff phrased this very simply: that, for the client, the simpler, the deeper.

Methods with Expressive Arts Therapy and Trauma

Historically, the Veterans Administration (VA) was the first large organization to realize that musicians, artists, actors, dancers, and poets could function as trauma therapists. After the First World War, VA hospitals hired musicians to use music to work with victims of *shell shock*. Music helped to 'heal the savage beast' who is suffering inside, and also enabled group activities for the many soldiers returning home with these issues. Similarly, after the Second World War, dancers, actors, poets, and visual artists were hired to assist with *battle fatigue*. The VA truly helped the arts disciplines develop into therapeutic approaches. The very names of war-induced traumatic disorders: shell-shock, battle fatigue, *combat stress* aids in understanding that trauma are a bodily sensory experience as well as an emotional one. Now expressive art therapists are working with many veterans diagnosed with *post traumatic stress disorder* (PTSD).

Current neurological research supports the intuition that trauma affects the homeostasis of the body as well as the organs and biological systems. In turn, these somatic experiences shape the perception of threat, attachment, and processing of memory. Trauma disorganizes, fragments, and dissociates memory into sensory shards, and there is little integration of narrative memory. Trauma therapist Bessel van der Kolk stated that traumatic memory is stored in the somatic, sensory, imagistic memory, and only later is it woven into narrative memory. He promoted the use of art making, an action orientation rather than verbalization, and this includes the use of multiarts approaches. Although still controversial, his ideas support much of the work of the early artists in the VA hospitals.

Lois Carey, in her book on trauma and the expressive arts, highlighted the ways in which the arts can be used with trauma. Modalities that address anxiety and encourage the building of a safe relationship are not solely verbal. Somatic awareness processes using the breath and imagery, playing soothing music, and/or drawing a safe place or protector can facilitate the decrease of anxiety and create an opening for an attachment to therapy. Using the body and drama techniques

can assist in reclaiming the essential elements of one's life. Rehearsing life tasks, and reclaiming the positive parts of life through movement and enactment, can rebuild the collapsed inner-structure of the trauma survivor. Visual arts can give a solid, strong reflective distance to begin to explore the trauma itself. These are among the many methods developed by expressive arts therapists to address and work through traumatic experiences and reclaim life. Addressing the effect of trauma on the soma and psyche has been one of the current major foci of expressive arts therapy today.

Expressive Arts Therapy Applications

The expressive arts approach has many applications, depending on the practitioner's training and goals. In addressing the application of expressive arts therapy and professional standards of practice, the International Expressive Arts Therapy Association (IEATA) has delineated three areas in which EXA can be practiced. The first is the expressive arts therapist, who combines mental health and psychological education with intermodal training. Expressive arts therapists may work in hospitals, private practice, clinics, schools, residential facilities, or for global organizations. They may work with deeper psychological issues or in long-term depth orientation with individuals, groups, couples, families, children, and adolescents.

The second mode of practice is of the expressive arts consultant/educator, who usually works within local, national or international organizations, conducting groups, and workshops, as well as addressing coaching and growth issues through the arts.

The third mode of practice is composed of artists who work in groups emphasizing the community, and growth aspects of the creative process. While there is tremendous overlap, and many IEATA members occupy all three categories and may conduct similar services, this differentiation might help reveal the breadth of expressive arts therapy applications and practices. For more information, refer to the IEATA's website listed in the reference section.

Conclusion

Expressive arts therapy has developed over the last 40 years into a strong therapeutic approach. It has created a solid theoretical foundation, strong methods, and expanded the application of the arts to address many issues of human suffering and potential in the last 20 years. Expressive arts therapy harkens back to earlier ideas that all members of a community have the potential to be creative in their lives, and to use all the artistic disciplines to heal themselves and their communities.

Families and Creativity

A Kohanyi, Kwantlen Polytechnic University, Surrey, BC, Canada

© 2011 Elsevier Inc. All rights reserved.

Glossary

Authoritative parenting A style of parenting characterized by high expectations and rules as well as freedom and flexibility. Dialogues about the rules and boundaries are also encouraged.

Child-centered families Families who spend a vast amount of time, energy, and resources on developing their children's interests and enriching their experiences. Some parents want to insure that the children they perceive as gifted receive early instruction in their domain of giftedness.

Complex families Families characterized by a balance between integration (i.e., seeking support and warmth) and differentiation (i.e., seeking independence as well as developing one's own identity and interests).

Eminent creativity Characterized by such originality and novelty that it is recognized by a certain field as

being culturally significant, and being remembered for altering a domain.

Enriched environment Home environments characterized by books and multitudes of other intellectually stimulating resources. Parents typically read to their children early on, hold serious discussions with them, and take them to interesting places such as museums, zoos, and theaters.

Everyday creativity Characterized by originality and uniqueness as well as meaningfulness and usefulness in day-to-day life. It might not revolutionize a field, but it makes a difference in the creative person's life.

Resilience The ability to function competently in a stressful situation that threatens development and adaptation. It has also been defined as the ability to recover from trauma.

Introduction

Families are lambasted or exalted in numerous works of arts such as plays, novels, songs, and operas. They are depicted mercilessly or indulgently in paintings. Playwrights, novelists, songwriters, composers, and painters thus hold particular views of families that may or may not be reflected in their work. Regardless, their families shaped their creative evolution. For example, Mozart's father resolutely turned away from his own (admittedly flailing) career and devoted himself almost exclusively to his son once he realized the boy's talent. Similarly, Picasso's father allegedly pledged to stop painting once he realized that the 13-year-old boy was better than him. He then dedicated much time and energy to his son's artistic education. Freud's mother adored her son and the family life was strictly structured around his work habits as a young person. Whether these eminent creators would have become equivalently eminent had their family circumstances been different is as infinitely intriguing as it is unanswerable. However, the influence of the family on the lifelong development of creative talent has received much theoretical and empirical attention. That is the topic that I will explore here. I will review family characteristics and the role of stress in the early lives of creators. I will then look at the set of responses that creative children develop as a reaction to stress, and will

examine how this very set of responses shapes their creative development. I will end by presenting a framework that ties together the overarching themes reflected on in this article. Even though it is generally accepted that creativity requires the input of both nature and nurture, I will not cover the hereditary aspects of creativity here because it is outside the scope of this article.

Family Characteristics

Parenting Style

Mothers who are warm, involved, caring, and yet willing to give their children the freedom to explore at their own pace are more likely to have creative and imaginative children. Mothers of creative children who scored high on creativity tests and were labeled as creative by their teachers seem to be less over-protective and more tolerant of the hostile feelings their children may direct toward them than mothers of other students. Naturally, many children labeled as creative do not necessarily become eminent creators. These women in general are well educated, successful in their careers, and self-confident. Moreover, parents of creative achievers tend to be more egalitarian, and creative young people themselves are less concerned about following rigid sex roles. Thus, they also seem comfortable

considering activities and fields that are not typically associated with their gender.

Families favoring independence are likely to have creative children. Indeed, highly original children were generally encouraged to be independent from their earliest age. Parents who value independence are also usually receptive to unconventional thinking and to particularly imaginary play, such as involvement with imaginary companions and imaginary worlds. This form of play is associated with various forms of creativity in adulthood. Thus, it seems that the child rearing style of creative achievers' parents tends to be less conventional, and more flexible, which promotes originality, and freedom of expression. Although they might appear lax, rules and expectations are firmly in place as well within these families. This style of parenting is sometimes referred to as authoritative, and is characterized by the presence of both boundaries and flexibility. Boundaries give children a sense of security, while flexibility offers children the freedom to discover, explore, and play, all of which have been associated with problem solving.

Parents of creative children have a particular approach to parenting. Likewise, they have a specific approach that is conducive to the development of creative potential, as evident in their interactions with their children, their home environments, and the experiences they expose their children to.

Family Background

Creative individuals had encouraging parents who were likely to be financially and culturally privileged. Finances, and more generally, socioeconomic status (SES) is relevant to creative development because it influences material resources available to the child, as well as whom the child is exposed to, how much travel he/she engages in, and which institutions the child visits. In addition, part of SES is education. The parents' level of education impacts what is discussed at home and how. Furthermore, it also carries the message that education is highly regarded in the family. Another aspect of SES is economical. Families with significant resources may be less concerned about gearing their children toward high salary careers and are willing and able to support nontypical interests. Thus, SES has an effect on richness of experience, which has been related to divergent and flexible thinking.

Creative achievers generally come from enriched, child-centered environments. Parents support, encourage, and are dedicated to the development of their child's innate creative talent. The climate at home is very stimulating with books and a multitude of other resources readily available. Parents make a conscious effort to regularly expose their children to various venues illustrating the richness and diversity of the life of the mind. Indeed, nothing is spared to feed the child's interest. Parents take their children to zoos, theaters, concerts, museums, and libraries. Creative achievers' parents respect learning and the pursuit of intellectual and artistic interests. They tend to be creative themselves in addition to broadly curious. These parents often love challenging debates, and are typically busy in cognitively demanding activities. They engage their children in serious discussions about complex matters. Parents also regularly read to their children from their earliest childhood. These parents respect their children's opinions

and consider what the children say and do as important. Hence, they regularly collect their children's work and highly value it. They also encourage their children to be independent, and foster as well as model values such as discipline and hard work.

Thus, through interesting books, enriching experiences, and stimulating conversations, creative children develop a certain understanding about the world that lays the foundations for the acquisition of further knowledge. A wealth of knowledge is indeed considered a prerequisite for creative endeavors. Moreover, a child centered environment builds the child's self-confidence and makes him/her feel valued and loved. However, a child centered environment does not preclude that tensions exist between parent and child, or that the child's life might be stressful because of other types of adversity of various degrees of seriousness. One type of stress is the presence of siblings.

Birth Order

In some families, particular children are clearly favored over others. This can lead the less cherished offspring to express their frustration creatively. Their creative efforts thus attract attention, and allow these creative children to distinguish themselves from their siblings. Indeed, birth order plays an important role in determining family expectations and resource allocations. It can also establish which child will occupy which niche within the family, including who will be deemed the 'creative one.'

However, there is a lack of consensus within the literature with regards to creativity and birth order. First born appear to be more creative based on some studies whereas others claim that it is later born who hold this merit. Another position is held by scholars who suggest that family size, age differences, and sex differences are the mediating factors in the birth order-creativity equation. There are also researchers such as Frank Sulloway who propose that first and last born do not seem to exhibit differences in their levels of creativity. Rather, they differ in the types of problems they attempt to solve, and in the particular creative approach they select to solve them with.

Sulloway argues that birth order affects the various stratagems that siblings concoct in order to win parental approval. Indeed, the overrepresentation of first born among creative achievers could be attributed to their special status within the family. As first and only children, they received all the attention from their parents and enjoyed all resources available. They are thus motivated to hold on to this privileged position when siblings arrive. They do so by identifying with parental authority and accepting the power structure within the family. They often act as surrogate teachers to younger sibling(s) to further please their parents, which gives them experience with responsibility and maturity. First born typically demonstrate early focus, and are more academically and achievement oriented than later born.

The exceptionally high number of last born among eminent creators might be due to birth order as well. As the youngest in the family, the last born also received a lot of parental attention, perhaps because he/she is the last child the parents will ever have. Last born, precisely because they are later born and never received undivided attention from parents, tend to be indifferent to power and to question and challenge the status quo. They are more rebellious than first born, who have clear

conventional and conforming tendencies. Indeed, last born must carve a distinctive place for themselves within the family sphere, and must experiment to discover their niche. Hence, they adopt a personality style and field of study that are distinct from that of both first born and parents.

Later born are thus much more likely than first born to accept and embrace new and revolutionary ideas (i.e., Darwin's theory of evolution). Whereas first born do not support radical revolution, later born do not back conservative ones. Likewise, first born demonstrate their creative brilliance within a field's accepted paradigm, while later born exhibit their creative virtuosity outside the *status quo*. First and last born also differ in the expression of their creativity through the two dimensions of openness to experience. Indeed, Sulloway proposes that birth order relates closely to this personality trait so that first born use the intellectual dimension of openness to experience (i.e., perceptiveness, curiosity, and culture) and later born the nonconformist dimension (i.e., risk taking, unconventionality, originality, and independence).

Furthermore, first born are disproportionately represented among eminent scientists, and tend to excel in the physical sciences, possibly because problems are well defined within this field. Numerous eminent scientists are last born as well, although less so than first born. Last born are more altruistic than first born, and thus likely to excel in domains that are socially oriented. They often prefer the biological and social sciences, where problem finding plays an essential role. In addition, last born tend to work simultaneously on multiple projects that often cross boundaries. When they win the Nobel Prize, it is in domains such as peace and literature, whereas first born tend to be honored for their contributions to the sciences.

Birth order therefore influences the personality of siblings because it shapes the approach they select to win parental favor. Thus, for Sulloway, birth order ultimately contributes to the ways first and last born reach creative eminence. Creative children also face much more taxing situations than competition with siblings.

Stress

Creative versus academic achievers (meaning, children who do well at school) present very different family profiles. The latter's families tend to be more stable, child centered, and favoring a conventional style of parenting. The former tend to come from troubled family backgrounds, where the relationship between family members is tense, the parenting style unconventional, and the likelihood of parental dysfunction high.

Indeed, studies on the childhoods of eminent individuals based on material culled from biographies and autobiographies reveal adverse family environments. Victor Goertzel and Mildred Goertzel examined the home environments of 400 eminent individuals, and then 317 additional ones. Forty-four percent of the entire sample of 317 eminent people experienced a stressful childhood, including a majority of the actors, novelists, composers, musicians, explorers, athletes, philosophers, and psychologists. For example, as children they were raised by single parents, moved frequently, witnessed parental alcoholism, fights between their parents, and other forms of family trauma. They experienced poverty, prejudice,

and racism. They were the victims of neglect, abuse, and abandonment. They suffered from the loss of a sibling or of one or both parents, mental illness in one or both parents, and suicide in the family.

Only 58 out of the 400 individuals studied by Goertzel and colleague had a normal, loving, and supportive family, which led the authors to conclude that a happy home environment does not predispose one to become creative. Nevertheless, limitations of studies based on biographical and autobiographical material are well documented, and the individuals reviewed by Goertzel et al. were eminent, which does not necessarily imply that they were creative.

However, these studies are not alone in their claim of a relationship between creative individuals and traumatic home environments. For example, Robert Albert found that a higher than average percentage of creative individuals experienced parental loss early in life (30% of eminent people studied suffered the loss of one parent, as compared to 8% in the general population).

Creative children are likely to experience more tribulations than their equally bright but less creative peers. It has even been intimated that a certain tension between parents and children furthers independent thinking, whereas a harmonious relationship tends to promote a more conventional thinking style. Children's response to stress may both be influenced by and play a role in determining the development of their creative potential.

Response to Stress

A distressing family environment does not automatically result in creative outputs. Indeed, William Therivel affirmed that different types of childhood afflictions may result in different outcomes. For example, trying relationships with parents, early parental illness, parental absence, or parental loss are tragic and painful for a child. However, these forms of adversity will not lead to feelings of hostility toward parents and other adults. Abuse, on the other hand, will often elicit strong opposition to all forms of authority. Individuals who underwent this type of trauma might be creative in their lifestyle, but will not be engaged in significant creative pursuits.

Children who experience a strained relationship with their parents may try to minimize contact and turn to intellectual and creative activities for solace. They are likely to feel in control within their domain of predilection. This feeling may help partially remedy the lack of control that they experience in their everyday life. They also involve themselves in creative pursuits to fulfill their emotional needs. In addition, being ignored or rejected by parents seems to lead to the development of a unique identity, distinct from those of the parents, which appears to be a critical element of the creative personality.

Furthermore, difficult home environments are likely to interfere with the normal process of socialization. Children sometimes have parents who are unable or unwilling to guide them through social mores, appropriate behavior, and rules. They may also fail to enroll them in traditional schools. These children then acquire limited knowledge of conventions, which Therivel referred to as 'scripts.' They are also prone to reject these scripts, and as a result, become autonomous, divergent, and independent thinkers. Further, absence of parents

automatically results in children being unable to create bonds and identify with the absentees. Lacking a role model, these children are likely to have more unconventional and unusual lives. More immediately, a problematic home life leads children to feel different.

Solitude

A lot of creative achievers and other gifted individuals were often rejected by others as children because they were deemed different. Rejection made them hypersensitive and tense. As a result, and because of their particular home situations, they spent a great deal of time alone as children. Time alone has been deemed critical to the development of the creative individual, and children used the time to read, learn, practice, and acquire new areas of knowledge. In addition, many creative and imaginative children who spend a lot of time alone develop a rich fantasy life. A vivid imagination is believed to stimulate the use of imagery and visualization, which can be used later on to problem solve. Furthermore, fantasy is an effective strategy to cope with emotional and psychological trauma and pain. Within their imaginary worlds, children are able to rectify the ills of their lives and play out scenarios in which they emerge victorious.

Regardless of the cause of their isolation, creative children come to develop a taste for solitude, and eventually even seek it out. This ability to be alone and enjoy it appears to be an important skill to possess, particularly in adolescence, when the lure of the crowd is particularly powerful. More generally, early adversity is likely to prompt children to develop a repertoire of responses and personality characteristics that are not only conducive to creative achievement but also prepare the individual for the risk taking inherent to the creative professions. Furthermore, these responses acquired in childhood may be very useful when facing the uncertainties, difficulties, and marginality often characteristic of the lives of highly creative people.

Outcome of Childhood Trauma

Children react in a multitude of ways to situations of dysfunction. As adults, they may try to capture the fear and panic and anxiety of their childhoods in their creative works. For example, early hardship could be a recurring theme in the individual's life, a haunting theme that the individual may revisit and attempt to rework and rewrite in a more satisfactory fashion. In addition, individuals may try to compensate for rejection or abandonment in childhood through a high desire to achieve. Indeed, inborn talent in addition to the motivation to surmount adversity might help account for the development of creative individuals who lack family support.

Further, Howard Gardner posited that creative individuals favor a certain level of anxiety and stress because it was a prevalent emotional state in their childhoods. They seem to crave some discomfort in their lives and feel anxious when tension is absent in the situation or within themselves. They then tend to generate stress in their professional and personal lives by engaging in different kinds of behaviors. However, it seems that there also exist creative individuals who did not develop creatively through tension and trauma, but through more conventional routes.

No Stress

As discussed previously, creative individuals tend to grow up facing adversity. However, there is a certain level of disagreement regarding the topic. Indeed, there are studies proposing that creative achievers also come from stable, happy, and supportive families. Contrary to Goertzel and colleague's findings, these scholars state that artists, musicians, scientists, and athletes also grow up in healthy atmospheres. Indeed, they claim that the most creative and productive of achievers come from such encouraging contexts. They also argue that outside the art world, there is little evidence of family malfunction. For example, scientists, inventors, and mathematicians are believed to come from stable families. Inventors in particular seem the less likely to have had stressful childhood homes.

These findings are reflected in Rogers' Theory of Creative Environment, which states that for constructive creativity to develop, the presence of two conditions is required: psychological safety and psychological freedom. Psychological safety is fostered when an individual is regarded by his/her environment as having unconditional worth, when the environment is nonjudgmental, and when the individual feels understood. The former is achieved when the individual is allowed to express him or her self freely. Rogers' theory was later empirically supported. According to this theory, the most central element to the development of creativity is for a child to receive unconditional positive regard from his/her family.

There are researchers who support neither the tense and tough home environment hypothesis nor the nice and loving home environment hypothesis and advance instead that happy families contribute to everyday creativity, where people live productive and helpful lives, whereas a certain amount of stress characterizes the background of eminent creators.

Stress and support are not irreconcilable, and it is possible to conceive of a family filled with stress and tension, and yet, giving the child unconditional positive regard and catering to his/her needs, interests, and achievements.

Reconciling Stress and No Stress

Stress alone does not necessarily promote creativity, but stress in addition to support is a more likely formula. For example, Cervantes, Picasso, Freud, Einstein, Goethe, Beethoven, Dickens, and Marx are believed to come from such a background. Moreover, although families of creative individuals tend to be tense and stressful, they may also be structured in a way that buffers stress. For instance, parental neglect may be counterbalanced by attentive siblings, relatives, or friends. A child with an abusive parent may receive attention and love from the other parent. Even in situations of poverty, parents of creative achievers attempt to shelter their children from adversity and emphasize the importance of books and education.

Thus, parents interpret the situations for their children, and these interpretations affect how the child will react to the events. In particular, this parental intervention might trigger a certain level of resilience in the children. Their creative talents and the enriched, child-centered home environment may also contribute to these children's ability to navigate difficult times. Resilience does not mean immunity from stress, but rather the capacity to cope well and be able to function even in the midst of adversity.

Further, resilient children and creative children share many characteristics. Indeed, both are likely to be curious, intelligent, and fast learners. They are able to concentrate and problem solve. Both also seem to have good self-esteem, and be independent. In terms of family background, and again, consistently with creative children's profiles, resilient children are close to their parents. These parents are likely to be authoritative, and are loving, communicative, and supportive. They hold high standards, and supervise their children closely.

It is important to note, however, that most childhoods marked by adversity lead to negative outcomes. For instance, poverty can prevent parents from having enough time for their children, and lack of parental involvement and support have been associated with low self-esteem and behavioral problems. Mihály Csikszentmihályi stated that when one has to fight to guarantee basic survival, there is no time and resources left for anything else. In addition, not all creative achievers are resilient since a higher than average percentage of creative writers and other creators suffer from a mood disorder.

Complex Families

Gary Gute, Deanne Gute, Jeanne Nakamura, and Csikszentmihályi applied a conceptual framework called the Complex Families Framework to the family's contribution to creativity. This is a fitting framework to include here because it pulls together a lot of the ideas and themes visited in this article.

According to this framework, complex systems seek to both differentiate and integrate in a continual, organic process. Family members differentiate by pursuing their own goals and developing a distinct identity. They value independence and involve themselves in activities that require increasingly more advanced skills. These activities also provide appropriate levels of difficulty. Differentiation includes parents facilitating the discovery of new interests and challenges for their children. Parents also model perseverance, self-discipline, and hard work. Thus, creative children observe their parents fully immersed in hard intellectual work and witness the satisfaction derived from it.

Family members integrate by pursuing harmony and continuity through emotional support. They also weave cohesive bonds with each other by establishing common values, traditions, and goals. Thus, integration provides support, security, and a sense of belonging. Integration also involves parents supporting their children's interests and skills, spending time with them, establishing values and rules, and responding to failure intelligently. Another aspect of integration involves the heterogeneous backgrounds, geographical or ethnic origins, ideological positions, or personalities of family members. Indeed, Goertzel, and Goertzel highlighted that first- and second-generation immigrants were well represented among the eminent individuals they studied. Likewise, first- and second-generation immigrants distinguish themselves on creativity tests. These findings are consistent with other empirical results suggesting that bi- and multilingualism, bi- and multiculturalism, as well as immersion in a milieu that tends to question or present alternatives to accepted norms and values stimulates creativity. This diversity within the family allows children to experience varied approaches to the world, as well as varied ways of thinking and doing.

Establishing a good balance between differentiation and integration seems imperative. An over-focus on differentiation would favor the development of eminent (and noncreative) levels of talent. An overemphasis on integration would result in stability and competence but neither in talent nor in creativity. Expectations and boundaries need also to be in place to create a healthy structure.

Conclusion

The contribution of the family to creativity begins early in life and continues as creativity progressively evolves during the lifespan. The family provides a climate conducive to the child's creative talent development. However, being child-centered does not exclude the presence of stress, and stress might elicit specific kinds of reactions and engender particular personality characteristics that are favorable to creativity but also to the creator's tumultuous lifestyle and career. Although trauma plays an important role in the evolution of creativity, it seems that normal, happy families can fuel creativity as well. It is possible that everyday creativity originates from such a milieu, whereas eminent creativity appears to necessitate some level of tension. It also seems likely that creative achievers come from hectic backgrounds that are also loving and supportive. Parents might filter external stressors and interpret the world for their children, and thus render the stress manageable.

Hence, high levels of creative achievement may rely on the desire to succeed, particular characteristics emerging from childhood trauma, as well as the need to fulfill emotional and psychological needs. It may be that a less dramatic balance of support and stress results in other levels of creativity. Creative achievers who lack family support may have to rely on their inborn talent as well as their motivation to overcome adversity in order to succeed.

Thus, elements conducive to the development of creativity in young people include both challenge and support. Young people are then likely to value and take pleasure in hard work and productivity, enjoy what they do, and thus derive self-esteem and feelings of competence from it. It also seems that one of the central aspects of creative people's lives is complexity. Complex families are able to establish a balance between supporting their children and establishing boundaries and rules; spending time with their children and yet resisting controlling them; having high expectations and yet recognizing that experimentation and failure are normal. It seems that families who find the right balance between integration and differentiation offer an environment that is optimally conducive to the development of lifespan creativity. Thus, the family context of creative children is likely to strongly influence whether the individual ultimately lives up to his/her potential or not.

Glossary

Auteur theory The critical position that film should express the unique vision of the filmmaker, most often viewed as the director. As such, a film has the same status as a painting, novel, or symphony that can also be attributed to a single recognizable creator.

Box office gross The total receipts during a film's theatrical run, most often expressed in US dollars. Most research uses the US domestic gross, but sometimes the figures are from another nation or even worldwide. Gross may also be broken down by week or weekend.

Dramatic awards cluster The set of movie nominations and awards in the categories of direction, writing or screenplay (original or adapted), lead male acting, lead female acting, supporting male acting, supporting female acting, and, occasionally, film editing.

MPAA ratings The evaluations published by the Motion Picture Ratings of America that indicate the audiences most suitable for a given film.

Music awards cluster The set of movie nominations and awards in the categories of score and song.

Production costs All expenses associated with the making of a film, but excluding the expenditures involved in promotion and advertising. Also called the film budget (or negative costs, i.e., the cost of producing the negative from which the positives are made).

Technical awards cluster The set of movie nominations and awards in the categories of special visual effects, sound effects editing, and sound mixing.

Visual awards cluster The set of movie nominations and awards in the categories of art direction (and sometimes set decoration), costume design, and makeup (and sometimes hair).

Introduction

Film has been called the 'seventh art,' after painting, sculpture, architecture, music, dance, and poetry. Yet the comparison is somewhat misleading given the great antiquity of the other six forms of artistic creativity. Where the six were already well established by the time of ancient Greeks, film did not emerge until the early twentieth century. Even then, film was not immediately recognized as an art form. The medium had originally evolved from the application of photography to the study of motion. Later these 'moving pictures' became a form of popular entertainment, a transition perhaps best symbolized by the advent of Nickelodeon theaters.

But, as films became longer and more complex, the medium's potential for artistic creativity began to become realized at the hands of several classic film-makers. By the 1920s, certain feature-length narrative films began to be viewed as works of art. By the end of the decade, the Hollywood film industry formed the Academy of Motion Picture Arts and Sciences, which soon began awarding Oscars for major cinematic achievements. Not long after the first film festivals began to appear, starting with Venice in 1938 and the famed Cannes Film Festival launching in 1946. During these years film criticism appeared as an independent branch of journalism, and eventually the form received academic endorsement with the appearance of film studies programs at major universities.

By the latter half of the twentieth century there seemed to be no doubt that film could claim its proper place as the seventh art. In the United States, for example, the National Endowment of the Arts created the American Film Institute dedicated to celebrating the art of film. Soon AFI was publishing ranked-order lists of the all-time masterworks in the form. Another development that took place in this period was the

materialization of 'Auteur theory.' This doctrine began in the mid-1950s with the critics of the French New Wave, and it was further developed by film critics and scholars in the United States. The basic idea was that film provides an artistic medium in which film-makers – most often the directors – should express their personal creative vision. This theory gave the seventh art a more even status with the earlier six. Just as painting has Rembrandt, sculpture Michelangelo, architecture Le Corbusier, music Beethoven, dance Balanchine, and poetry Shakespeare, so does film have such creative geniuses as Pedro Almodóvar, Ingmar Bergman, Luis Buñuel, Sergei Eisenstein, Federico Fellini, Werner Herzog, Alfred Hitchcock, Akira Kurosawa, Spike Lee, Roman Polanski, Jean Renoir, and Yimou Zhang.

Although film is now recognized as a legitimate medium for artistic creativity, it has received much less research attention in comparison to the other arts. It is likely that one reason for this neglect has to do with its recent entry into the list of artistic media. Yet another reason may be no less crucial: Film is inherently a collaborative product. Even the core crew and cast consist of dozen of individual talents who must collaborate in the creation of the final product. As an instance of group creativity, it does not lend itself well to the most common research methods, such as laboratory experiments. Indeed, laboratory investigations of film tend to focus on empirical questions that are only tangentially related to cinematic creativity. For instance, a large number of experiments have been devoted to assessing how music can affect the processing of visual information. Despite the importance of the findings from the perspective of cognitive psychology, the connection with cinematic creativity is more remote. As a case in point, empirical research by Simonton (2002–2009) shows that the quality of a film depends very little on the quality of the film score. It is possible that the more the

music draws attention to itself the more it detracts from the film's overall impact.

The last point raises a critical question: How does one assess cinematic impact? On what basis can one film be called a masterpiece, another mediocre, and yet another a turkey or bomb? This question can be answered more than one way – a point that must be demonstrated next.

Impact Criteria

Scientists who study cinematic impact have a multitude of choices for the criterion variable. For example, investigators will sometimes use consumer surveys or, more recently, popular assessments posted on the Web (e.g., Internet Movie Database 'user ratings'). Nonetheless, the vast majority of investigators tend to use one or more of the following three sets of criteria: critical evaluations, financial performance, and movie awards.

Critical Evaluations

Professional critics provide evaluations of the hundreds of films released each year. These assessments are often expressed in quantitative form, most often stars. Thus, one film might get five stars, another 2½ stars, and yet another just one star. This practice permits the direct comparison of the degree of critical consensus. Research has shown that the agreement is extremely high even if not perfect. For the most part, the best films tend to receive consistently high marks whereas the worst films earn consistently low marks. As a consequence, composite measures using the ratings from multiple critics will exhibit reliabilities comparable to standard psychometric instruments. In addition, the critical evaluations display considerable stability across time. This stability becomes apparent when the assessments published during the film's theatrical release are compared with the assessments published after the film becomes available for rent or sale in video or DVD format. Despite a temporal separation of two or more years, this 'test-retest' reliability also compares favorably with that seen in the best psychometric measures. Composite critic evaluations have another feature: the scores tend to be normally distributed, masterworks and turkeys being much rarer than mediocre films. Finally, because critic evaluations constitute expert judgments, such assessments have strong face validity as well. The composite measures can be considered a version of the consensual assessment technique.

To be sure, critic evaluations have been disparaged as representing elitist evaluations. Film critics seem to prefer foreign-language, small-budget art-house films over the mainstream Hollywood wide-distribution blockbusters. However, this complaint is not completely justified by the research. Critical evaluations are positively correlated with consumer judgments. The main difference between critics and consumers is the quantity of films watched. Those consumers who are avid movie-goers are more likely to concur with critical opinion. Still, researchers concerned about critical elitism can turn to the next impact criterion instead.

Financial Performance

Although film is recognized as art, it must also be acknowledged that the film industry is big business. Like any business, the goal is to make a profit, and that end is only achieved if the film attracts large crowds of consumers to the movie theaters. Admittedly, films can also earn money through video/DVD rentals and sales as well as television broadcasts. Yet even these earnings depend very heavily on previous box office success. People are more likely to buy or rent a DVD of a blockbuster than a financial flop. Accordingly, financial performance can be used as an indicator of popular acclaim, as distinguished from critical acclaim.

Financial performance can be assessed a multitude of ways. The most common measure is US domestic box office gross. Less common is world gross earnings, which is not always available. Another alternative is the first weekend gross or the first week gross. Yet it should be noted that all of these figures could be misleading without introducing some adjustment for budget (or production costs). Budget is strongly associated with advertising and promotion expenses, and the latter are highly correlated with box office returns. Profit is what is left over after these costs and expenses are subtracted. Usually a film must gross at least twice its budget to become profitable. Consequently, most films lose money in the theaters. If it were not for the minority of blockbusters that reap huge profits, there would be no film industry, at least not without substantial government subsidies.

Interestingly, although critical evaluations are normally distributed, financial performance has a highly skewed distribution with a long upper tail. So poor are the financial expectations for films at the bottom end of the distribution that a significant percentage of the films made each year go directly into video/DVD, bypassing the theaters.

Movie Awards

The third way of assessing cinematic impact is to use awards. Various organizations offer numerous nominations awards each year. Besides honors for best picture, these can include recognition for direction, writing, acting – male/female and lead/supporting – cinematography, art direction, costume design, makeup, score, song, special visual effects, sound effects editing, and sound mixing. Some of these awards are bestowed by professional or guild organizations, such as the Academy of Motion Picture Arts and Sciences or the Screen Actors Guild, whereas others are distributed by critics associations (e.g., the New York Film Critics Circle). The Hollywood Foreign Press Association, a society of journalists, grants the famed Golden Globes each year. Despite the diversity of award organizations, they tend to display a consensus regarding the recipients. The agreement is almost as strong as that seen for critical acclaim, albeit the consensus is greatest for the most salient honors, such as best picture, direction, and acting. Furthermore, the consensus does not extend to awards earned at film festivals. The latter tend to be more capricious regarding the competition.

One major advantage of movie awards is that they provide a more finely differentiated profile of cinematic impact. Critics assign a single overall rating just as the financial records

provide a single figure. Although best picture honors are similarly global, the remaining honors are more specific. However, these more specialized awards cluster into four groups: (a) dramatic (direction, writing, acting, and editing); (b) visual (cinematography, art direction, costume design, and makeup); (c) technical (special visual effects, sound effects editing, and sound mixing); and (d) musical (score and song). Some films might receive the major dramatic awards without receiving recognition in the other clusters. It is significant that the dramatic awards correlate highest with best picture honors.

Movie awards do have some drawbacks as impact criteria. First, like financial performance, counts of awards and nominations are highly skewed. Only a minority of films are even nominated for any award, and a smaller proportion of these actually receive one. Second, the awards and nominations are often influenced by factors that are extraneous to actual cinematic merit. For instance, the larger the number of prior Oscar nods a director receives the higher the probability that he or she will win the award. Third, certain genres are favored over others. Dramas are far more likely to win a best picture Oscar than are comedies. Horror and science fiction are even more disfavored than comedies.

Criteria Correlations

If these three sets of impact all highly intercorrelated, then it would not matter which one was actually selected for study. One might serve as a proxy for all. Better yet, the three sets could be combined into a single composite measure of cinema greatness. Unfortunately, the empirical results yield a more complex picture.

To start with, the correlations between critical evaluations and financial performance are only weakly positive. Some researchers even find zero or negative correlations. Many of the inconsistencies can be attributed to the specific criterion in each category. For instance, although critic evaluations will often correlate negatively with first-weekend gross, they will more often correlate positively with total gross earnings. The early financial success of a film is often heavily influenced by promotion and advertising, whereas its ultimate success is contingent on aesthetic quality, which the critics do a good job assessing. The connection between critical acclaim and box office success is moderated by other factors, too, such as the presence of stars. Moviegoers will often buy tickets to see a star-studded film even if it is panned by the critics.

Financial performance also has an ambivalent relation with movie awards. One complication ensues from the timing of a film's release. If a film comes out toward the end of the calendrical year, then its receiving special recognition can enhance its box office success. But if a film is released early in the year, it may no longer be in the theaters by the time the award ceremonies begin. In that case, the question becomes whether its financial performance might earn it some honors. Another nicety concerns the distinction between nomination and actual award. These are seldom announced at the same time, and this temporal lapse can affect the association. As an example, consumers may go see the movies that have received Oscar nods for best picture, but not go back to see again the film that actually won. In that situation, the nominations but not the

awards influenced financial performance. One final complication is that only high-profile recognition bears any relation with financial performance. Few consumers go see a film to enjoy its sound mixing.

In contrast, the correlations between critical evaluations and movie awards are consistently and unambiguously positive. It is rare for a critically acclaimed film not to receive such recognition. Indeed, the correlation would probably be much stronger if it were not for the rather divergent distributions for the two sets of variables. The fine distinctions that critics make at the lower end of the distribution have no repercussions because nominations and awards are almost never allotted to the films at the bottom. Nevertheless, it is essential to point out that not all movie honors are in accord with critical commendation. In particular, critical evaluations correlate most strongly with the awards in the dramatic categories, with direction and writing having the greatest weight. Critics seem to prefer most a great script realized by great direction; the actors and editor merely helping to achieve that realization.

It would seem that of the three sets of criteria, box office is the 'odd person out.' Critical evaluations and movie awards agree more with each other than either agree with box office indicators. To appreciate the basis for this split, we need to look at the factors that predict each set of impact criteria.

Criteria Predictors

The three sets of impact criteria – critical evaluations, financial performance, and movie awards – can be predicted using a large inventory of variables. Because these predictors have contrasting relations with the criteria, the latter are clearly not assessing the same type of cinematic impact. In fact, it should become evident that there are really two general kinds of film, one concentrating on artistic creativity and the other on the entertainment business. This discrepancy shows up in the following sets of predictors: budget, screenplay, personnel, and distribution and exhibition.

Budget

Aficionados, consumers, critics, and professionals routinely distinguish films according to their production costs. Big-budget films seem to be most favored by the Hollywood studios while small-budget films are more often produced by independents. The costs of making a film have decided repercussions for all three sets of criteria. In the case of financial performance, the size of the budget correlates strongly with first-weekend earnings and with total domestic gross. In other words, it takes money to make money. As noted earlier, part of this relation is mediated by expenditures on promotion and advertising. The more producers spend the more they are willing to pay for selling the film. Big budgets mean big business for everyone in the industry. Yet, as also mentioned earlier, all of these expenditures on production and promotion do not necessarily result in big profits. On the average, every additional dollar spent on the film brings only about half that amount in return.

By comparison, critics seem disinclined toward big-budget products. Production costs have a negative association with the

reviews that a film receives during its theatrical run as well as the reviews received after its video or DVD release. The relation with movie awards is more equivocal. Although costs are positively associated with awards in the visual, technical, and music categories, production costs have no correlation with awards in the categories of best picture, direction, writing, and acting. It seems that money can buy excellence in the secondary aspects of the film experience, but cannot necessarily do so in the primary aspects. Many of the greatest films were actually medium- or even low-budget products. However, because the correlation is zero, there will be instances of big-budget films that obtain awards in the dramatic categories.

Screenplay

From what has been indicated so far, film as art focuses on drama. And the key component of drama is the script or screenplay. The best directors and actors cannot salvage a bad story with implausible characters. Naturally, these scripts vary tremendously not just quality but also in content. So far, research has identified the following seven sets of attributes as being particularly important in separating out the three sets of criteria.

1. *Sequels* are successors to an earlier film, such as the last two parts of the *Godfather* trilogy. Sequels do well in terms of financial performance. At least they gross more, especially in the first weekend. They are not necessarily more profitable, however, because sequels often have higher production costs. There is pressure on the producer to outdo what came before. It is interesting to report that sequels are more prone to receive awards in the technical categories because this implies that the extra money is being spent on bigger and better explosions and car chases. Yet this success has a price because sequels are less likely to win honors for best picture and for the dramatic categories of cinematic achievement. In line with this negative result, sequels receive lower praise from film critics.
2. *Remakes* are similar to sequels in being dependent on an earlier film, only the dependence is even greater. Remakes have very similar consequences as well. On the one hand, they tend to gross more, especially in the first weekend. On the other hand, remakes are less likely to win awards in the major dramatic categories – direction, writing, and acting – and they are more likely to be panned by the critics. Remakes, like sequels, are show business, not artistic expression.
3. *Adaptations* are like sequels and remakes in bearing some link with a previous creative product. Yet the predecessor now comes from a different medium, especially plays and novels. In terms of box office, adaptations from novels are neither better nor worse than average while adaptations from plays have poorer financial performance. As might be expected, adaptations have higher odds of winning awards in the principle categories of cinematic achievement. If the adaptation comes from a classic literary work, the resulting film is also prone to receive recognition for art production, costume design, and makeup. Such visual honors represent the typical ‘costumer’ based on a novel by Charles Dickens or Jane Austin. Given the critical preference for fine art, it should come as no surprise that adaptations are more apt to earn critical acclaim.
4. *True stories* purport to represent real events, albeit with varying degrees of factual accuracy (e.g., ‘based on a true story’). A special case of true stories is the *biopic* that claims to narrate the life of a real person. Because the scripts of true stories and biopics are often adaptations from nonfiction, they have somewhat similar correlates. They tend to do less well at the box office but score higher in critical reviews, plus earn more awards for best picture and the dramatic and visual clusters.
5. *Genre* is an extremely complex attribute simply because there are so many different varieties that can be combined in almost unlimited ways – like the horror sci-fi comedy. Even so, one genre dominates film scripts, namely, drama. Well over half of mainstream films are dramas of one kind or another. Dramas make for good art, too, for they tend to receive higher critical praise and they have a higher likelihood of winning awards in the principal categories. On the down side, they are less likely to earn recognition in the technical categories, and they earn less at the box office. Film dramas are too serious to make business sense.
6. *MPAA ratings* are determined by the Motion Picture Association of America. They are designed to ensure that films are exhibited before appropriate audiences. For current purposes, the most relevant ratings are R and PG-13. The former indicates “Restricted, children under 17 would not be admitted without an accompanying parent or adult guardian” and the latter “Parental Guidance advised, parents strongly cautioned because some material may be inappropriate for children under 13.” Films rated PG-13 do the best in the box office, those rated R the worst. Yet R-rated films earn higher critical acclaim and receive more recognition in the dramatic cluster of movie awards – but less recognition in the remaining three clusters. Needless to say, many R-rated products are dramas.
7. *Mature content* indicates serious material unsuited for children or unwelcome by some adults. The most conspicuous types of mature content are highly graphic sex and violence. Although this attribute is partly captured by the MPAA ratings, the latter are too broad to make appropriate distinctions. For instance, an R-rated film might contain no sex or violence, but just profanity, while a PG-13 film might contain some nudity and killing. Consequently, it is of interest to learn the impact of mature content apart from the MPAA ratings. Here the contrast between art and entertainment is quite conspicuous. On the artistic side, both critical acclaim and movie awards in the major categories are positively associated with tense family scenes, controversial topics, and, oddly, smoking – the latter perhaps a sign of a ‘serious’ film product. On the entertainment side, box office gross is positively associated with scary or tense music, frightening or tense scenes, but negatively associated with sex and nudity, profanity, and alcohol or drugs. These financial measures hold for US domestic, UK, and worldwide box office.

Although the preceding variables all have contrasting associations with the three sets of impact criteria, one attribute has been found to be positively correlated with all three, namely

runtime. Evidently, the longer the film the more opportunities it has to display the full range of cinematic effects. It then earns more money, gets better reviews, and wins more awards in all categories. Yet film length is also a rather crude indicator of screenplay characteristics.

Personnel

Shakespeare's plays can be read with pleasure and profit without seeing them on the stage, but screenplays rarely enjoy that expressive autonomy. Instead, the script must be translated to the screen, a translation that demands the direct contributions of cast and crew. The impact of the final cinematic product will also depend on those contributions. Let us start with the cast and then turn to the crew.

The cast consists of the talents in front of the camera, especially those actors in leading roles. The bulk of the empirical studies narrowed their analyses to the impact of the 'movie stars' occupying those roles. With respect to critical evaluations, there is some reason to believe that acclaimed films are more likely to feature performances by male and female actors who had previously won Oscars. Moreover, performers who have accumulated previous acting nods are more likely to deliver Oscar-winning performances. Regarding financial criteria, the impact of stars is inconsistent and unstable. Although films with star names on the marquee are likely to gross more, such films are often not cost effective. Because stars earn so much more money, the increase in budget frequently cancels out any gains in box office. One last point is of interest: the impact of male stars exceeds that of female stars. At least this holds for both financial performance and best picture awards.

Research on members of the crew has so far confined attention to producers, directors, writers, and composers:

1. Producers have only been studied with respect to financial performance, but with paradoxical results. On the one hand, producers with prior box office success are more likely to continue that success. On the other hand, the greater the number of prior films produced the lower the odds of exceptional box office for a current film.
2. A similar paradox happens to directors: prior box office performance predicts positive box office for current films but the greater the number of prior credits predicts negative box office for current films. As a result, the net effect of 'star' directors is zero. But when we turn to movie awards, these do tend to be predicted by prior movie awards: outstanding directors continue to win. Yet with respect to critical acclaim, directors display an inverted-U function of age similar to what is found in other forms of creativity. The films for which a director receives the highest critical praise tend to appear mid-career.
3. While award-winning writers are prone to write additional award-winning films, the findings are less simple for that subset of writers who also direct their own scripts. On the one side, films made by writer-directors tend to be favored by the critics, and on the other side, films written and directed by the same creator tend to do less below average at the box office. Because Auteurs are often writer-directors, these findings suggest that Auteur theory applies more to film as art than to film as entertainment.
4. Composers appear largely irrelevant to a film's financial performance. At least box office is unrelated to awards received for best score or best song. In comparison, award-winning compositions are positively associated with best picture honors. The critics are less enamored of film music, especially in the case of songs. One curious finding is that the aesthetic impact of a film composer's work is largely decoupled from the overall cinematic impact of the film. Sometimes a composer's best work is found in a lesser film.

All in all, the cast and crew make rather divergent contributions to a film's cinematic impact. The magnitude and direction of their effects depend on the specific criterion.

Distribution and Exhibition

Obviously, a film cannot even receive critical evaluations, earn a box office gross, or win movie awards unless it has some theatrical release. This leads to two final variables that are differentially associated with the impact criteria.

The first variable is the season of release. Regarding financial performance, it is patent that the big blockbusters are released in the summer months, when children and adolescents are on vacation. In contrast, critically acclaimed films as well as those with the highest odds of winning movie awards are most likely to be released toward the end of the year, during the so-called Christmas season. Interestingly, the worst movies by any standard are usually released early in the year – a dumping off period for films that do not go directly to video.

The second factor is the number of screens on which the film is exhibited opening weekend. Wide-release films not only do better on the first weekend, but also tend to gross more in the end. Yet such films are more likely to receive negative reviews from the critics, who lean toward films that do the art-house circuit, a few screens at a time. Although the number of screens is unrelated to movie awards for best picture and in the dramatic and visual clusters, wide release is positively associated with honors in the technical and music clusters. This pattern suggests that wide release is reserved for entertainment rather than for art.

Discussion

An overall pattern is apparent in the above review: films can be separated into those devoted to creative art and those dedicated to the entertainment business. The former are inclined to receive critical acclaim and movie awards in the primary categories, whereas the latter are more disposed to do a handsome box office and to earn awards in the secondary categories, such as special visual effects and sound effects editing. The two types of film can also be distinguished with respect to production costs (small vs. big), screenplay (e.g., sequels vs. adaptations, R vs. PG-13 MPAA rating), personnel (e.g., writer-directors), and distribution/exhibition (e.g., summer vs. winter release). Although there are a few variables that cut across the two cinematic types – most notably long runtimes contributed to both art and entertainment – these exceptions are rare. Often the predictors will have opposite signs for the two types.

To consolidate these findings further, it is necessary to discuss some methodological and substantive issues. This discussion can help improve the quality of future research on cinematic creativity.

Methodological Issues

The empirical findings summarized earlier represent the most common results. Nevertheless, it is important to admit that the literature is not always consistent, and sometimes outright contradictory. After subjecting these discrepancies to scrutiny, it becomes clear that they often emerge out of methodological differences. The following four contrasts are the most telling:

1. *Sampling* – Research varies greatly in the criteria used to obtain a sample of films. In the first place, studies might differ in the historical period covered, some taking films from the Golden Age of Hollywood while other studies taking only very recent films. This difference has been shown to affect the outcomes. Even when the periods spanned by the sample are the same, researchers will often employ inconsistent sampling criteria. To illustrate, the films might be defined by (a) a random sample from all released films, (b) films that received at least one nomination for some movie award, (c) those that earned a certain minimum amount at the box office, (d) those that featured at least one movie star, or (e) films that received a certain minimum number of critical reviews. Rendering matters worse, investigators do not always agree on whether to include documentaries, animations, foreign-language films, or even shorts. It is unreasonable to expect the same results to come from samples so different.
2. *Variables* – Because researchers in this area hail from a great diversity of disciplines – among them psychology, sociology, economics, management, marketing, communications, journalism, broadcasting, and statistics – they often approach the subject from rather divergent theoretical perspectives. Consequently, each study will contain a different mix of variables. For instance, marketing researchers are more likely to want to put expenditures on promotion and advertising into their prediction equations. Yet the omission of these expenditures by other investigators can alter the conclusions. For example, much of the relation between budget and gross earnings vanishes once expenses on promotion and advertising are controlled. Hence the latter provides the most proximate predictor of financial success.
3. *Measurement* – Even if two studies used identical sampling criteria and included the same variables, they might obtain contrasting results because of disagreements on how to best define the key variables. Undoubtedly, the most irksome illustration comes from the concept of the ‘movie star.’ Stars have been defined in terms of (a) best-acting awards, (b) consumer surveys, (c) box office performance, (d) total film credits, (e) investigator subjective assessments, and (f) industry-based identifications. A star by one definition is usually not a star by another definition.
4. *Analysis* – It is still possible for two investigations to concur on sampling, variables, and measurement, but obtain different findings because of divergence in how their

respective data sets are analyzed. One investigator might just look at the basic correlation coefficients while another conducts a multiple regression or constructs a structural equation model. Even a single method like multiple regression can get distinguishable results if the analysis is carried out differently (e.g., simultaneous vs. stepwise). Finally, researchers will often differ in how they handle highly skewed distributions. Such divergence is especially crucial with measures of financial performance.

Until some consensus is reached on sampling, variables, measurement, and analysis, it is too optimistic to presume that researchers will come up with identical conclusions.

Substantive Issues

Assuming that the foregoing methodological issues can be resolved, it is hoped that researchers can address a wider range of substantive issues. These can be put into two broad categories.

First, future research must greatly augment the inventory of variables that might contribute to cinematic impact by any of the three criteria. Film is one of the most complex forms of artistic creativity ever devised – perhaps the most complex ever. Although researchers often feel satisfied if they incorporate a few dozen variables into their studies, such satisfaction is quite complacent. Of special importance is a more detailed attention to the screenplay. The published studies to date deal with the most basic features of the screenplay, such as genre, MPAA rating, sequel/remake, and adaptation. Even though there have been attempts to subject screenplays (or synopses) to content analyses, these attempts are clearly exploratory. The analyses come far from capturing the rich complexities of plot, character, and other dramatic components.

Second, further inquiries should also shift the unit of analysis from the film to the filmmakers – the cast and crew engaged in creating the film product. Even if film is a collaborative product, it remains the case that collaborations require collaborators. These collaborators range from creative talents to technical experts, but they all have a responsibility for the final film. There has been some empirical attention devoted to directors, writers, actors, cinematographers, and composers, but these inquiries are rather sporadic and scattered in approach. At present, the literature lacks findings that must be considered essential. As an example, although we know how the personality of artists differs from the personality of scientists, and even how scientists practicing in different disciplines vary in their dispositional makeup, we know nothing about the distinctive personality profiles of producers, directors, writers, actors, and composers – even less the rest of the core crew. Developmental experiences, such as family background and education or training, have also been ignored.

In time, we may come to comprehend cinematic creativity in all of its manifestations. Such scientific knowledge might even enable producers to improve their product. If scientists could determine what was necessary to create a film that was acclaimed by the critics, made a big profit in the box office, and won major movie awards, more than one film-maker would take advantage of that information.

Ella Fitzgerald 1917–1996

J Piirto, Ashland university, Ashland, OH, USA

Ella Fitzgerald: The Life

Ella Jane Fitzgerald was born on 25 April 1917 in Newport News, Virginia, and she died in Beverly Hills, California on 15 June 1996, at the age of 79.

Her parents were William Fitzgerald and Temperance (Tempie), who were not married. Her birth father did acknowledge paternity; however, he left her life when she was about three. Her mother began to live with a Portuguese immigrant, Joseph Da Silva and they moved north, following the streams of immigrations from south to north of the poor to find work. Her mother found a job as a laundress, and Da Silva worked at a sugar factory while living in one room at a rooming house. A half-sister, Frances da Silva, was born and they moved a few blocks away, to an apartment house. Ella went to elementary school at a public school nearby, where she was a good student. Although the school was integrated, and she lived in an integrated neighborhood, she was a cheery girl, dancing and singing constantly among her friends. Ella also had a chance to sing at the Bethany African Methodist Church.

When she went to junior high school, she and a male friend, Charles Gulliver, would take the train into New York City, emerging at 125th street. They would go to the Savoy ballroom and dance for hours, learning the new steps, and then take the train back. They would practice on the street in Yonkers, and people would watch them and learn the steps. By the age of 15, the couple were getting jobs in local dance clubs. The radio was becoming a phenomenon in the early 1920s, so Ella listened, and imitated her favorites including Louis Armstrong and the Boswell Sisters. Ella later said, "When I was a girl, I listened to records by all the singers, white and black, and I know that Connee Boswell was doing things that no one else was doing at the time" (liner notes for Connie Boswell album, *Sand In My Shoes*, MCA MCFM 2739, cited in Nicholson, 2004: 246).

In 1932, when Ella was 15, her mother died of a heart attack at the young age of 38, and Ella's stepfather began to mistreat her so much that her aunt Virginia, who lived in Harlem, took her out of the da Silva home and into her own home. She lived with her aunt for two years, during which time she dropped out of school and began to engage in illegal numbers running. She also got some money by being a lookout for a brothel. The truant officers caught her and she was sent to Hudson, upstate, near Albany, to the New York State Training School for Girls. The place was brutal, and she experienced beatings, deprivations, and racism. She ran away in the fall of 1934, when she was 16, and went to Harlem, where she lived on the streets. She joined a crowd of street performers, dancing on the street for pennies, staying where she could. (Later on, in 1947, she would begin her lifelong charity work for abused and neglected children, working with war orphans. She founded the Ella Fitzgerald Child Care Center in Los Angeles in 1977.)

In the mid-1930s, the theaters of Harlem were in competition with each other in offering amateur shows. Every night of

the week another theater had a competition. Ella entered these competitions. One night in November 1934, at the Apollo Theater, she was waiting to go on as a dancer, but two of the other competitors were dancers, the Edwards sisters, who were well known, and who were dressed in sequins, with the proper dance shoes. Ella was attired in street clothes; she needed a bath; she had on men's boots and pants. When she saw that these sisters were going to dance, she switched her act and sang instead. She won. A little while later, at another amateur hour, she was booed off the stage. Then, at another competition, at the Apollo Theater, she again won. Despite her dirty and ragged appearance, the jaded and critical audiences loved her singing. The winner was supposed to get a job singing for the next week at the theater, but because of her appearance and lack of hygiene, Ella was not hired. However, Benny Carter, the orchestra leader at the Apollo during that time, thought she was talented and took her to audition for the band leader Fletcher Henderson. Again, Henderson was repelled by her, and refused to hire her. She continued to dance on the street and to enter amateur shows, hoping to make enough money to eat, sleeping wherever she could. In January of 1935 she won the show at the Harlem Opera House, singing 'Judy.' This time she was able to work for the promised week.

Chick Webb was a rising jazz drummer and band leader in the Harlem clubs and theaters. His group played mostly instrumentals and he realized he had to have a singer to be more popular with audiences. He hired Charles Linton, who soon got an offer to join the singing group, the Ink Spots. Webb noticed that other bands were able to charge more because they had good looking female singers. He asked Linton to try to find him a female singer. Linton asked around, and one of his female friends mentioned the singer who had won at the Apollo, whom he could find on 125th street singing and dancing on the sidewalk. When Linton brought her to Webb, Webb said, "You're not puttin' that on my bandstand. No, no, no." (Nicholson, interview with Linton, p. 35). Linton threatened to quit and Webb relented, letting Ella watch from the wings for a few weeks to see whether she could learn the music. Ella was a quick learner and could read the charts and memorize the words. Webb began to put her on stage, and the audiences responded with applause and admiration. She got paid in cash and they gave her a room at a boarding house nearby, but she did not have enough money for the proper evening clothes that female singers usually wore.

She got her first positive press that same year, from George T. Simon, a reviewer for *Metronome* magazine, who was impressed with her animation and the quality of her voice. She began recording with Webb right away. Her first recording was 'Love and Kisses' in June, 1935. Her first recordings demonstrate her ability to 'swing.' Swing was becoming a dominant form of jazz. It featured brass, winds, and percussion, which would play a basic melody. Then the instrumentalists and the singer(s) would improvise over that basic melody. A good

example is her first big hit, in 1938, “A Tisket, A Tasket,” based on the well-known children’s nursery rhyme. She introduced it during a concert in Colored Town in Miami. Ella, influenced by such musicians as Louis Armstrong, was able to recreate her voice as a musical instrument, using nonsense syllables to ‘scat.’ Her big break came right away, and she capitalized on it. When Chick Webb died at the young age of 30, she led the band and toured it for three years, even though she was only in her early 20s.

Ella Fitzgerald, at the age of 30, was one of the most popular singers in the United States. She toured and traveled nonstop, as well as constantly recording. She made her first trip to Europe in 1948, where audiences wanted her to sing more pop ballads than bebop. She gave her first concert in Carnegie Hall in 1949. Her manager, Moe Gale, disapproved that she was doing such concerts, and wanted her to continue recording for Decca where she had sold over 20 million records (Gioia, 1998). However, Norman Granz, who was the organizer of the very popular Jazz at the Philharmonic (JATP) concerts, which had begun in 1944, saw a different future for Ella. Granz was a canny and skilled jazz manager/promoter who changed Ella’s means of exposure to the world from the jazz club to the concert stage. Granz was adamant that the concert audiences be integrated and that the venues reject Jim Crow practices in the South. Ella’s popularity grew among whites as a result.

LPs and Songbooks

Ella Fitzgerald released over 6000 singles and made about 250 albums. She is mentioned in 135 entries in the *Biographical Encyclopedia of Jazz* (Feather and Gitler, 1999). In 1948, Columbia Records introduced the long-playing record, a sturdy vinyl 10 or 12-inch disc. Previously records had been 78 rpm, on shellac. Ella did not release her first LP album, *Miss Ella Fitzgerald and Mr Gordon Jenkins Invite You to Listen and Relax*, until 1954, but she released several popular singles collected on that album, including ‘I’m Gonna Wash That Man Right Out of My Hair’ from South Pacific, in the late 1940s. She continued recording for Decca until 1955, when she released her first recordings from her new record company, Verve which was run by Norman Granz. They began by issuing LP albums featuring Ella singing ‘songbooks’ of famous popular composers such as Cole Porter (*Ella Fitzgerald Sings the Cole Porter Songbook*, Verve, 1956; *Ella Fitzgerald Sings The Rodgers & Hart Song Book* (1957); *Ella Fitzgerald Sings The Duke Ellington Song Book Vols 1 & 2* (1958); and *Ella Fitzgerald Sings The Irving Berlin Song Book* (1958). These songbooks included, *Ella Fitzgerald Sings The George and Ira Gershwin Song Books* (1959), which topped the *Billboard* magazine popularity charts soon after its release, even though it was five records. The songbook series concluded with *Ella Fitzgerald Sings The Harold Arlen Song Book* (1961), and a songbook of Johnny Mercer songs. She continued the trend, with *Ella In Hollywood* (songs from soundtracks) and *Ella Swings Brightly* (and *Ella Sings Gently*) *With Nelson* (Riddle, her orchestral leader) (1962).

Subsequent albums resulted from her frequent European tours, and the 1960 album *Ella in Berlin* won her a dual Grammy, one for Best Vocalist – Female and one for Best Vocal Performance Album – Female. The live albums were

viewed as her most creative, as she was invigorated by the presence of the audience. She was the first African American to win a Grammy Award. She received 14 Grammys throughout her career.

The orchestras she sang with were legion. Among them were her husband, Ray Brown and His Trio, Teddy Wilson, Benny Goodman, Dizzy Gillespie, Louis Jordan and His Tympany Five, Gordon Jenkins and His Orchestra, Benny Carter and His Orchestra, the Nelson Riddle Orchestra, Duke Ellington and His Orchestra, the Billy May Orchestra, and the Quincy Jones ensemble. Even jazz scholars are not sure of Ella Fitzgerald’s complete discography. Many concerts and appearances were videotaped or broadcast on television or radio but not released on recording. Vocal groups with whom she recorded included the Ink Spots, the Four Keys, the Song Spinners, the Ray Charles Singers, and the Mills Brothers.

She sang with many vocalists, but made few duet albums (Louis Armstrong being an exception). The 1950s and early 1960s were the heyday of variety shows led by famous singers, and Ella was a frequent guest. Vocalists included Frank Sinatra, Ray Charles, Pat Boone, Tom Jones, Bing Crosby, Ray Charles, Glen Campbell, Andy Williams, Dean Martin, Jimmy Durante The Carpenters and John Denver among others. Her discography lists no recorded duets with females, although she did sing with Julie London on the *Ed Sullivan Show* in 1957, on the *Dinah Shore Show* in 1960 and on the *Jo Stafford Show* in 1961. She also appeared on *The Steve Allen Show*, a late night comedy show, where Allen accompanied her. However, duets with other vocalists were rare in her issued recordings. She was primarily a solo singer with various backup orchestras, including symphony orchestras (Ella Fitzgerald Discography).

A hiatus between recording contracts occurred in the late 1960s, when Verve/MGM stopped releasing her recordings and no one picked her up, even with her immense oeuvre. Fitzgerald began recording for Pablo Records, Granz’s new label, in the early 1970s, and Pablo continued to release cuts from her various concerts, for many years. She released a double album with Columbia in 1974 (*Newport Jazz Festival – Live At Carnegie Hall, July 5, 1973*). She also recorded for the Atlantic label (*Ella Loves Cole*, 1972). Her latest release was in 2009, *Twelve Nights in Hollywood (Live)*, from Verve/UGA, which has 77 songs from live concerts in the early 1960s.

She also released albums with only one instrumentalist. Ella Fitzgerald recorded four albums with jazz guitarist Joe Pass, *Take Love Easy* (1974) among them. Pass described their studio sessions. She came in and he asked her what song she wanted and what key she sang in. She hummed a few notes, he caught the key, and they began. She could change keys and “She’s there, she hears it, no problem. It’s like another musician. I play with her and she’s sort of like a horn player” (Nicholson, 2004: 218). She also recorded *Ella and Oscar* (1976) with Oscar Peterson on the piano Peterson was her long-time orchestra leader on the JATP tours, and a famous jazz pianist. The 1991 CD *The Intimate Ella*, featured a recording she did in 1960 after she appeared in the movie *Let No Man Write My Epitaph*, as a heroin addict. Here, she had just one collaborator, the pianist Paul Smith. She recorded other albums with just Smith and various bass players, including her ex husband, Ray Brown. Nicholson (2004) said that these albums with Pass and Smith were “among her finest work on

record" (p. 218). Smith said that Ella was "an accompanist's dream" because she sang the songs so consistently from session to session. "She never did anything that wasn't very musical" (Nicholson, p. 177). The reviews were not so positive for the Peterson collaboration, as critics thought it was spotty, with Peterson swaying from being a solo performer to an accompanist in an erratic manner (Nicholson).

Smith also was in a position to notice the inevitable deterioration of her voice over time, as he was with her on tour for many years. Once, when he had not heard her for 16 years, he commented, "I realized Ella's voice wasn't what it used to be" (Nicholson, p. 236). He attributed this to her lack of formal voice training. "If you don't do it correctly and don't take it easy on the voice, there comes a time when the vibrato begins to go on you" (Nicholson, p. 218).

Ella had chronic health problems stemming from diabetes, but she continued to tour the world, often ignoring her symptoms. She began to lose her eyesight and had to cut a tour short in Nice, France, in 1971 to have a cataract removed. Later, she had toes, and then both legs, amputated. In some of her last concerts she had to be led onstage and guided to a chair. But her popularity continued and she sold records. She continually tried out new songs, covering many of the latest hits, seeking to have her own number one song again. She was an enthusiastic participant in her own concerts, often giving as many as five encores. She also became a household image to people who knew nothing about her long career in jazz and pop. In 1981, she did a commercial for Memorex audiotapes, in which she shattered a glass with her voice, with the voiceover saying, "Is it real or is it Memorex?" These commercials continued for several years, and her fees provided a comfortable income.

Ella Fitzgerald tried to keep up with the times, and she also cast herself back in time. One type of song she did not sing much was the blues. However, she studied Portuguese so she could sing bossa nova better, and she listened to and attended shows by fellow musicians and easily adapted her style to include and flavor her music with their styles. Critics viewed her cover tunes of rock, disco, and soul as some of her weakest.

Grammy Awards

Fitzgerald, as a standard-bearer in jazz and as a pioneer among women in jazz, received many awards. In 1965 The American Society of Composers, Authors and Publishers (ASCAP) recognized her in its first recognition of an artist. She had been a member of this organization since 1940, and had composing credit for several songs (e.g., 'A-Tisket, A-Tasket,' 'Deedle-de-Dum'). In 1958, she received the first two of her 14 Grammy (Gramophone) Awards from the first Annual awards ceremony of the National Academy of Recording Arts and Sciences, as Best Jazz Performance, Individual, for *Ella Fitzgerald Sings The Duke Ellington Song Book* and as Pop: Best Vocal Performance, Female for *Ella Fitzgerald Sings The Irving Berlin Song Book*. In 1959 she repeated the double awards in pop and jazz, for *But Not For Me* (Pop) and for *Ella Swings Lightly* (Jazz). In 1960, she received two Best Female Pop Vocal Performance Awards, one for album (*Ella in Berlin*) and one for song ("Mack the Knife"). In 1962 she won for Pop: Best Solo Vocal

Performance–Female, for *Ella Swings Brightly With Nelson Riddle*. In 1967, she received the Bing Crosby Lifetime Achievement Award. In 1976, she again won Best Female Jazz Vocal Performance Award, for *Fitzgerald And Pass . . . Again* and she sang 'Lady Be Good' in duet with Mel Tormé, who also won a Grammy. "The standing ovation you received was the single longest standing ovation" in the history of the Grammys, the President of the Academy wrote to Tormé (Nicholson, 2004: 223). In 1979, she won again for best Jazz Vocal Performance, for *Fine And Mellow*. In 1980 she won for Best Jazz Vocal Performance, Female, for *A Perfect Match – Ella And Basie*. In 1981, she won Best Jazz Vocal Performance, Female, for *Digital III At Montreaux*, in 1983 for *The Best Is Yet To Come*, in 1990, for *All That Jazz* (http://www2.grammy.com/GRAMMY_Awards/Winners/Results.aspx). In 1987, her song, 'A Tisket-a-Tasket' was entered into the Grammy Hall of Fame. The fact that she won for both Pop and Jazz illustrates the blurring of these genres that she constantly did. Some jazz critics derided her for being too popular and accessible.

Other Awards

Universities and college gave her awards, even though she herself had not graduated from high school nor attended college. In 1974, the Ella Fitzgerald Center for the Performing Arts was named at the University of Maryland. In 1976, Dartmouth College gave her an honorary doctorate. In 1980, Howard University and Talladega College of Alabama gave her an honorary doctorate. In 1982, she received the Hasty Pudding Club Woman of the Year Award, and in 1987, the UCLA Medal for Musical Achievement. In 1990, Princeton University awarded her an Honorary Doctor of Music.

In 1979, she received the Kennedy Center Honors Award; in 1983, the Peabody Award for Outstanding Contributions to Music in America; in 1987, she received the National Medal of the Arts. In 1988 she received the National Association for the Advancement of Colored People Image Award for Lifetime Achievement. A commemorative stamp bearing her likeness was released in 2007 by the US Postal Service (www.ellafitzgerald.com).

Marriages and Children

She had had an abortion after becoming pregnant by one of the saxophonists in the Benny Goodman band when she sang with them. After this, she never had a child. She never discussed this. Her first marriage in 1941 to Bernard Korngay, an admirer of the Chick Webb band, was short-lived and ended in mid-1942 in annulment, after Ella's managers discovered Korngay's criminal past and conveyed to her that they thought he was using her. Ella met her second husband, Ray Brown, a bass player, on the first tour with Dizzy Gillespie. They were married in December, 1947. They divorced in 1953, but continued to work together over the years. They adopted one son, Ray Brown, Jr., the son of her half-sister, Frances, who died young, and to whom Fitzgerald was very close. During the years she also had several affairs, but after she and Brown divorced, she never remarried.

Summary

The literature on Ella Fitzgerald reveals little about her intimate life, the life lived with the people in her life. The books are full of accountings of concerts, trips, band rosters, albums, constant travel, awards, and the like. Picture a middle-aged, overweight Black woman, not beautiful, the darling of audiences all over the world. She is an optimist, a cheery person. She owns a mansion in Beverly Hills, California, and she lives alone sometimes, and at other times, with relatives who stop in, and with her son, who comes back after some estrangement. She is constantly traveling and recording. One night she might be in Rio de Janeiro, and two nights later she might be in Amsterdam, The Netherlands. She has a secretary who travels with her, as the details of travel would be overwhelming otherwise. (Granz thought Ella was “temperamentally unsuited to negotiating the real world – the airline-ticket-buying, hotel-reservation making, letter writing, doctor calling, musician hiring, musician firing, contract reading, interview giving, getting her age right and the everyday problems of human existence” (Nicholson, 2004: 243).)

As she travels, she likes to go out into the neighborhoods and shop for food, talk to people, even sing to children. When she is at home, she visits her charities for children and sings. She likes to watch soap operas and is an avid baseball fan. She works constantly, with about six weeks off per year, two weeks near Christmas and a month in the summer. Her health begins to suffer the ravages of diabetes, and her eyes and limbs weaken. People do not know her telephone number, and she has few known close friends. She works with all men, and so she has few girlfriends. Peggy Lee is one of them, though her friendship with Sarah Vaughan, a fellow client of Norman Granz, is often fraught with jealousy over who is better-paid.

As she ages, she continues to keep the frenetic schedule, and when the audiences cheer, she livens up, gives many encores, and opens her arms in mutual love. By the late 1980s, she is led onto the stages as she is nearly blind, and she sits down while singing, because she is weak. Still she sings. She sings when the doctor orders only three concerts a month, and then one concert. She sings until the end, and the audiences love her. Her last concert was at the Michigan Music Hall, in 1992. Her legs were amputated in separate operations in 1994, and she died under 24-hour nursing care, in 1996.

The Direct Interpreter

Over the years, critics have debated the inner meaning of Fitzgerald’s interpretation of the songs she sang. Was she truly involved in the words she was singing? Did she care about the meaning of the poetry of the songs? Did she want to interpret them? Comparisons between Fitzgerald and Billie Holiday, Edith Piaf, and Judy Garland continue to be made. The consensus seemed to be that Fitzgerald retained her sense of childlikeness and approached her songs directly, without irony, and without insinuating her own feelings upon the lyrics and music. She continued to show a breezy, happy tone of voice as she aged, and she did not deeply interpret the lyrics, but treated her part as if her voice were a musical instrument, part of a combo, and not the soloist. Her life story was full of

pain and she had risen above it to reach a state of being that sometimes made her audiences who listened to her reach transcendence. Other singers were more like movie directors, auteurs, who shaped the music and lyrics to their own emotional lives and painful experiences, but Ella seemed to hide her emotional life and her pain, singing the ballads and the up tunes without revealing her personal interior. She sang as a musical instrument does. The words do not matter. You can just as well scat them or spit them. They convey no meaning. They are just another voice in the choir. You do not put an Ella Fitzgerald album on when you want to feel the blues and wallow in self-pity. She is just the right antidote to a bad day or a mild downer. Her music says you should go on.

This controversy was written about in her obituary in the *Washington Times* (Ella Fitzgerald’s Life and Art, 1992: 18).

Having known true pain, and the healing that the love of a grateful audience could give, she chose to give pleasure to those who would listen to her. Miss Fitzgerald concentrated not on herself and her own emotions, but on creating a thing of beauty that could be a source of pleasure and solace for everyone. What an extraordinary gift that was . . . Pain is easy. Pain is everywhere. Anyone can yowl and keen in pain, horror and desperation. But how many musicians have transcended the inescapable pain of being human? Miss Fitzgerald created a rarefied, almost Platonic musical world in which suffering was trumped by beauty. Miss Fitzgerald did not express her pain, but neither did she ignore it: Instead, she triumphed over it. Hers was an ennobling vision of art, and it can only be hoped that it has not been lost with her.

Perhaps a fitting ending is the opening patter for her Grammy-award-winning single, ‘Mack the Knife’: “We’d like to do something for you now. You haven’t heard a girl sing it and it’s so popular we’d like to do it for you. We hope we can remember all the words.” And then she began the journey of the song, a journey in time, invoking Bobby Darin and Louis Armstrong, making it up and swinging as she went along.

The Voice

The quality of Fitzgerald’s voice was considered sweet, young, and pure. Her range was extraordinary. She could sing from low D-flat to high B-flat. This bottom range is very rare, even for professional opera singers. She did not have a visible voice break, as most singers do, from the middle range to the highest range. This voice immediately engaged hearers and she was noticed right from the beginning. She did not sing breathy or loud to disguise voice weaknesses. The voice changed over the years, as evidenced in the recordings, but it was always pleasant and clear to listen to. There was no dusty whiskey voice, no pained enunciation, no emotional wavering on the high notes. The straightforwardness of her voice shows its quality – and its limitations, according to some critics.

The Rhythm

Along with having an extraordinary voice quality and range, Fitzgerald also had a sure sense of rhythm. She was able to catch a beat, and to drive a beat. She could syncopate and hold a note just long enough to tip it in staccato to the next note, or

hold it long enough to just catch the curve where the next note begins. MacInnes said she had:

an inborn sense of rhythm, so strongly felt that she can vary the beat to a preposterous degree without ever for a second losing it. Clear, precise diction, and a sixth sense for pace. Easy, assured and infinitely flexible phrasing, graceful, undulating and vivacious. (in Gottlieb, pp. 247–249)

The Female Singer Situation

The situation was one female singer and various male musicians traveling the world and crisscrossing the country together. Many female singers married and dated members of the band. The list is long and includes Billie Holiday, Sarah Vaughan, Doris Day, among others. However, the female singers were popular with the audiences even though the jazz aficionados and critics valued the male instrumentalists while the public wanted to hear the singers. The female singers, however, were viewed by the male band members as marginal and replaceable, and were diminished in importance. In a deconstruction of their role, Willis discussed the place of women in jazz:

Like elusive and untranscribable blue notes, women in jazz exist, invisible, in-between the spaces, creating voices through subversion and speaking in ways that are nearly impossible to transcribe into a discourse traditionally owned by men, and where questions of gender are nearly always overshadowed by questions of race (p. 2).

Racism

In the world of jazz and popular music, racism was a major influence. Several key incidents in Ella's career may suffice to illustrate. Once, while playing in Houston, Texas, Granz, Ella, and the band were put into jail for allegedly playing dice illegally. The real reason was Granz's insistence that the concert they were giving welcome all races equally. Leab (1995) quoted a movie studio publicity release that had Ella Fitzgerald supposedly responding to a compliment on a performance with: "I'se glad I done okay, this job sho am going to change my mode of livin" (p. 130). (Ella's northern American English accent is well documented in countless recordings.)

Once, in 1945 in Columbus, Ohio, Leonard Gaskin, the tenor saxophone player, described the group having a meal after the concert waiting to go to their hotel. The hotel manager came over to them and said to Ella how much he and his wife had enjoyed their show and her voice. However, he said, he had to tell them that they could not stay in the good rooms in his hotel, but he would have to put them up in the back somewhere (Stokes, 2005). More tellingly, in 1959, on the Bell Television Hour, Ella was scheduled to play with a combo that included a white musician. Producer Roger Englander told the tale:

I remember we had a show with Ella Fitzgerald as one of the five or six acts. Her accompanist, whose name I've forgotten, was white. To have Ella Fitzgerald and the pianist in the same frame, however, was against Bell Telephone's policy, because they were afraid of Southern Bell. So, at the last minute, we had to . . . hang a very fancy drape that was slit gold-foil placed between Ella and the pianist, thus preventing your seeing the pianist (Rose, 1992: 138).

Other sources (e.g., Nicholson, 2004, say that the white person was the guitarist, Herb Ellis). To have a black person and a white person on the small screen at the same time was taboo. Soon thereafter, Norman Granz took out a two-page ad in *Variety* on 12, December 1959, to protest the practice.

Ella Fitzgerald and Creativity

Scat

Scat singing is improvisation with the voice. The singer uses nonsense syllables and moves along with the accompaniment, becoming, virtually, one of the musical instruments. Scat singing is arguably what Fitzgerald is most famous for. Porter (2002) said she made scat singing "a household term" (p. 155). She was able to improvise and range over two octaves, always perfectly in tune. Another scat singer, Mel Tormé, said of her, that "It's a god-given talent . . . here is a woman who can run through chord patterns as deftly and with as much facility as any great tenor man or trombone player or pianist or trumpet player." He commented on her "extraordinary ears," and said, "her notes float out in perfect pitch, effortless and, most important of all, swinging" (quoted in Nicholson, pp. 89–90). Her recording of George Gershwin's 'Oh, Lady Be Good' in 1947 is a classic of her scat style. Lees (1998) said that her ability to scat sing "with impeccable rhythmic imagination and accurate intonation at high speed was incomparable" (p. 141).

BeBop

Ella Fitzgerald was also credited with coining the term 're-bop,' on her recording of 'Flying Home.' The type of music became known as 'bebop.' Bebop was the form of jazz that followed swing. In bebop, the tempo is increased, and the drummer is more dominant. The players (e.g., Dizzy Gillespie, Charlie Parker, Coleman Hawkins) improvised in a way that took the music out of the constraints of the melody. Audience's ears were not used to the sound, as it was often jarring and sounded disorganized, preferring the predictability of swing. Ella traveled with Dizzy Gillespie in 1946, where she fully embraced the new music. She credited that tour with Gillespie as "my education at learning how to really bop" (Nicholson, p. 96). Gillespie and Fitzgerald gave a concert at Carnegie Hall in 1947, which Porter (2002) said "symbolized bebop's growing, albeit contradictory, cultural legitimacy, provides a window into the wide range of artistic visions and stylistic influences maintained by musicians associated with the bebop movement" (p. 77). Fitzgerald's incorporation of bop and chromatic intervals "helped to move jazz singing in new directions" (Porter, p. 77).

Creativity

Ella Fitzgerald's life trajectory is similar to those of other popular musicians as noted by Piirto (2004). Using her Pyramid of Talent Development as a framework, Piirto noted that in families of popular musicians, the genetic factor may be present in the family's playing and singing of popular music together among the generations, and noted that popular musicians often learn their instruments from their parents. This did

not happen for Fitzgerald, as she seemed to be the only one of her known genetic relatives with a propensity for music.

The emotional aspect emphasizes personality attributes. These were derived from studies completed at the pioneering Institute of Personality Assessment and Research (IPAR) in the 1950s by Frank Barron and Donald Mackinnon and others. More recent personality studies of creators by researchers such as Gregory Feist have also shown certain consonances.

Ella Fitzgerald demonstrated many of the attributes. Here are a representative sample: (a) passion for her domain of jazz music; (b) intuition in the choice of songs and collaborators; (c) motivation to create in her constant performing, even while ill and disabled; (d) perception in her decisions about orchestra leaders, band members and knowing when to make a career move; (e) perfectionism in her insistence on such while performing; (f) androgyny in that she was one of the only women to lead a band when she first began; (g) naivete, or openness to experience, in her constant inclusion of new songs and trends in her shows, and in her many guest appearances on the television shows of musicians of many different styles; (h) resilience in her ability to bounce back from early trauma and adversity, including incarceration; and (i) introversion, in that she was quite shy, and preferred to stay home except when she was performing.

Ella Fitzgerald and Improvisation

Researchers into creativity have emphasized the importance of improvisation in the creative process. For example, Keith Sawyer noted the necessity of collaboration in improvisation in both theater and jazz. The Live albums reveal an Ella Fitzgerald that the studio albums do not. Nicholson (2004) said, "The creative sparks that flew in front of an audience were rarely ignited in the studio" (p. 191). The feedback between singer and band, singer and band and audience, is palpable on the live albums. Ella Fitzgerald was a master of improvisation, and she would sometimes not even know what song was coming up until she heard the chords, and then she would scat or sing wrong words until the right words kicked in. The improvisation in the studio albums was also inimitable, however. Tenor saxophonist Sonny Rollins said:

Fitting the melodies onto other changes takes discipline. You can't take 'Sunbonnet Sue' and put it into anything anywhere. The chords have to match, and the feeling has to match. Ella Fitzgerald had it down. It's one of the tools of jazz improvisation. The beautiful thing about jazz is that it can absorb everything else and still be jazz (Santoro, 2007: 126).

Tirro (1993) called Ella Fitzgerald's improvisation abstract: "Her artistry has developed more in the realms of abstract

music – motive, melodic development, sequence, virtuosic flights" (p. 252).

In summary, Ella Fitzgerald's life as a creator is an interesting and evocative reprise of the jazz history of the twentieth-century. Born in the First World War, she welcomed the popularization of radio and learned her first licks from harmony singers and jazz trumpeters. She danced with her childhood friends to the music of the twenties, and sang when she could not dance. She was confirmed into the sound of swing and moved it along with her own interpretations. She moved from the 78 to the 33 1/3 and the 45 and commanded the 8-track, cassette, and the CD. She was a pioneer in bebop and segued into and out of pop all the while retaining the respect of both jazz and pop. She backed into rock and died before rap. All the while she entertained.

Flow and Optimal Experience

M Biasutti, University of Padova, Padova, Italy

© 2011 Elsevier Inc. All rights reserved.

Glossary

Autotelic Doing something for the pleasure of doing it and not for the expectation of an external reward or benefit (autotelic derives from two Greek terms *auto* which means self, and *telos* which means objective).

Ecstasy A trancelike state of very strong feelings in which an individual transcends normal consciousness.

Peak performance Performance of an individual at an optimal level, producing his/her best.

Timelessness The experience of transcending time while being involved in an activity.

Introduction

Mihaly Csikszentmihalyi introduced flow theory in the 1970s based on research examining people who did activities for pleasure, even when they were not rewarded with money or fame. He considered artists, writers, athletes, chess masters, and surgeons – individuals who were involved in activities they preferred. He was surprised to discover that enjoyment did not result from relaxing or living without stress, but during these intense activities, in which their attention was fully absorbed. He called this state flow, because during his research, people illustrated their intense experiences using the metaphor of being carried by a current like a river flows.

Participants were motivated by the quality of the experience they had while they were engaged in the activity. The flow experience came when the activity was difficult and involved risk. It usually stretched the person's capacity and provided a challenge to his/her skills.

The concept of flow became the key element for the theory of optimal experience, since it provided the best user experience. Flow refers to a state of mind which brings together cognitive, physiological and affective aspects. Flow experience corresponds to an optimal psychophysical state: participants said it is like being in the zone, being on the ball, being in the groove. Flow also inspires peak performances so some use expressions such as 'everything clicks' and 'experiencing a magic moment'.

Csikszentmihalyi reported that flow occurred more often during work than free time. It was easier to achieve the flow state in activities such as performing music, dance and writing since they had rules and required the learning of skills. In these activities people were deeply involved and motivated because they were participating in an enjoyable experience. While almost any active involvement can potentially lead to flow, activities which are passive, such as watching television, do not normally lead to flow. However in 2007 Steven Pritzker proposed that audience flow can occur if a television show is relevant to the viewers' life.

Flow is an interdisciplinary field of research, addressed by psychologists working in the fields of positive psychology, cognitive psychology, arts, sports, science, sociologists and by anthropologists interested in altered states of consciousness, spiritual experiences, and rituals in different cultures.

Characteristics of Flow

Csikszentmihalyi (1990) identified nine characteristics of flow. These aspects were extracted from research in which different people described optimal experience in similar ways. Qualitative approaches, including semistructured interviews, were used to gather information about the absorption of people in an activity. Questions were structured in order to elicit the feelings of people during these conditions with the aim of defining the general characteristics of flow state. In addition, diaries were used, which allowed the collection of data in a more systematic form than the semi-structured interviews. The experience sampling method (ESM) was also introduced later, which consisted of asking participants to carry around an electronic paging device for a period of time (normally a week), asking them to answer a series of questions and rating a number of items about how they feel and what they are thinking about whenever the pager activates a signal. A radio transmitter triggered the pager about eight times a day at random intervals. In this way, it was possible to gather data about instantaneous moments of internal life.

The personal experiences of participants provided an account of flow in real life contexts and were used for defining the phenomenon. Flow was reported by both young and old men and women, with no difference in terms of economic status and social class. Other studies verified the influence of cultural variables. Results indicated that, people from all over the world experienced flow state, proving the transcultural validity of the flow model. However, the regularity with which people experience flow is not directly connected with the content of the activity done. Although such cultural differences were clearly present, there were several common features. The nine characteristics of flow were the following:

- Challenge and skill balance.
- Action and awareness merging.
- Clear goals.
- Unambiguous feedback.
- Concentration on the task.
- Sense of control.
- Loss of self consciousness.
- Distorted sense of time.
- Autotelic experience.

1. *Challenges and skills balance.* A good match between challenges and skills is a necessary condition. Flow is controlled by the ability of balancing challenges with skills.
2. *Action and awareness merging.* The action must be combined with awareness in order to facilitate concentration and high performance of the task. Participants need to be focused and have a great deal of control over what they are doing. Developing a link between body and mind (action and awareness) is a very good way of achieving flow.
3. *Clear goals.* There is a clear purpose and a precise idea of what to do next. For example, the painter is aware of how to choose the color for completing the painting; the musician knows what note to perform in a fragment. Although the activity advances towards a higher goal, the activity is driven by the progressive realization of the next small goal.
4. *Unambiguous feedback.* Feedback is used for controlling the progression of the activity and the achievement of the goals. It is a process that happens in real time without it being necessary to stop. This allows adjustments to be made in order to meet the objectives.
5. *Concentration on the task.* In flow, people are focused on aspects relevant to the task and distractions are excluded from consciousness. All attentional resources are used for the performance of the task which becomes the exclusive content of the working memory buffer. Narrowing the focus of awareness, it allows the introduction of a sort of filter for perceptions and thoughts which are not relevant.
6. *Sense of control.* In flow, people do not worry about failure and possible loss of control, because they are deeply involved in the activity and all the external elements, such as failure, are less relevant. They feel a sense of control over the demands of the activity without conscious effort.
7. *Loss of self-consciousness.* Self-consciousness can be considered a meta-representation involving higher order processes. In a flow state, people are too focused on an activity which requires most of their mental resources to be self-conscious. There are no other intellectual energies to process any other information such as worrying about how one appears to other people.
8. *Distorted sense of time.* In flow the perception of time can be transformed. Time generally flies when people are performing activities in which they are engaged. On the contrary, time seems to slow down when doing tasks in which they are not really involved. A sense of timelessness is also one of the features of any altered state of consciousness.
9. *Autotelic experience.* Flow is a pleasant experience which is intrinsically rewarding. This gratification is directly connected with the activity. Autotelic is a word used to describe people who are internally driven and have a purpose within themselves. They are motivated by a strong sense of intention and curiosity. The autotelic experience is a reinforcing property of the state of flow and the activity becomes its own reward.

Flow in Artistic Activities

Flow states have been addressed at length in the study of creative activities, such as painting, music, dance, and poetry, during which artists were challenged to create new concepts

and meanings. All these are structured activities which require concentration, involve divergent thinking, and offer the opportunity to go beyond the confines of ordinary experience. They stimulate a sense of discovery and introduce artists to new dimensions encouraging higher levels of performance. Some aspects of flow are common to all the artistic expressions, however music, dance, and writing are considered extensively here, because they are the fields in which the most research has been produced.

Flow in Music

Flow has been examined in many musical activities, such as composition, performance, and listening. Flow has been mentioned in some of the psychological models of musical improvisation. Musical performance and composition offer many opportunities for musicians to immerse themselves in the activity. They feel completely absorbed due to a strong sense of identification with the music.

In musical composition a number of processes and variables have been found to be associated with flow, which indicated high levels of flow are connected in many ways to higher levels of creativity and higher quality compositions. In 2006, Raymond MacDonald, Charles Byrne, and Lana Carlton examined the links between flow and the creative output of student compositions showing a significant correlation between optimal experience levels and the quality of students' group compositions as measured by creativity ratings.

A high level of absorption and concentration is also needed to have an accurate performance which in turn requires much effort. When involved in a flow state, musicians concentrate only on what they are performing without any distraction, focusing on the creative moment. Musicians who report having an optimal experience go beyond their cognitive limitations, and perform in a relaxed way. In flow state the power of their expression and imagination increases, and musicians are facilitated in risk taking and in experimenting new musical ideas.

Musicians describe flow as an ecstatic state, in which the music flows out spontaneously, without obstacles. They feel an inexplicable sense of complete harmony between body and mind. Musicians are described as being in a trance state when they produce their best performances. Flow seems to be an important aspect in enhancing high levels of performance and expression, and involves some discovery or novelty. Optimal experience is a dynamic, creative force that leads the individual to repeat the same actions in order to experience the flow again. In music performance, flow is a predictor of emotional aspects. Patrick Freer examined the experiences of six young singers and found the following indicators for flow: high levels of perceived challenge; clear objectives; deep personal involvement and concentration; self-directedness; self-awareness; direct feedback; and a lack of awareness in time constraints.

Music learning is a complex process which necessitates the acquisition of basic abilities which are necessarily involved in performing. One of the fundamental steps to becoming a musician requires hours of practice each day. Musicians spend a lot of time completely absorbed in the task, learning to master the technique and pieces of music. They are focused on the task and involved by the music. It is not sufficient for

the practice to be mechanical; it must also be internalized in order to develop awareness.

Musicians use all their mental energy to concentrate on the activity which is very complex and involves motor, cognitive, and expressive aspects. Musicians translate the visual elements of the score into acoustic signals by using motor behaviors. There is an expressive dimension in music which creates the complex dynamics of the emotional content of the piece. Musicians also have corporal and physical contact with the instruments which they consider an extension of their body. The last step of this process is the transposition of all the details of practice to the production of a fluent performance.

The ability to interact with the audience is also necessary, transferring the intense and focused practice to the concert situation. Flow can be experienced at different levels, with the highest form often occurring during the concert. It can be transcendent experience when performers play at their highest level. This process is complete when the individual aspects are functions of a whole coherent musical event. The concert activates complex dynamics with the audience, and it allows musicians to better express the flow state. The concert and the audience could be catalysts for entering into flow, giving inspiration to the performers. In live performances, such as rock concerts, the audience attends the event with similar attitudes focusing on processing the same musical signal. This joint participation produces a collective involvement and a focused attention on the music which could induce flow.

However, the appearance of flow is difficult to predict in advance because of the indefinable variables that could occur. There is also a large interpersonal variability, and in cases such as 'stage fright,' the feedback from an audience may interfere and reduce the potential ability of the performers to reach the flow state.

Flow principles were also used for observing and analyzing musical engagement. Lori Custodero developed behavioral observable indicators of flow in music, based on nonverbal communication such as gesture, expressions of interest, and energetic body movements, and it is musically evident in the production of more animated performances.

The use of flow principles has been proposed in music education for monitoring and regulating music learning, including planning tasks for enhancing the student's enjoyment. The goal is designing activities that create the right balance between skills and challenges. Defining clear and achievable goals is important in order to avoid a sense of fear of failure and in setting rewarding activities for students. It is also important to provide constructive feedback that inspires students.

Flow in Dance

Dance flow has recently attracted the attention of researchers. The main components of flow were identified and the importance of environmental, social, and physical factors was shown. Dance is considered to be a proficient field of research for flow experience, since dance, as much as other activities, has "rules that require the learning of skills, it sets up goals, it provides feedback that makes control possible" (Csikszentmihalyi, 1990: 72).

Professional dance involves practice and concentration which are prerequisites for flow. The dancers develop their

confidence through recurring rehearsals and situations which involve high challenge and high skill. Dancers try to reach perfection every day which creates ideal conditions for flow. Dancers have clear objectives about the dance they are performing. They receive direct feedback from their actions, the other dancers and the music, which give indications if they are performing accurately or they have to adjust some movements. Dance is also imaginative, inducing participants to create an alternative world in which complex feelings are activated. The complete absorption in the performance could enhance a loss of self-consciousness and time: dancers lose their idea of self and unify themselves with the activity they are performing. Dancers on stage may drop their ability to distinguish themselves from the dance.

An interpretive phenomenological analysis was adopted for examining the subjective experience of flow in nine professional dancers by Kate Hefferon and Stewart Ollis in 2006. The results showed the following three main higher order themes consistent with Csikszentmihalyi's theory: enjoyment and autotelic experience, absorption in the task, and challenge versus skill. They experienced enjoyment during flow, and they believed that flow was, in itself, an autotelic experience. The majority of the participants reported they dance 'for themselves,' suggesting that flow is an experience practiced for intrinsic enjoyment. Flow was described as an experience where dancers felt extraordinary confidence in themselves and their performance abilities. Confidence is reached with many rehearsals, commitment and definite objectives about the abilities to be developed.

Also, facilitators and inhibitors of the flow experience in professional dance were considered such as music, choreography, preperformance routines, costumes and make-up, stage setting, and relationships with others. Being comfortable with the choreography and feeling the music facilitated the occurrence of flow. Flow was greatly reduced when dancers did not have the opportunity to engage in preperformance routines which include mechanisms for controlling anxiety such as relaxation, breathing techniques, stretching and mentally rehearsing. Costumes facilitated dancers entering another reality while make-up acted as a mask while on stage. Traveling and dancing in unfamiliar environments was considered a negative influence on the ability to experience flow. Feeling comfortable and confident in the social environment – for example, receiving corrections and criticism in a constructive way from the choreographers – was reported as an important facilitator of flow. These elements could be used for developing applications to produce flow friendly environments.

Flow in Writing

Research to understand and encourage flow in creative writing has also been conducted. In 1999, Susan Perry interviewed 76 creative writers (36 poets and 40 fiction writers). She asked them questions such as "At what point in the writing process did flow begin? Did you feel more in control or out of control as you entered flow? What are your personal patterns of flow?" Writers used several metaphors for describing flow such as "moving into the movie screen," "tapping into a vein," "opening a faucet," "enter the poem," or "diving underwater" (p. 21). The idiosyncratic nature of flow in writing was shown,

since writers had different preferences such as having or not having deadlines, using or not using music during writing, working during the day or the night. Flow occurs more frequently for some writers when working on the first draft while for other writers it only appears during rewrites.

Writers face the challenge of many choices which might lead to avoidance of the task. Successful writers overcame obstacles to get into a flow state and used strategies for controlling external and internal conditions. Some writers use behavioral rituals and routines to enhance the focus on the task. Creating a predictable environment by doing routine activities such as having breakfast, going to the gym, or taking a walk helped set up a ritual to get work started. Some writers begin the day rewriting and revising the previous day's work, as a way of developing new material with a process defined as "going backward to go forward" (p. 176).

Arranging the schedule is important for entering in flow as well as having a continuous stretch of time. No one time is perfect for writing for everyone. Having a quiet environment and avoiding interruptions is crucial for focusing on the task and being able to enter in flow. Some writers have specific necessities for writing tools which seem to have special properties for helping the creative process.

There are also internal elements that could be oriented and regulated for writing. Meditation helps in focusing the attention and entering into another way of thinking, far-away from daily troubles. Anxiety is one of the most common elements that could keep a writer out of flow. Blocks are common and there are several strategies for breaking the blocks, such as forcing yourself to write whatever comes to mind, getting up earlier than usual to write, having a writing session of at least 15 minutes every day, and reflecting on your mental, physical, and emotional states.

Feelings of People in Flow Condition

Csikszentmihalyi's research reported in great detail the feelings of the people who experienced flow. This research involved over 200 people with different background such as athletes, chess masters, rock climbers, dancers, high school basketball players, and composers of music (Csikszentmihalyi and Csikszentmihalyi, 1988: 7). They were people who spent a lot of time in exhausting activities which gave them no money and little recognition. Results of the research demonstrated that flow was characterized by high involvement, deep concentration, intrinsic motivation, and the perception of high challenges matched by adequate personal skills. People involved in flow state described themselves being completely focused and attentive during the activity. They were totally involved in what they were doing. People illustrated flow as an altered state of consciousness, bringing them outside common life, as if they were transported into a new reality. They described the feeling of a sense of transcendence, in which the awareness of time disappeared and a sense of ecstasy appeared.

Flow was described as a state of mind in which consciousness is harmoniously ordered. Participants reported heightened awareness that helped inspire increased internal clarity. Attention was used to order, make sense of, and structure personal experiences as well as adequately shape their

behaviors. They were facilitated in obtaining an ordered state of mind.

Participants said they understood what they needed to do and how well they were doing. They were also confident that their skills and abilities were adequate to the task. The situation was clear without any kind of doubt, conflict or contradiction. It was likely that the participant felt in control of the situation and was able to impose a mental order. This happened because attention was focused on tangible objectives and the skills required were adequate for the activity.

There was a feeling of intense calm and no worries about anything other than performing the activity. The space-time perception was distorted and hours seemed to pass by in a minute.

Intrinsic motivation was the driving force of flow, rewarding all activities that produced flow. People wanted to continue the activity for its own sake. This is a general principle: people are inclined to replicate actions which are pleasant and generate a positive state of mind. People normally avoid tasks which generate feelings such as boredom, stress, and anxiety.

Induction of Flow

Research indicated that with appropriate training, musicians, writers, or athletes can develop control over flow experience. In 1995 Susan Jackson asked 28 elite athletes whether flow was controllable. 71% thought physical and mental preparation could help inspire flow. On the other hand, participants considered the factors that disturb the appearance of flow to be largely uncontrollable such as changes in the weather.

According to Csikszentmihalyi, it is difficult to make flow happen, but it is possible to learn how to develop a mental attitude for reaching flow. Flow occurred when: (1) people were focused and convinced that nothing was more important than the activity at hand; (2) when the skills of the person were adequate to what the task demand; and (3) when individuals demonstrated the ability to direct what happened in consciousness during the activity which required a different level of skill, effort and inspiration in each person.

Every individual can reach flow on the basis of his own individual efforts and commitment. There are individual differences in the ability to reach flow, and there are psychological characteristics which facilitate this process, such as the autotelic personality. Additional factors include level of confidence, having a mental plan for the performance, knowing in advance all the variables, and what to do in particular occasions.

There are also external and internal conditions that inhibit flow, such as unfavorable environmental and situational conditions and internal states such as anxiety and impatience. A busy or noisy environment could be a factor that prevents the concentration necessary for flow although there is a wide variation in individual tolerance. Another obstacle could be weather conditions such as a windy and a rainy day during an open air performance. The internal conditions include anxiety, which occurs when people doubt their abilities or the situation makes them uncomfortable. Another factor may be impatience which interferes with attention; according to Csikszentmihalyi, it is difficult to 'turn on a switch' and enter into a state of flow. It takes some time to get into what one is doing. It is necessary

to set in motion something like an 'activation energy' and this requires effort. The challenge is to focus on the activity and to use internal energy in the task while avoiding distractions. Being impatient and making phone calls, surfing on the Internet, and checking e-mail frequently are behaviors that take one away from the activity and the potential to enter the flow state. It is obvious that breaks are necessary in normal life: it is not possible to perform on the trombone for 24 hours a day and alternating challenging activities with more routine ones is common. A level of daily practice on instrumental technique is indispensable for musicians, and it is normal to move back and forth from high challenge/high skill activities to low challenge/low skill activities several times a day.

Group Flow

Group flow, which depends on interactions among members of the group, was observed in different contexts including sports, creative activities, and social groups. The Bosozone Japanese motorcycle gangs used expressions such as 'our feelings get turned up,' 'all of us feel for others,' and 'all of us become one' to describe flow during a motorcycle run.

Examples of group flow from sports include basketball or volleyball teams where members reported reaching a flow state. Expressions such as 'we were in sync with each other' (Keith Sawyer, 2006: 157), were used to describe team flow. Team flow stimulates the synchronicity between players, develops awareness of the environment, and thereby creates the conditions for building stronger groups focused on a definite goal.

Group flow also emerges in creative activities in the arts in which group performances are involved, such as music, dance, and theatre. Musicians employ several expressions to illustrate group flow such as 'riding a wave,' 'lovemaking,' or 'groupmind' (Sawyer, 2006: 159), which refers to a group working in the same direction focused on the same objectives. Dance is also considered to be an activity that makes participants feel part of something larger and harmonized. Group dance connects people, involves them in coordinated movements and induces articulated group dynamics.

In music, group flow performances can provide stimuli to the members of the group: they are able to create a musical universe that they would not have been possible performing alone. Musicians are inspired by the group and focus their attention and mental energy on the production of the piece. The level of collaboration seems to be an important characteristic of group flow: all the members are focused in obtaining the same result, sharing aims and objectives.

In group flow, musicians develop a strong emotional feeling, deeply involving all the members and inducing synchrony in their interactions. It is as if all the members of an orchestra are breathing together, are listening together, are tuned to the same frequency, feeling each other in a very deep way. In such a state, the performers of a jazz group might also be able to predict what the other members of the group will perform before they do it.

In creative activities, reaching group flow requires individuals to interact collaboratively with other members. Sharing emotions and feelings with the other members of the group is

important, in order to synchronize mentally and generate group strength. During flow performance there is attunement to self and other. The connection between group and individual flow creates an interesting dynamic in which the group flow provides energy to the individuals which in turn generates individual flow back to the group. Principles for managing group flow include defining clear goals and sub-goals which are shared and reachable for the group, organizing the work so there is a minimum of competition and providing support to each member of the group including appropriate feedback.

In musical performances, flow can emerge at any time, but it is usually more likely to emerge during the concert than during a rehearsal. During rehearsals of classical music, performers try to coordinate their timing and expression, whereas during the concert they look for spontaneous variations. In rehearsals, performers focus on achieving a cohesive performance and do not stray from their musical knowledge base, often playing without taking risks or challenging their individual or collective creativity. During the concert the musicians can reach flow by responding to each other in an atmosphere of risk taking and challenges which amplify their group creativity. Performers in the ensemble are able to interact musically, interpreting each other's musical viewpoints. They are focused on their collective time-keeping role, striving to achieve a unitary intelligibility of sound where each part is perceptible. They can take risks with many musical characteristics such as timbre, phrasing, timing, and dynamics, challenging each other's musical creativity. Risk taking is particularly significant in group performances because of the interactions and the challenges between members. The output could be the realization of novel musical variations when participants engage each other in challenging musical interaction. The final result is also unpredictable, since there are several levels of indeterminacy and possible combinations.

Assessment of Flow

A number of psychometric problems were considered related to measuring flow, given that it is an inner state linked to subjective experiences. Defining forms of flow assessment was a necessary step in order to develop the research and have accurate and reliable measures. Several methods were adopted, including qualitative and quantitative approaches. Qualitative approaches, including interviews and open-ended questionnaires, were used at the beginning for defining the general characteristics of flow. In quantitative approaches, flow was considered a multidimensional construct, composed of several dimensions, in order to account for the complexity of the concept. Some structured instruments were developed, such as the Dispositional Flow Scale-2 (DFS-2) and the Flow State Scale-2 (FSS-2). These are self-report closed-ended questionnaires developed for measuring flow state in sports, but they have also been adapted and applied to different contexts and with different participants, for example, for measuring the flow state of musicians, of Internet consumers or in gaming. The DFS-2 assesses the frequency of flow experience in a specific activity; the FFS-2 (which is the most well known and applied instrument for assessing flow) measures the degree of flow experienced in a particular event. Each questionnaire is

composed of 36 items (four for each factor) articulated in the following nine dimensions: challenge and skill balance, action and awareness merging, clear goals, unambiguous feedback, concentration on task, sense of control, loss of self-consciousness, time transformation and autotelic experience. The psychometric properties of the DFS-2 and the FSS-2 were tested in different contexts and activities, confirming the validity of the scales. Two shorter versions of these questionnaires were also developed, which could be used as alternatives in situations where the use of the full-length versions is not possible.

Qualitative and quantitative approaches are complementary. They provide different elements of the same phenomenon: qualitative methods are useful for understanding the general aspects and quantitative methods allow the verification of the links between flow and other psychological variables. An approach integrating qualitative and quantitative elements could be the best solution to account for the richness of flow state.

Some Flow Research Studies

Flow research flourished as it considered more complex objectives such as the associations of flow with other psychological constructs and was developed in many directions, including fields such as sports (the most prominent field) and education.

Research in sport psychology has considered the relationship of flow with athletic competitive advantage, and the relevance of flow for peak performances and the final results. It has also been shown that flow influenced movement patterns by improving coordination. Recent research also considered both positive and negative consequences of flow in athletes, such as big wave surfers. Flow was associated with positive aspects such as improved mood states, performance, self-esteem, and fulfillment, but also with negative aspects, such as the symptoms of dependence on the surfing activity. Moreover, the correlation of flow with the cognitive domain and with psychological constructs has been considered, as well as the relationships between flow and dimensions of self-concept and athletes' use of psychological skills. How to generate and maintain flow, focusing on psychological processes has included the importance of confidence, precompetitive strategies, motivation, and self-concept. Some models were developed showing that needs satisfaction and athlete engagement predict dispositional flow.

The applications of flow in sports have been addressed at both an individual and a team level. At an individual level, in sports including golf and tennis, aspects such as mental coaching and how to control concentration and attention have been considered. Possible applications at a team level include creating synchronicity between players, developing awareness of the environment, and creating the conditions to build a stronger group which is better focused on a definite goal.

The importance of flow in education has been highlighted in many studies. It has been noted that the degree of enjoyment during the classes was a good predictor for final grades of high school students. Flow also predicted semester end performance of university students, and flow was considered a mediating variable for the effect of motivation on performance. The enjoyment of teachers in teaching depends on the

attention of the students, and teachers' intrinsic work motivation was linked to the flow experienced by students. The more flow states professors encountered, the higher the occurrence of similar experiences among their students (Arnold Bakker 2005: 38). Research indicated a positive correlation between flow and perception of autonomy, competence and relatedness. Another study concluded that teacher autonomy, performance feedback, social support, and supervisory coaching had a positive influence on the balance between challenges and skills which is a basic element for inducing flow. In a research study with secondary school teachers, it was demonstrated that personal resources (e.g., self-efficacy beliefs) and organizational resources (e.g., social support climate and clear goals) facilitated work-related flow (work absorption, work enjoyment, and intrinsic work motivation); and that work-related flow had a positive influence on personal and organizational resources. Also the didactic approach has an influence on flow and a method which directly involves the students induces more flow than passive activities such as listening to a lecture.

The concept of flow has also been considered in the field of cognitive science and neuroscience, in an attempt to give a more complete and global vision than pure description in psychological terms. Flow experience has been discussed when trying to identify possible neurocognitive mechanisms. The mechanisms of flow were compared to other expressions of exceptional human experience. Arne Dietrich in 2004 stated transient hypofrontality is a necessary prerequisite to experience flow. More research is needed in this field.

Applications of Flow

Flow is not only a speculative theory developed in the academic field, but it has also led to the formation of principles which are applicable in working towards psychological well-being, the enhancement of performance, and the quality of relationships. Flow has inspired the development of school programs, the training of business managers, and the design of products and services. It has been applied in many fields, such as work and sports with the general principle that, in order to improve quality of life, it is important to improve the quality of experience.

Basic steps have been considered for enhancing the possibility of entering into flow state including defining a general objective and as many subobjectives as are practicably possible; assessing the progress by verifying the achievement of goals; using feedback to monitor the results of the activity; remaining concentrated on the activity by avoiding distractions; developing the necessary skills involved in the activity and making the task challenging when the activity becomes boring.

Some companies have tried to apply principles based on flow theory to increase productivity and the satisfaction of employees, training their managers to recognize strengths and to define with the workers clear and appropriate objectives. Flow was considered a condition for gaining both performance and enjoyment as well as helping create a sense of organizational well-being. The following points were considered: focus on the personnel (taking care of workers); setting clear

expectations and goals (through the negotiation of a performance contract with the manager); finding an appropriate level of challenge; providing feedback; not interrupting (since sudden interruptions are very disturbing for concentration and inhibit the attainment of flow).

Conclusions

Research has indicated that flow has a central role in the creative process and is directly related to optimal experience. By experiencing flow, people may exceed their cognitive limitations, allowing the expressions of their imagination and the experimentation of new frameworks. Further research should try to integrate the aspects of flow, since what is missing at the moment is an extensive theory that incorporates behavioral, cognitive, emotional, and neuropsychological characteristics of flow experience into a definitive model.

Glossary

Creolization The contact and assimilation of two different cultures, music, art, language, or other aspect, blending together and creating a unique new form.

Culinary art Professional knowledge and technique of the arts and sciences involving food sciences, food preparation, esthetics, and food culture.

Culinary globalization The blending of culinary concepts from various nationalities and cultures, including cookery techniques, ingredients, and condiments through a process of localization in creating new food types and culinary cuisines.

Food R&D The production or modification of new recipes, formulas, and products based on the solid knowledge of

ingredients, sauces, and other foods, perception of the food market, understanding of consumer needs and preferences, and grasp of consumer trends and fashions.

Idea incubation Making ideas stronger and more viable by looking for other ways of thinking and resources, evaluating and modifying again and again in order to find new solutions.

Idea verification The realization of new or modified ideas into creative products through continuous experimentation and trial and error and by overcoming all obstacles.

Nouvelle cuisine Emphasizing authenticity, lightness, simplicity, and imagination, nouvelle cuisine reduces the use of complex, heavy sauces in traditional French cuisine, in order to bring out the food's natural flavors and freshness.

Food and Creativity

Food Identity

All creativity and innovation must be established upon the foundation of tradition. Likewise, the creative development of food is based upon the foundation of food culture. Food identity is established in order to seek *differentiation*, distinguishing features, and the orientation of local food, as well as to accentuate the unique and attractive qualities of local cuisine. As food is a part of culture, it is an important factor in distinguishing between the cultural differences of various areas and social groups. Moreover, it is an essential cornerstone of cultural identity and shows food differentiation, with examples such as German sausages, French champagne, and Italian pasta. Local food identity also fulfills the role of *symbolization*, in which the production process of traditional ingredients, dishes, menus, and cuisine are categorized and assembled into various menu and food types. Many creative foods develop or expand its traditional food identity while inserting new and popular elements, balancing innovation with the preservation of local and regional culture.

Culinary Globalization

The rise of culinary globalization is a result of the rapid movement of the world's population and resources, including the impact of tourism, relocation of immigrants and their culture, and the advancement of transportation and technology. Culinary globalization has also had a great impact on the creative development of food. Various culinary practices are joined in one kitchen, where a chef must incorporate foreign ingredients, adapting unknown cookery techniques to deal with familiar ingredients, and using unfamiliar spices in known dishes. Under these conditions, never-before-seen food types

are created through localization and a blend of ingredients from different regions, various cookery techniques, diverse food cultures, and other historical factors. For example, influenced by Western cuisine, Japanese cuisine has developed the eclectic Japan–Western cuisine, using its staple food rice to create dishes such as the Katsu-Don (fried pork chop with rice), a product of Japanese history in the late 1920s, and the Omuretsu, an adapted form of the French omelette. On the other hand, Japan has also influenced Western cuisine, leading many renowned Western chefs to adopt Japanese culinary techniques and ingredients in Western menus, creating items such as the California role. With the universality of ingredients and dishes being a major culinary trend in the late twentieth century, the process of localization creates new hybrid types. Cultural image is used in food industries to produce variety among existing food types. The *creolization* of ingredients, cookery techniques, flavor, and eating habits continues to provide stimulation for the culinary arts.

Nouvelle Cuisine

In the late eighteenth century, the concept of *modern cuisine* began to surface in the French culinary world; renowned French chefs began to view their status as that of an artist, and their cuisine and dishes as works of art. The later rise of *nouvelle cuisine*, whose name can be traced back to the 1730s, continued to emphasize the spirit of innovation. Adhering to the four main principles of authenticity, lightness, simplicity, and imagination, nouvelle cuisine favored simple cookery techniques, reducing the use of traditional heavy sauces, and introduced the concept of healthy dishes, in order to bring out the food's natural flavors and freshness. Chefs of the nouvelle cuisine style began to abandon the rigidity of the traditional French cuisine and find inspiration in exotic and regional

cooking techniques and ingredients. Adapting concepts of Italian and Moroccan cuisine to traditional dishes, they created a new style for French cuisine. For example, the traditional dish, *pot au feu*, which originally used beef as the main ingredient, was updated by trading the beef for fish. The influence of nouvelle cuisine can be seen in the ingredients and menus of many Michelin-star restaurants, in which the chefs apply *avant-garde* concepts for French cuisine. The pursuit of innovation and experimentation in the culinary arts, as well as the various combinations of cooking methods, provide customers with a delightful dining experience and a feast for the five senses.

Food Research and Development

Research and development of foods and dishes, including modification processes, are crucial to the success of many food organizations and corporations, such as those in the food industries, fast food industries, and chain restaurants. Due to the ever-changing needs and trends in the food market, researchers study market analyses, transform trends into products, and predict future development and needs. Research teams combine the knowledge of culinary training, food sciences, and food chemistry to create innovative new standard recipes and menus using formulas, proportion, mass production, and cooking techniques. In addition, research is also applied to scientifically analyze the various characteristics of existing food in order to modify or design newer and better products. During the research and development process, the researcher creates a prototype production according to the proposed formula, which then undergoes sensory evaluation, using human senses or scientific instruments to test qualities such as color, flavor, smell, and texture, in order to ascertain the product's quality. Taste tests are conducted on clients in order to collect more feedback regarding modification. After a series of experiments and analysis, the final product is

then quantified into detailed and accurate data, creating a standardized production procedure to ensure the uniformity of the product.

Molecular gastronomy is a scientific discipline involving the study of physical and chemical processes that occur in cooking. It pertains to the mechanisms behind the transformation of ingredients in cooking and links the social phenomena, artistic and technical components to culinary activity. The molecular gastronomy study tries to explore existing recipes, introduce new tools, ingredients and methods into the kitchen, invent new dishes, and use molecular gastronomy to help the general public understand the contribution of science to society. Many Michelin-star chefs are joining the ranks of molecular gastronomy, this "tasty, novel, and fun" culinary revolution.

Creative Cuisine and Recipe

Generally speaking, creative culinary works must carry the attributes of originality, usefulness, and balance. Original dishes have the ability to surprise and provide a novel sensory experience; the usefulness of a dish includes the possibility of commercialization, customer satisfaction, market acceptance, and cost consideration and production feasibility; balance of a dish includes harmonious flavor and appearance. These three attributes interact with the five elements of culinary products, namely professional technique, flavor and seasoning, esthetic appearance, ingredients, and conception (see [Table 1](#)), and bring the content of the creative cuisine and recipe together.

Professional Technique and Innovation

Knowledge of the characteristics of ingredients and their application is fundamental to innovation. The understanding of the

Table 1 Creative culinary product criteria matrix

	<i>Originality (novelty; originality; newness)</i>	<i>Usefulness (value; appropriateness; significance; utility, adaptability)</i>	<i>Balance (harmony)</i>
Professional technique	Nontraditional techniques or tools	Good solid cooking Excellent skills	(Prepreparation, cutting technique, size of portions, cooking method and garnish in balance)
Flavor and seasoning: aroma, taste, and texture	Unique aroma, taste, texture	Matches customers' favorite flavor(s), 'less is more,' natural	All flavors are matched and in balance, harmonious flavor
Esthetic appearance: colors, modeling, arrangement	Unique colors	Appetizing colors, natural colors	Harmonious colors
	Unique and elegant modeling: arrangement, shapes	Amount, size, position of dishware appropriate, well-crafted (strong lines), slicing in sequence, pleasant facing and flow	Balance of dishes
Handling of ingredients	New, extraordinary and diversified ingredients	Seasonal and local ingredients; good understanding of the special features of ingredients, foods well-balanced in size, texture and quality, digestible	Fine balance of ingredients
Conception	Original interpretation of traditional cuisine, introduction of different culture(s), attractive, alive, tells interesting stories	This idea has practical value; the culinary product or dish has an easily remembered name	This artist has created a harmonious feast

physical and chemical changes during the preparation and cookery process, including the different cuts, heating methods, and the resulting style and flavor from various combinations of ingredients and garnishes, are key to creating richer variations of ingredient mixtures and dishes. In addition, the use of nontraditional kitchenware, equipment, and tools have been instrumental in breaking through old cookery techniques. The advancement of technological progress has brought about constant changes in the culinary arts and propels the modification of products. For example, the invention of the Combi oven has improved upon the design of traditional ovens, allowing for the preservation of moisture during the baking process. However, only with solid, basic culinary skills can one begin to innovate and realize one's creativity.

Aroma, Taste, and Texture

Creative dishes are a combination of unique aroma, taste, and texture. First and foremost is the harmonization of flavors, including the arrangement of strong and mild tastes and the balance between sour, sweet, bitter, spicy, and savory tastes. Coupled with complementary textures, the suitable combination of aromas provides a harmonious satisfaction of taste and texture upon eating. Taste is the core of culinary art; it is the overall sensory stimulation achieved through the use of food, spices, condiments, and cookery methods. By using condiments only to assist or accentuate the presentation of the ingredient's natural flavors, good creations are able to bring out the inherent value in a food's simple, natural taste.

Unique Appearance of Cuisine

A creative and esthetic appearance of cuisine provides visual enjoyment and elevates the dish to a work of art. The natural color of the food itself should be used and colors which whet the appetite should be chosen based on concepts from color psychology, creating a harmonious effect between the colors of different ingredients. The unique form of the dish should be based on the cut and size of the portion, the size and style of the dishware, as well as the orientation, positioning, placement, and number of dishware. Many creative dishes are presented upon unique dishware, which emphasizes or complements the food and achieves an overall look.

Handling of Ingredients

Food is the cornerstone of cuisine, and fundamental skills for creative cuisine include knowledge in choosing ingredients, understanding their features, and the handling of ingredients. Depending on the season, location, or weather, ingredients may

have different characteristics. Creative dishes should use suitable ingredients in order to produce new styles. Clever combinations of local and exotic or specialty ingredients often result in creative cuisine, which brings out a unique cultural style or flavor to the dish. The joining of local culinary techniques and exotic ingredients also produces culinary variety.

Culture and Conception of Creative Cuisine

The concept and spirit of the creator is often imbued in creative cuisine, emphasizing the essence of the creation and its interaction with the eater, as well as providing the culinary work with deeper meaning and vitality. Creative cuisines use storytelling methods and cultural backgrounds to increase the value and attraction of the dish, which draws the attention and interest of customers. At times, creative cuisines may present cultural stories, such as the melding of various cultures through the suitable combination of food cultures or the emphasis on adapting local culture to produce a dish of local flavor. In general, creative cuisine should provide a rich feast for the senses of sight, taste, smell, touch, and hearing.

Creative Culinary Process

The creative culinary process can be seen as the evolution of thoughts, which will lead to truly creative culinary products. The process can be divided into several stages: preparing the new ideas, idea incubation, idea development, and verification of culinary work (see Figure 1).

Preparation for New Ideas

New ideas for the culinary arts come from a variety of channels. The personal culinary experience of the culinary artist is a direct source of inspiration. Innovative chefs use words and pictures to document and analyze their experiences in different restaurants, locations, or countries to form a database from which to transform external stimulation into internal creative potential. In addition to enriching one's knowledge, culinary books and recipes all serve to stir up inspiration by providing new ideas or reinterpreting old ones. Many ideas can be found not only in food itself, but also in culture and art – fashion, art, music, and historical artifacts – whose creative concepts can often be transformed into culinary elements.

Idea Incubation

During the idea incubation period, the creator draws upon a database of past experiences, knowledge, and inspirations and comes up with many diverse culinary ideas through divergent thinking, a process which is often swift, automatic, and

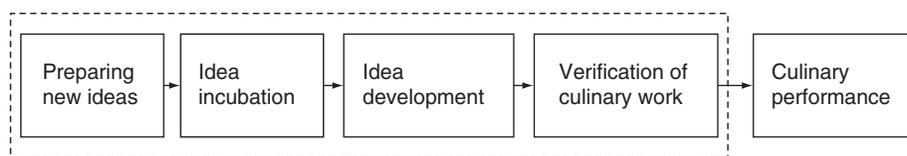

Figure 1 Model of creative culinary process and culinary performance.

subconscious. The culinary artist may at this time put ideas aside due to present difficulties, make due considerations, evaluate various opinions, incubate ideas, or give them up in order to search for other ideas. This constant evaluation, modification, and adjustment of perspective will continue to produce new solutions. Then, after thorough analysis and comparison and through convergent thinking, a feasible idea will emerge.

Idea Development

At this phase, the design and concept of new culinary ideas are interpreted into actual drawings or words. Technical difficulties may be encountered during the refinement of the idea, but a surprising breakthrough may often be reached after more thorough introspection or consulting additional information and others' opinions. Obstacles often provide opportunities to improve upon the culinary idea and its feasibility by clarifying the concept and direction.

Verification of Culinary Work

After the development of the idea, it must be executed into an actual culinary work. Initial prototypes often undergo a series of evaluation and modification in taste, production method, ingredients, and cost. Constant testing, comparison, and revision is needed, including a trial of different solutions, modification of cookery techniques, or adjustment of food content, in order to realize the ideal product.

Factors Influencing Food Creativity

Individual and environmental factors have an enormous influence on food creativity (see Figure 2). The environmental factors can be positive or negative. Creativity is nurtured through the interaction between human beings and the environment. Therefore, the environment is an important factor that needs to be considered carefully.

Personality

An innovative culinary artist embodies personal characteristics which are conducive to creative development, including: imagination, curiosity, sensitivity, openness, having a broad array of interests, huge appetite for art, being passionate, self-confidence, taking reasonable risks, achievement-oriented, perseverance, a sense of honor, and having strong motivation. In addition, the artist must straddle creativity in both art and science, think independently and outside of the box, and possess rich professional knowledge and life experiences.

School Environment

An important developmental environment for the culinary artist is the school, the place of nurturing for their ingenuity. The sense of achievement derived from the performance in related courses, activities, and competitions motivate students to invest more time and effort in the field of culinary arts. Participating in culinary activities and competitions in and

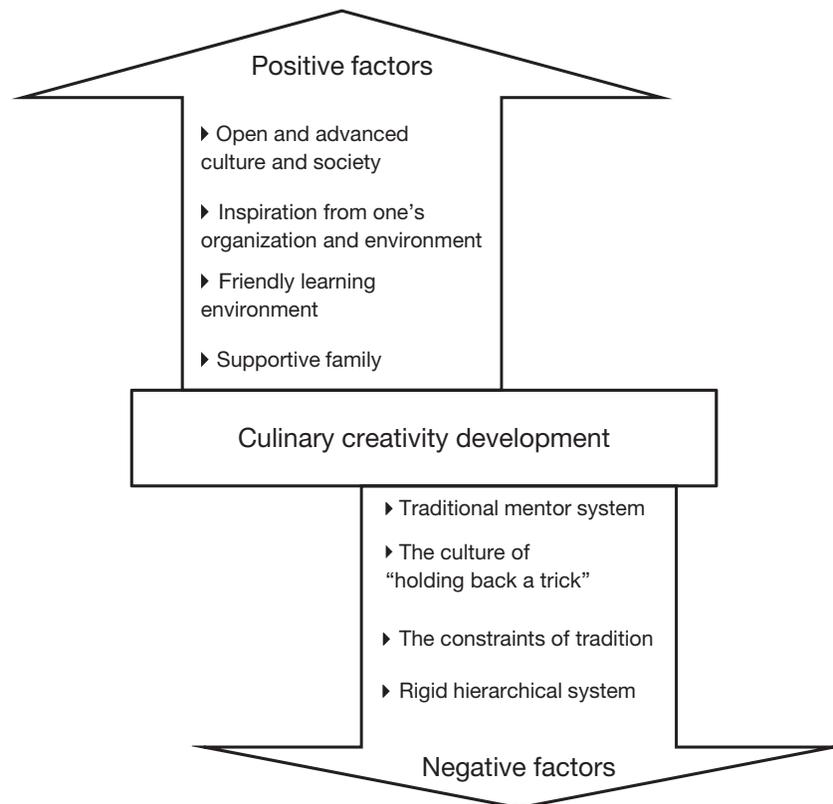

Figure 2 Extrinsic factors in the development of creativity.

out of school provides great opportunities for the students to realize their creativity and learn more about the culinary arts through the guidance and support of teachers. Thus, the school's educational style, courses, teachers, and activities all play a part in the continued development of the student's culinary creativity.

Working Environment

Rich working experience in the culinary arts and in various working environments, such as in Western and Eastern cuisine, pastries, and Japanese cuisine, is beneficial to the development of culinary creativity. Drawing upon the knowledge and skills acquired in various areas of culinary art, the artist can then cleverly and harmoniously blend them in a new conceptual product. Adopting an open leadership style in an organization can nurture a creative environment and stimulate innovation. Creative role models can inspire their peers through the Pygmalion effect, forming a virtuous cycle of self-motivation and improvement. On the other hand, traditional kitchens often operate like a military environment using a hierarchical system which rarely allows lower level chefs to realize or express their creativity.

Social and Culture Environment

In a multicultural region or country, the tastes of various culinary and food styles blend and mesh to create a new flavor. Influenced by a multicultural environment, chefs often have a broader world perspective and more creativity. In fact, many innovative master chefs have experienced more than one culture and created their own unique style out of a multicultural mix. In recent years, the status and image of chefs have become more and more visible as many chefs are transformed into public figures and the main attraction of restaurants. With increased respect for personal culinary style in today's culture, a chef's ability to continue creating astonishing new works is key to his or her success.

Creative Menu Design

A creative menu not only expresses the character of a restaurant, but also serves to attract customers. Creative menu design can be categorized into the following: menu content and layout; and menu presentation and formal design.

Menu Content and Layout

The content of a creative menu should not only be expressed in a language the customer understands, but also introduce creative concepts which fulfill the customer's needs, such as functional foods (environmental or healthy foods), introduction of new eating methods, and foods with rich stories or symbolism. The layout of a creative menu can be arranged in order of the courses, such as appetizer–entrée–dessert, aperitif–appetizer–entrée, or entrée–beverage, etc. Another layout method is to create new combination dishes, such as a wine dine menu.

Menu Presentation and Formal Design

A creative menu with a strong formal design can accentuate a restaurant's characteristics and boost sales by presenting dishes in a way that entices the customer's appetite and desire. Creativity in menu presentation and formal design can be realized in a number of ways, but should always take into consideration the restaurant type, dining psychology, and changes in consumer attitude. Different presentation methods can be adopted, such as booklet form, suspended menus, blackboards, or presenting daily specials in electronic format. Some restaurants even choose not to present a menu, preferring instead to have the culinary artist directly consult and decide on a course based on the customer's desire and needs, and on the fresh ingredients available on that day. Creative elements for the formal design of the menu, including a variety of material, paper, type, font, numbers, and symbols, can all be combined in an infinite amount of possibilities.

Conclusions

Food creativity provides variety and richness in our dining experience and invigorates our food culture. Based on solid cookery techniques, creative food and menus modifies traditional methods, utilizes technological breakthroughs and cleverly combines different ingredients into harmonious and astonishing flavors, presented in an overall display of artistry upon carefully chosen dishware to relate traditional cultural or multicultural concepts. Creative cuisine combines food sciences, knowledge of food preparation, cookery techniques, esthetics, and food culture into a final product of both art and science. During the creative process, the culinary artist draws upon a broad database of knowledge and past experiences and comes up with culinary ideas in the beginning of the creative process through divergent thinking. The idea is interpreted, modified, and refined into a feasible culinary concept, which is then transformed into a product through a series of experimentation. A number of factors affect a culinary artist's creativity, including personality, educational role models, encouragement from related competitions and courses, the work environment, creative atmosphere resulting from open leadership, and the social and cultural environment. A multicultural environment is more able to stimulate new ideas and works from a culinary artist.

The Four Ps of Creativity: Person, Product, Process, and Press

M A Runco, University of Georgia, Athens, GA, USA

D Kim, University of Georgia, Athens, GA, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Alpha press Environmental pressures that have an impact on behavior independently of the individual's interpretation of them.

Beta press Environmental pressures that have an impact on behavior only if perceived by the individual and meaning is assigned to them.

Four Ps Person, product, process, and press (or place) approaches to the study of creativity.

Persuasion The view that creative individuals and products change the way that people think.

Potential The capacity for something, such as creativity, but not actually employing that capacity. A person has the potential for creativity *or* performs in a creative fashion, but not both.

Introduction

Creativity has been tied to everything from artistic achievement to entrepreneurship to cultural evolution. It may very well represent one of the most basic and important human capacities, as evidenced by its role in so many and such diverse domains and endeavors. The list of endeavors and domains would go on for pages if given in its entirety. No wonder there is so much research on the topic – and an *Encyclopedia of Creativity*. Given the large amount of research on the topic, it is also not surprising that there have been several attempts to organize the field. Perhaps the best known effort is that of Mel Rhodes, who in 1962 published *'An Analysis of Creativity,'* within which was an organizational framework that is still widely cited, even 50 years later. There have been modifications to this framework, which are summarized below, after Rhodes' original scheme is presented. This review of Rhodes' 'Four Ps' and subsequent organizational approaches has several functions. Not only does it provide a way of distinguishing the different perspectives on the topic of creativity. It also suggests where new research might be needed.

The Four Ps

Rhodes is famous, within creativity studies, for his identification of the Four Ps. These are categories, or what he called strands, in the creativity research. Each strand represents a unique perspective on creativity. The four Ps are Person, Process, Product, and Press. The last of these is now often called Place, though this is not entirely consistent with what Rhodes meant. He used the term 'press' because it was common before 1961 to view influences on human behavior as pressures. Murray seems to have gone into the most detail about press factors and distinguished between alpha and beta presses. The former are a part of the objective world. The latter have an impact only when an individual interprets them as significant. This distinction is entirely consistent with what the cognitive sciences say about perception. It is a matter of interpretation, and events and stimuli generally have no impact unless the individual attributes significance to them.

Person and Personality

Research on the creative person often looks to personality. It may also examine intellect, temperament, physique, traits, habits, attitudes, self-concept, value systems, defense mechanisms, and even idiosyncratic behaviors. Much of the research is intended to identify creative individuals, often by comparing someone with the profile of a highly creative person. Obviously there is no guarantee that if one person shares traits with a creative individual that he or she will also be creative. In fact, just because one person has demonstrated creativity there is no guarantee that he or she will continue to do so. It could be that the individual had the potential to be creative, perhaps because of certain traits, and when in the right environment was in fact able to perform in a creative fashion; but when removed from that environment, the support may be lacking and creativity is less likely. This is close to what personality psychology calls the Trait X State interaction. The idea is merely that traits interact with situational states to govern actual behavior. Actual behavior is not controlled by one or the other, traits or states, but only by the interplay of them both.

Interviews, personality tests, and in-depth case studies have all been used to identify the core characteristics of creative individuals. Each approach has strengths and weaknesses. Personality tests, for example, are often self reports, and as such may be biased by honesty, memory, and socially desirable responding. Case studies allow triangulation and detail but there are sampling biases and few controls. That being said, there is a fair consensus about a few characteristics, including intrinsic motivation, wide interests, curiosity, autonomy and independence, and flexibility.

Even here, domain differences need to be taken into account. A great deal of research suggests that the traits that are common to one domain, such as mathematics, may differ from other domains, including the arts, science, and so on. Additionally, there are several reports of creative persons having paradoxical personalities. These are apparent when creative individuals have one tendency, but also the opposite tendency! A good example of this is psychological androgyny, which is defined as being open to both stereotypically masculine and feminine tendencies. The androgenous

person may, for example, be sensitive but also quite independent.

It is possible that this capacity, and perhaps even the more general appearance of a paradoxical personality, is a reflection of some overarching trait, such as flexibility. The person might be flexible, or perhaps tolerant, and as such goes through life spontaneously, where ever that leads, without worrying about maintaining a consistent stance. If this reasoning is accurate, it implies that the paradoxical personality is the result of some deep tendency and not necessarily the determining factor in creative performances. Both creativity and the paradoxical personality could both be the results of flexibility or tolerance of ambiguity, just to name two possibilities.

The Creative Process

While the 'person' approach to creativity focuses on 'who is creative', the process approach asks 'how are insights and new ideas found?' Often the question of 'how' is answered by pointing to the stages of work and thought. In fact, this brings us to another famous resource in creativity studies, to go along with that of Rhodes – namely *The Art of Thought* by Graham Wallas. He described four stages of creative process: preparation, incubation, inspiration, and verification. Preparation is composed of the steps of observing, listening, asking, reading, collecting, comparing, contrasting, and analyzing information so that the individual is ready or 'prepared.' Incubation, the second step, is supposedly necessary, however, and this means that the person takes time away from the task and allows the subconscious to operate. Part of the benefit here seems to be that many of the constraints and censors imposed by the conscious mind are relaxed during incubation so a wider range of options can be considered. Then there is the third step, which is illumination. This is where the insight actually makes itself know. There is an 'ah ha' as the original idea pops into consciousness. Interestingly, the sudden appearance of the idea may imply that insights are quick or sudden, but Howard Gruber's careful research on discovery indicates that they are actually protracted and cover quite a bit of time. Since the person is incubating, and not conscious of the work on the topic, he or she does not realize that insights are protracted. They feel sudden but are not. The last stage, for Wallas, is verification. Here the idea is tested and applied. There may be recursions, however, if the idea falls short. The individual might revisit earlier stages, preparing anew or taking more time for incubation.

There is an interesting overlap of process and personality perspectives on creativity. Personality research often identifies flexibility, openness, and risk tolerance, for example, and each of these is easy to relate to creative thinking. Flexible ideation, for example, may very well lead to original insights and allow an individual to avoid the ruts and routines that make creative problem solving difficult. Openness allows ideation to move into different and perhaps divergent directions, and tolerance allows the person to consider unusual, unconventional, and contradictory lines of thought. These same points of overlap have also been identified in research on creative places and the press factors that support creative thinking.

Press Factors

The term, *press*, refers to factors that have a potential influence on behavior. Some things in the environment have an influence regardless of the individual's interpretation of them. Loud noises, for example, lead to reactions and can certainly be distractions. In fact, the best examples of such 'alpha press' factors are those that depend on our sensory systems, for these operate reflexively. The human cognitive system begins with such sensory information, but the individual only becomes aware of what is in the environment if something demands attention and is then processed further into the system. Meaning is assigned at that point and an interpretation constructed. Many environmental factors depend on interpretation. Noises that are not loud enough to be disruptive, for example, might be music to one person but aesthetically unappealing to his or her parents! Environmental factors which depend on interpretations are beta press factors.

Most environmental influences on creative behavior are more beta than alpha press. Admittedly obnoxious sensory stimuli will preclude creative thinking via distraction or perhaps even discomfort, but at least among the factors examined in the research, interpretations are critical.

Many press aspects of the classroom environment have been examined. At least as many press aspects of the organizational setting have been investigated. These suggest that resources can be quite important. They include material resources, as well as social resources. Time is especially important, in part because original ideas may require incubation or at least time to associate and consider alternatives. Time exemplifies the idea of press since people can be under pressure from deadlines. Note also that some people work well under pressure, while others prefer to take their time and are distracted by deadlines. The key social press factors include support for new ideas, challenges, trust, and permissiveness and latitude that supports risk taking.

Studies of press factors have demonstrated that there are both supportive aspects of the environment, such as those listed above, but also things that can inhibit creative efforts. Ruth Richards, in her article on the 4Ps that appeared in the first edition of the *Encyclopedia of Creativity*, described how in some settings, including education, it can be difficult to support innovation and creativity. After all, there is quite a bit of accountability in current education, at all levels, and educators must have clear objectives and objective assessments that can be used with all students. There is pressure on conventional knowledge as well as conventional behavior, and to accomplish what is required by the mission of a school system, uniqueness and individuality are frequently relegated. Richards also made the important point that innovation and adaptability, two benefits of creativity, are of increasing importance. Things are changing at an accelerated rate, so creative talents are of even more importance today than ever before.

Products

The term, *product*, refers to a tangible form converted from idea. Creative products may be paintings, poems, novels, inventions, designs, or patents, or they may take another form. Sometimes performances are considered to be products,

in which case they are not really tangible, though they can still be counted. That is probably the outstanding virtue of products: they allow highly objective analysis. The problem is that they may not be very predictive. Sometimes the past is indicative of future efforts, but not always. Additionally, products say little about the actual creative process.

Some research on products is intended only to examine the product and draw no inferences about the creative process or the talents and efforts that went into the product. The Creative Product Matrix, for example, contains a list of dimensions that allows comparison and ranking of various kinds of products.

Many studies of creative products involve eminent persons or experts. This makes sense because they are very likely to be productive. Consider, for example, the research on scientific creativity. Products may be publications and citations to them. The latter would be indicative of the quality of a scientist's work because higher quality research is the most likely to be cited by others working in the field. Studies of publications as products suggest that there are advantages to interdisciplinary work – some highly creative scientists being polymaths – and that a minority of the field produces the lion's share of the research. This last finding is known as *Lotka's Law*.

Persuasion

Various lines of research have suggested that the actual insight, produced by an individual, is only one part of creative achievement. Clearly, there are social factors involved in creativity, and some of the most important are the judgments and attributions to a new idea or product. Dean Keith Simonton took a social perspective on creativity and defined it specifically in terms of *persuasion*. This label fits nicely into the alliterative scheme (as a fifth P), but more importantly acknowledges social and historical factors. Put simply, from this perspective, creative achievements are those that change the way that others think. They are in that sense persuasive.

Simonton's extensive empirical research on social factors also supports Lotka's Law, but goes well beyond that. He has tested a large number of cognitive, developmental, and historical hypotheses and derived several compelling *nomothetic theories* about creativity and its impact. Nomothetic theories apply broadly, often across historical eras and, to a certain degree, across cultures. They parallel what are sometimes called universals and can be contrasted with *idiographic theories*, which focus on how individuals differ from one another.

Persuasion is also assumed by social theories that focus on attributions as part of the creative process. Attributions of creative value may be given by judges and individuals making up a field of study. The idea here is that an individual may produce something with creative potential, but if judges do not attribute creativity to it, very likely it will have no impact and may very well be ignored and forgotten. If this line of thought holds up, there would be reason to direct one's creative efforts not just to the product, but also to impression management that will increase the likelihood of favorable attributions. This notion has been criticized since it suggests that an individual might benefit from taking time away from creative work so there is time to manipulate attributions. Still, case studies sometimes confirm that eminent creators tend to care a great deal about how their work is received.

Creative Potential

Each of the perspectives reviewed have been organized into a hierarchical framework. This is presented in **Table 1**. Of most importance may be the placement of creative potential and creative performance at the top of the hierarchy. The rationale for this is that many factors, including those describing the creative person and the press factors, may influence creative effort, but do not always do so. They therefore describe creative potential but do not guarantee actual creative performance. Products, on the other hand, are end results. An actual performance is required. Similarly, new ideas and products are only persuasive if they are complete, or at least manifest. A performance is again required and potential has been fulfilled, or at least actually utilized. There is, then, a fairly clear separation between perspectives on creativity that describe potential and those that describe actual performance. It is even possible that a chronology of sorts can be hypothesized, with particular traits providing creative potential that is then supported by various press factors, the result being that a product is created and it earns social attributions of 'creativity.'

There are advantages to the study of those things categorized in **Table 1** as indicative of creative potential. The most notable is probably that something might be learned about how to fulfill potentials and thereby increase creative productivity. Given the role of creativity in psychological and physical health, and in technological and cultural evolution, this is definitely a desirable objective. No wonder there are so many programs, techniques, and theories about enhancing creativity. The advantage of research on actual performance and those things on the right side of **Table 1** is that there is a high level of objectivity. There is often a consensus about creative things, for example, and little ambiguity. The problem with some performance approaches is that, to apply what is learned we must draw inferences from the past to the future. Sometimes these are warranted, but other times there is a risk in inferring that just because Hemingway enjoyed travel or Einstein played a musical instrument that travel and music will benefit everyone and always enhance creativity.

Table 1 Hierarchical framework for the study of creativity

<i>Creative potential</i>	<i>Creative performance</i>
Person	Products
Personality	Patents, inventions, publications, works of art
Traits, Characteristics, Idiosyncrasies	Ideas
Process	Persuasion
Cognition	Historical impact
	Systems
	Individual-Field-Domain
Press	Attributions and Social Judgement
Distal influences	
Evolution	Interactions
Zeitgeist	State X trait
Culture	Person X environment
Immediate influences	
Environments and settings	

Conclusions

There are several intersections among the six Ps reviewed in this article (person, process, place, product, persuasion, and potential). This is clearest in the case of products and persuasion; both apply nicely to eminent creators and assume a social component. Another example involves process and person categories of research. Personality research has identified several tendencies (e.g., flexibility) that have also been uncovered in studies of the creative process. Press and place research fits here as well since it points to factors in the environment that support the same traits. Importantly, environments that support creative efforts offer certain things and avoid others. There are both supports to creativity as well as barriers. Both should be taken into account to facilitate creative efforts. Also recall that the impact of environmental factors is frequently moderated by perceptions and interpretations. These are by definition constructed by each individual, so recommendations that apply across all people or settings and organizations are difficult to make.

The hierarchy in [Table 1](#) is skeletal but nonetheless underscores the fact that some perspectives on creativity assume that only manifest performances are important, while others recognize the more personal side. It is possible to

take both into account, almost in a developmental manner, such that what is important at first is creative potential, but if the supports are present (perhaps in creative press and places), that potential might be fulfilled and actual creative performance result. The creative performance may very well be apparent in actual products, and perhaps in performances that have impact and persuade an audience to change the way it thinks. This certainly is a practical implication of the various perspectives on creativity; it would be to everyone's advantage if creative potentials were in fact fulfilled and creative products and performances common occurrences.

This article is reproduced from the previous edition, volume 1, pp. 745–753, © 1999, Elsevier Inc.

SIGMUND FREUD was the creator of psychoanalysis. Psychoanalysis is a form of psychotherapy, a set of methods for collecting data on human behavior, and a system of psychological theories. Freud developed a variety of concepts that have become central to the understanding of creativity, including unconscious motivation, sublimation, defense mechanisms, and the resolution of neurotic conflicts through creative activity. Though Freud's ideas have been often modified, criticized, and challenged since his death, psychoanalysis remains the most broadly influential approach to the study of creativity.

Sigmund Freud. Used with permission from Snark /Art Resource, NY.

Background

Freud was born on May 6, 1856, in Freiburg, Moravia (now Příbor, Czech Republic). His father Jakob was a 41-year-old wool merchant who had two adult sons from a previous marriage. Freud's mother, Amalia, was 21 years old at the time of his birth. Sigmund, her firstborn child, was followed by six more children, five of whom survived to adulthood.

The Freud family moved to Vienna amid serious financial difficulties when Sigmund was nearly four. As Jews, they lived in the Jewish ghetto of a predominantly Roman Catholic city. Sigmund remained in Vienna for all but the final year of his life. Though he proclaimed his hatred for it, the city was a center of European culture, science, and politics. Sigmund was his mother's favorite child, whom she called her "golden Sigi." She often repeated a gypsy woman's prediction that he would be a great man. His father was not so optimistic; when the 7- or 8-year-old Sigi urinated inappropriately in the parental bedroom, Jakob Freud exclaimed, "The boy will never amount to anything!" Sigmund soon began to fulfill his mother's expectations. In Vienna he attended a classical German-style *gymnasium* (an advanced secondary school), where he was inspired by the

works of such great writers as Goethe and Wordsworth, plus scientists such as Darwin. His school performance was outstanding; at age 17 he entered medical school.

Early Adulthood

As a medical student at the University of Vienna from 1873 to 1881 (with a year out for required military duty), Freud received not only a basic medical education but some of the best training in scientific research that Europe had to offer. The professors with whom he worked closely were distinguished in their fields, and Freud was expected to follow their paths in anatomy and physiology: Carl Claus, Hermann Nothnagel, Theodor Meynert and Ernst Brücke. However, in contrast to much of today's scientific training (especially in psychology), the research skills Freud developed there were not experimental or correlational but observational, mainly involving dissection and microscope work. Freud became a scientist without ever performing a controlled experiment. His initial interest was in physiological research; his first published paper answered a long-standing question by establishing the presence of testes in the male eel. His other research topics included the nerve cells of fish and crayfish. Freud was one of the first scientists to suggest the general outlines of the modern neuronal theory of the nervous system. Later in his life, long after he had abandoned physiological research altogether, Freud continued to compare his explorations of the deeper layers of the unconscious to the process of peeling away surface layers of skin or tissue—the kind of thing he had done as a physiologist when he was trying to get at a nerve cell.

Though Freud was regarded by his professors as a promising neurophysiologist, this was not a career in which he could make enough money to support a family. He had already fallen in love, not long after he completed his research training, with a young woman named Martha Bernays. Therefore his professors advised him to go into clinical practice, specializing in neurological problems. Getting the necessary clinical experience and establishing a practice took him four years beyond medical school, during which time he and Martha remained engaged though often apart. Among the factors that frequently separated Freud from his betrothed was his continuing effort to obtain the most progressive training available. He traveled to Paris to observe the treatment of hysteria and other psychological syndromes by the great Jean Martin Charcot, and to Nancy (also in France) to study the hypnotic techniques of Hippolyte Bernheim. In his own early psychiatric work, Freud became an expert on aphasia (an assortment of syndromes involving the inability to speak) and a respected authority on childhood paralyses. When

he began to treat patients whose main symptoms were evidently psychological rather than physical, Freud administered the latest therapies—such as electric shock and hypnosis—but found them unsatisfactory. Then he tried a technique developed by another prominent scientist, Josef Breuer, who was already a fatherly friend and mentor to Freud. Several years earlier Breuer had treated a friend of Martha Bernays, with some success. That patient later became a pioneering social worker under her real name of Bertha Pappenheim, but she has gone down in psychological history under the pseudonym of Anna O.

The Beginnings of Psychoanalysis

When she came to Breuer for treatment, Anna O. was suffering from a variety of paralyses, aphasias, inhibitions, and periods of confused thinking. Breuer found that if he asked Anna under hypnosis to talk about the original circumstances associated with each of her symptoms, she reexperienced the circumstances vividly and her symptoms were thereby relieved. When Freud subsequently tried a similar procedure on his own patients, he soon gave up hypnosis. Instead, he simply (or perhaps not so simply) insisted that his patients tell him, as fully and with as little mental censorship as possible, what came into their minds whenever they began to think of their personal problems. Thus was born the practice of free association, the earliest element of psychoanalysis as a general therapeutic technique.

Over the next several years, Freud developed an array of techniques that became essential both to psychoanalytic psychotherapy and to Freud's accumulation of psychological data as a foundation for his development of psychoanalytic theory. While encouraging free association, Freud found that his patients were often more willing to free-associate to their recent night dreams than to events of the day. When he got them to free-associate to each element of a dream, he saw emerging patterns that revealed the patient's underlying motives and psychological conflicts. In the process of engaging in such dream interpretation, as well as having patients free-associate to slips of the tongue, to temporary forgetting of names or words, and to other psychological anomalies, Freud developed a general approach now known as the "intensive study of the single case."

Freud did not try to study large numbers of similar individuals at one time, as in the standard psychological experiment or survey. Instead, he closely examined one patient at a time. "Intensive study" has two meanings here. One is that Freud obtained a great deal of information on any particular individual. He typically saw each patient for three to six hours per week for anywhere from several months to several years. During the hundreds of hours of each patient's free associations, then, Freud could observe changes in the patient's behavior and memories, could double-check his developing hypotheses, and could alter those hypotheses as new developments emerged. The other meaning of "intensive study" is that Freud was not content to accept new information from a patient as it first appeared, or to categorize it in terms of superficial criteria. If certain information supplied by the patient seemed to have no immediate significance, Freud probed further into the patient's memories and free associations. He checked out possible connections with other material

provided by the patient, and generally tried to relate the information to an organized and coherent picture of the patient's personality. Freud constantly evaluated the material's internal consistency—the omissions and contradictions evident in the patient's statements. He sometimes compared himself to the great fictional detective Sherlock Holmes, tracking down tiny clues that might lead to the solution of a crime—or in Freud's cases, tracking down clues that would lead to a fuller understanding of a patient's psychological problems.

In addition to dream interpretation, free association, and the intensive study of the single case, Freud developed two other techniques to obtain data salient to his theories. He was quite aware that his severely neurotic patients were not a random sample of the human race, and that he could not base a general theory of personality entirely on them. Neither, however, could he reasonably expect mentally healthy individuals to volunteer the most intimate information about their psychological functioning as part of a research study. Therefore Freud turned to other sources of data that were readily available: first, himself, and second, works of art.

His self-analysis was, according to his friend and biographer Ernest Jones, "one of the two great deeds of Freud's scientific life." (The other great deed was the development of the free association method.) The German researcher Hermann Ebbinghaus had already discovered several basic laws of learning and memory by studying himself as he learned and forgot emotionally neutral stimuli. Now Freud proposed to examine, as objectively as possible, his own memories of such highly unneutral topics as his love and hate toward his parents and siblings, his most repulsive desires, and his most shameful behavior, all the way back into early childhood. When Freud found the same kinds of emotional conflicts and irrational urges in himself that he had discovered in his most neurotic patients, he came to feel that his hypotheses about personality were essentially correct and broadly applicable.

Freud was aware, of course, that even adding himself to his sample of late-19th century Viennese patients did not provide sufficient basis for generalizing his conclusions to all humankind. But Freud also read and studied a wide range of the world's creative writers, from the ancient Greeks and Romans (especially Homer, Sophocles, and Virgil), through more recent masters (including Shakespeare and E. T. A. Hoffmann), to such contemporaries as Mark Twain, Fyodor Dostoyevsky, Rider Haggard, and Arthur Schnitzler. Their work teemed with detailed depictions of psychologically complex characters, who exhibited much the same motives and behavior as Freud kept finding in his patients and himself. He saw such literary creations as valuable confirmation by other brilliant thinkers of his own hypotheses. When even mediocre writers offered characters who described their dreams and fantasies in detail, as in the German novelist Wilhelm Jensen's popular romance *Gradiva*, Freud took such works as additional instances of unconscious motives expressed in conscious behavior, both by the fictional characters and by the writer.

A core concept in Freud's early psychoanalytic theories is named after a literary work: the *Oedipus complex*. Freud's reference here is to Sophocles' play *Oedipus the King*, written 2300 years earlier. The play depicts what modern audiences typically perceive on first viewing as a strange set of events: a Greek king, warned by an oracle that his newborn son will

eventually kill him, takes the baby into the countryside and leaves him to die. The infant Oedipus is saved by a shepherd and is then raised by adoptive parents. As a young adult, Oedipus finds himself in circumstances where, unaware of the family relationships involved, he kills his father the king and takes his mother the queen as his wife. Upon discovering that he has committed patricide and incest, Oedipus blinds himself in shame over his terrible acts.

Why, Freud asked, does this ancient play from an unfamiliar culture remain so disturbing to us? Because, as Freud answered his own question, Sophocles captured in the play's characters and symbolism a set of feelings that most of us experience in childhood but have driven deep into our unconscious: a desire to monopolize the body and the attention of our opposite-sexed parent, and to eliminate our chief competitor, the same-sexed parent. Freud saw a similar emotional pattern in the most powerful work of the greatest English-language writer, Shakespeare's *Hamlet*. From early in his psychoanalytic practice, Freud had been aware of the power of sexual motivation, as well as of his patients' struggles to keep it under control. They often tried to avoid thinking about sex altogether, though without complete success. The repression of distressing childhood sexual experiences was so consistently a problem among his patients that Freud formulated what he called the "seduction hypothesis": the idea that severe neurosis always originates from a child's "seduction" or sexual initiation by an older sibling or adult. In repressing such memories of early sexual abuse, the child removes important aspects of his or her sexuality from conscious access, with various unfortunate impacts on later adult behavior and psychological functioning.

After several years of psychoanalytically rescuing these early memories of sexual abuse from repression, Freud began to doubt their literal truth in a number of cases. They were just too frequent, he felt, and in certain instances they appeared to be contradicted by other kinds of biographical evidence. Freud therefore gave up his initial seduction hypothesis in large part (though he never abandoned it completely, as some critics have charged). He turned instead to his newly formulated concept of the Oedipus complex. Freud now argued that the child naturally comes to focus sexual and aggressive feelings on the most convenient and emotionally charged objects, his parents. He proposed that the four- or five-year-old child typically fantasizes about sexual or sensual contact with the opposite-sexed parent, and that the child as adult later recalls such fantasies as real events (under pressure from the eager psychoanalyst). Freud was thus the first person to recognize that some retrospective reports of abuse are actually signs of what is now called a "false memory syndrome," just as he had been the first person to pay serious attention to the long-term psychological effects of childhood sexual abuse. He has also been the only person to be criticized from both sides of the current controversy over such matters—that is, to be criticized both for treating his patients' reports of childhood sexual abuse as sometimes false, and for treating them as sometimes true.

During the course of considering the role of sexual motivation in personality development, Freud came up with another concept that remains important in discussions of creativity: the process of sublimation. Sublimation was not an entirely original concept with Freud, but he made it his own, and he

considerably elaborated earlier and more casual uses of the term. According to Freud's initial conceptualization, sexual urges that are not permitted direct expression will go in one of two directions: they may be converted into anxiety and other neurotic symptoms, or they can be expressed in creative work and other culture-building acts. The process of redirecting sexual energy (as well as, to some degree, aggressive energy) into creative acts was what Freud called sublimation. It can never completely satisfy an individual's sexual desires, according to Freud; only actual sexual intercourse can do that. But he viewed sublimation as certainly a better way to gain indirect sexual satisfaction than through neurotic symptoms, and at the same time he regarded sublimation as the chief source of human cultural accomplishments.

Freud had personal reasons to consider the effects of incompletely expressed sexual urges at this time. He and his wife had quickly established a family; Martha gave birth to six children during the first eight years of their marriage. Sigmund and Martha Freud had attempted by various means to prevent the conception of the later children—especially the sixth, the daughter they named Anna—but every birth control method they tried had failed. Finally, after Anna's birth, husband and wife simply stopped having sexual relations. Sigmund was 39 at the time and Martha was 34. During the first several years after their sexual relationship ceased, Freud experienced an explosion of creative ideas. It is probably no accident that one of these ideas was his concept of sublimation as the creative transformation of unexpended sexual energy. (Certain of Freud's critics, beginning with C. G. Jung, have accused him of conducting an affair with his sister-in-law during this period, and have argued that the supposed affair may have influenced his ideas about sexual motivation and other matters. The evidence for such a relationship is highly speculative at best, and there are much clearer sources for Freud's principal theoretical concepts.)

Psychoanalysis: The Middle Years

For Sigmund Freud, psychoanalytic theory was not a static body of ideas but a constantly growing and changing structure. Freud first conceptualized the personality as composed principally of consciousness, of a deep unconscious that contains our basic urges and repressed memories, and of a preconscious that includes temporarily forgotten or ignored memories. As his theories developed, Freud began to differentiate aspects of the psychological structure more clearly: the id, a completely unconscious mass of primitive biological urges which insists on immediate sensual gratification; the ego, largely conscious but with unconscious components, mediating between the id and external reality; and the superego, the internalized representative of the parents' (and through them, of society's) moral standards. In this middle-phase formulation by Freud, the id controls most of the personality's psychological energy; the relatively weak ego struggles constantly to delay or redirect the id's demands, through repression and other psychological defenses; and the superego tries with limited means to block the id's more outrageous demands completely.

As his theories changed, Freud's therapeutic treatment objectives shifted as well. Where he had sought mainly to encourage the patient to express previously hidden memories and desires,

he now began to analyze the patient's transference of early emotional patterns onto Freud himself. Freud had at first experienced such transferences as an annoyance and an embarrassment, since they often took the form of female patients falling in love with him and even throwing themselves at him physically. In time he came to recognize that he was serving these patients as a target of displacement for feelings originally aroused by parents and other figures from early childhood. (Freud's male patients redirected their emotional patterns toward him too, but they more often did so by making him the object of unreasonable hostility.) By bringing to a patient's attention the transference patterns expressed toward the therapist, and by working with the patient to develop an understanding of the patterns' origins and their current inappropriateness, Freud felt he was able to gain much more extensive and lasting therapeutic success than through his previous efforts.

It took him a while longer to recognize that in addition to each patient's transference of emotions onto him, Freud was engaging in a constant process of countertransference of his own long-established emotional patterns onto the patient. This recognition enabled Freud to overcome previously unacknowledged or uncontrolled difficulties in the therapeutic interaction. Finally in this sequence of new recognitions, Freud came to realize that transference and countertransference are not limited to the interaction of therapist and patient, but extend through all human social interactions beyond those of child and parent. With this recognition, Freud finally achieved what he regarded as a general psychology of human personality. For several years before and after his 50th birthday, Freud felt that he had become creatively exhausted and was experiencing a decline into old age. During this time he revised his ideas about sublimation to say that only students were able to make effective use of unexpended sexual energy, and then only to fuel their studies; sublimation was of no use to creative artists or theorists. Then Freud experienced a brief resurgence of his own sexual urges, and at the same time he began to write his longest treatment of creativity, his psychobiography of Leonardo da Vinci. [See DA VINCI, LEONARDO.]

According to Freud, Leonardo as a child lived with his single mother, felt sexually aroused by her before he could deal effectively with such feelings, and at the same time strongly identified with her. In attempting to manage such complex emotions, Leonardo as an adult became a celibate homosexual, expressing his sexual desires both for his mother and for young boys mainly through his painting. Eventually his super-ego forced him to steer away from even the indirect artistic expression of these morally and socially unacceptable urges. Leonardo shifted his attention to focus for a while on his scientific research, a less obviously sexual use of his psychological energy. Then, at about the same age that Freud had reached at the time of writing, Leonardo experienced a rearousal of his repressed desires for his mother, stimulated by the woman now known as Mona Lisa. Leonardo thereby regained his artistic creativity in midlife, and maintained that creativity into old age. Freud too experienced new creative urges at this time in his own life, and over the next three decades he formulated further important revisions in psychoanalytic theory.

In addition to a degree of sexual renewal, Freud experienced another kind of psychological stimulus in midlife: the acquisition of a band of disciples, who endorsed Freud's ideas and

who practiced therapy under his tutelage. The most important of these followers was Carl Gustav Jung, a Swiss psychiatrist who was Freud's closest friend and colleague from 1907 to 1912. Jung influenced Freud to give more weight, for a time, to ideas about inherited symbolic configurations and behavioral tendencies, which Jung called arche types. But after 1912, Jung went off to advocate a distinctive version of psychoanalytic theory and therapy, in which creative activities were seen largely as variations on those inherited archetypes. Freud then reemphasized his own previous concepts of creative patterns as emerging out of the crucible of the individual's early family life.

Psychoanalysis: The Later Years

Though Freud continued to worry about the effects of age and illness on his own creativity, the years from his late fifties into his seventies were among his most productive. In terms of broad theoretical tendencies, he placed increasing emphasis on the power of the ego to control the unruly id, and on the psychological importance of the person's interactions with other individuals—emphases that were amplified and modified by later psychoanalytic theorists, who called themselves ego psychologists or object-relations theorists. In terms of his thinking about creativity, Freud moved from: (a) early concepts about artistic works principally as symbolic expressions of unconscious motives and conflicts, to (b) artistic works as also involving the artist's conscious manipulation of the audience's aesthetic responses, in order to lead the audience into close contact with potentially disturbing latent content, to (c) the artist as using his or her art to confront and creatively resolve the artist's own psychological problems. Freud discussed both Leonardo and Michelangelo as examples of the latter process, which has been referred to by later theorists as a restitutive or restorative use of art by the artist.

Freud's essay on Michelangelo's statue of Moses, in which Freud appears to identify strongly with Moses as a man who has reached an inner peace after the backsliding of his followers, was written on the eve of World War I. The war brought great physical deprivation to Freud and his family, as well as anxiety about his sons who were fighting in the war and distress over the deaths of relatives, friends, and ex-patients. Freud had already begun to elaborate his concepts of the id's basic drives, which he had originally conceptualized as including both self-preservative drives and species-preservative (sexual) drives. Now he perceived a new division, between the life instincts (self- and species-preservative drives together) and the death instincts (including self-destructive and other-destructive urges). The horrors of the war solidified the position of this new drive schema in Freud's theoretical system. In his first postwar book, *Beyond the Pleasure Principle*, Freud proposed that a more basic urge than the desire for pleasure is the "compulsion to repeat" earlier states of being, even unpleasant ones—a compulsion that ultimately drives us to restore our original state of being, which is zero stimulation or nothingness. This theoretical postulate (or, as Freud described it, this "speculation") led Freud to his grimmest pronouncement: "The aim of all life is death." But in spite of his assumption that the death instincts will triumph within all of us in the end, he maintained the companion assumption that the life

instincts will continue to struggle against the death instincts for as long as possible, and can give us considerable pleasure along the way. In the 1920s, Freud achieved worldwide fame as the greatest psychological theorist of all time—much to the dismay of Jung and other theoretical dissidents. Freud's ideas had increasing impact on novelists, poets, painters, sculptors, and filmmakers, who incorporated Freudian dream symbolism or free-associational content into their work. As W. H. Auden put it in a famous poem, Freud was "no more a person / now but a whole climate of opinion / under whom we conduct our different lives."

But Freud's fame did not prevent the Nazis from targeting him as a Jew, or from burning his books. Freud narrowly escaped from Austria as the Nazis solidified their hold there in 1938. He and his daughter Anna moved to London, where Freud continued to write during the final year of his life—working especially to complete a speculative work that he first titled, *The Man Moses: A Historical Novel*. Translated into English as *Moses and Monotheism*, this book was not really a novel, but a creative consideration of the origins of the Jewish people. Had Moses really been born as a Hebrew slave and raised as Egyptian royalty (as the Bible says), or had he been born and raised as a member of the Egyptian royal family, who then adopted (and was adopted by) the Hebrews as their spiritual and political leader? In proposing the latter answer to his own question, Freud developed a preliminary theory of charismatic leadership that has been elaborated by Saul Friedländer and others.

Freud died of cancer in 1939, in the midst of work on a final *Outline of Psychoanalysis*. After his death, his major ideas and certain minor ones have retained their power to stimulate the thinking of many other theorists and psychological

practitioners—and to provoke what Freud called "continued resistance" to these ideas. (Others would call it criticism or hostility.) Though few psychologists and psychiatrists now wholeheartedly accept Freud's specific versions of theory and therapy, most current personality theories and psychotherapies incorporate his broad positions at some level. His influence is most strongly visible in two areas: first, in the academic practice of critical and cultural theory, plus psychobiography and psychohistory, and second, in our society's most widespread conceptions of personality, which include many "pop psychology" versions of unconscious conflict, the retention of the "inner child," psychological defenses such as denial and reaction formation, and the variously named contrasts between male (rule-oriented) and female (relationship-oriented) personality patterns. Every few years—sometimes every few months or even weeks—a new book or magazine article announces that Freud is dead and that his ideas are in total disarray. But such repeated insistence on his death suggests that Freud is still a very lively ghost, continuing to haunt our most anxiously and aggressively defended ideas of our own basic nature.

Glossary

Collaboration To work with another or others on an intellectual or creative endeavor, focused on a product or performance.

Conflict Mental struggles based on opposing or incompatible internal needs, desires, or feelings as well as on external forces, such as competition or power.

Domain A body of organized knowledge, skills, and traits underlying a discipline, requiring specific preparation to reach high levels.

Eminence A position of high rank or prominence socially bestowed by the field of endeavor.

Follower One in the service of another; a fan, devotee, or enthusiast.

Friendship A voluntary caring relationship between two or more persons who are not kin that is emotionally based, nonrational, and promotes mutual support, feelings of interconnectedness, and self-esteem.

Peers Belonging to the same group in society, typically by age, status, or culture.

Power Possession, control, or influence over others.

Validation The process of confirming, supporting, and accepting the value of another's work or being.

The role of friendship in the lives of creative individuals has had very little systematic research attention. In fact, friendship is a neglected research topic throughout the social and behavioral sciences, according to philosophers Sandra Lynch and James Grunebaum, and it has been overlooked in research on collaboration as well. Although most biographies of eminent individuals discuss friends and relationships, little attention has been given to the role of friendship in creative lives.

Defining Friendship

Definitions of friendship vary, depending on whether we are talking about business relationships, childhood buddies, or best friends, each with a set of norms and demands. Early definitions from the ancient Greeks idealized friendship as a virtue and viewed it as only possible between good men. More current views recognize its complexity. Jan Barkas described friendship as a relationship that is voluntary and caring between two or more persons who have no kinship or legal bonds that reinforces self-esteem and a feeling of being needed or liked. Robert Wubbolding viewed friendship as based on the deepest human need for belonging, interconnectedness, and the satisfaction of power. According to James Grunebaum, friendship is based on caring, with willingness to assist or benefit the other. One treats one's friends well, helps and does not harm them. Friendship involves responsibility to receive personal confidences and thoughts, the promise to do one's duty and not defraud or wound. In friendship, there is concern for each other, the sharing of passionate interests, and giving to each other wholeheartedly based on affection and fondness.

Sandra Lynch stated that friendships involve a mutual and reciprocal emotional bond that is at its core nonrational. It involves not just feelings, but knowledge of each other's character, affairs, and personality. On the other hand, she noted that friendship is not necessarily free of self interest. The experience of pleasure, personal gain, or support may motivate such engagement. At the same time, friends are vulnerable to

disappointments, pain, or hurt in their relationships, so trust is important. There are both rewards and challenges in these voluntary relationships.

Professor and creativity scholar, Alfonso Montouri, described his own close friendship, which allows open-ended conversations, exploration of ideas, concepts, feelings, fears, and joys in a spirit of mutual respect, caring, and affection. He noted that through walks and talks with this friend, intuitions and ideas, self-expression, and points of difference and agreement are aspects of their bond that lead to a union of knowledge and are vitally important for creative thought. Yet, he lamented, both organizational and academic cultures in their bureaucratic and often adversarial approaches, mitigate against such exchanges, relegating friendships to the private sphere. He suggested that the safety of exploring not-knowing with an intimate friend, or a discourse as a collective improvisation based on trust, caring, and excitement at being together is a valuable opportunity. For Montouri, as people develop trust and take risks together, are vulnerable and open and admit uncertainties, the quality of knowledge and inquiry is greatly improved and creative capacities supported.

Collaboration and Friendship

Although there are numerous biographies of eminent persons that describe the importance of individual friendships and detail exchanges of letters and ideas, there has been little in the creativity literature that focuses specifically on this important aspect. Jock Abra and Gordon Abra noted that even collaboration among creative individuals has been rarely studied, which they considered strange, given that almost every creative act involves working with others. A book on the topic by Vera John-Steiner, published a year later, addressed the importance of collaboration in creative work and viewed creativity as a social phenomenon, rather than an individualistic one, wherein the collaborative relationship scaffolds the construction of new ideas and also strengthens the creator's sense

of self, providing support in overcoming self doubt and vulnerability.

Abra and Abra specified that most creators communicate with an audience of some kind, implying a kind of collaboration. They also suggested that collaborative relationships may be intimate (such as Watson and Crick) or remote (an orchestra that does not meet the composer). They may be homogeneous (same service, i.e., musicians in an orchestra) or heterogeneous (different, such as the composer, conductor and orchestra members). Collaboration may also be horizontal (democratic, with equal weight, as in Gilbert and Sullivan's productions) or hierarchical, with differences in power and dominance, such as Jerome Robbins' final say in choreography and direction.

However, collaboration is more a required or necessary relationship, such as that between a choreographer and a dancer, or among a group of scientists working on a problem, while a friendship has no formal requirements but results in caring and reciprocal bonding. While collaboration may grow into friendship or vice versa, the two are not synonymous.

Role of Peers

Jean Piaget considered the period of early childhood as the most creative as the child invents the world, trying it out before assimilating through symbolic play and imagination. Likewise, Russian psychologist Lev Vygotsky described the origins of creative imagination and later creativity in the early play of childhood. Play with peers allows the making of errors without sanctions, the stretching of imagination, the trying on of roles. Although some researchers find creative children crave solitude, they also describe the desire and emotional satisfaction that comes from being with others and having friends in order to 'try on different hats.'

Psychologist Howard Gardner, in his study of highly creative lives representing each of the Multiple Intelligences, delineated the crucial aspect of informed peers, who play a supportive and caring role as an essential element in the creative process through their beliefs in the revolutionary ideas of the creators. At the same time, the seven eminent individuals he studied had problems forming deep emotional attachments or close friendships. Friends, spouses, or lovers were important, but more for their contributions to the needs and purposes of the creator, rather than for their inherent value. These creators benefited from supportive relationships during periods of major work toward breakthrough, but caring others were less important once the breakthrough occurred and were sometimes discarded. This implies that the friend or significant other's personhood was less central than his or her supporting role. However, "what has been overlooked is a discussion of supportive persons themselves as creative forces in their own right with the 'object' of creation being the development of others for the greater good: *engendering*", according to Erin Miller and LeoNora Cohen, creativity researchers.

Although more typical among peers, friendships can also be cross-generational, especially those that develop between mentors and their protégées. The relationships can blossom into friendships if values and interest are shared, as noted by Vera John-Steiner.

Domain Basis for Friendships

Often, friendships of creative individuals come from the same or related domain of endeavor. "People become friends because they are passionately and emotionally involved in the same pursuits. They have common ground and become friends because of their common interests," according to creativity scholar, Jane Piirto. Although adult creators often describe great loneliness in childhood, they may develop strong peer friendships in late adolescence, particularly if they are able to learn or work together in their domain, which may sustain them throughout life.

Friendships among creative children are important for development of self-esteem and for intimacy, particularly as students become teenagers. To share passions with like minds is important for well-being, as well as for generation of ideas, testing novel ideas, and growing cognitively and creatively. However, such friendships may be fraught with problems. Creative young people have the need to be valued and to share their interests with others. At the same time, there is a need to have time and space alone to focus on their own work. There is also the competition for the same scholarships or awards, for accomplishment, and the need to be 'the best,' especially among young performers. Such conflicts may lead creative young people to eschew one aspect for the other. How to find a balance that is both personally satisfying and allows for the freedom to create is a challenge.

A Look at One Domain: Music and Friendship

Some fields, such as music, are more conducive to collaboration and possible friendships. Alfonso Montouri and Ronald Purser noted:

Music is an emergent property of other relationships in a group. The organic nature of musical groups can ideally create a situation where the collaboration is enormously enriching, and the music emerges out of the constant interplay of musicians rehearsing, performing, and recording.

At the same time, as noted earlier, there may be a tremendous level of competition, especially among aspiring young musicians where only the best succeed. While the friendships incubated in the conservatory evolve from passion for their craft and field, there is both the need to beat out the competition and the simultaneous need to share the joy of music, according to Judith Kogan and Lauren Sosniack, scholars of music development.

In western music, particularly orchestral, there is a natural tripartite: the composer, the conductor, and the soloists or orchestra. Musical creativity is complex, occurring within a given timeframe and place, involving all three roles, wherein the music is cocreated. This suggests that the relationships among these three types of musicians would necessarily be collaborative, while those relationships among specific instrumentalists (such as violinists) might be more conflicted. Although conductors and soloists certainly play works of dead composers, the dependence of the living composer on the conductor and soloists to get heard is central.

In a study of the friendship between two Brazilian composers, Heitor Villa-Lobos and Walter Burtel Marx, LeoNora Cohen found that the relationship started badly, with perceptions of each other on the one hand as unschooled and wild and on the other as an upper crust snoot overly concerned with form. However, Marx, sent to Europe at age 18 to study piano, composition, and conducting with the musical masters there, grew to love the deeply Brazilian works of Villa-Lobos and began to emulate them, also championing Villa-Lobos' works through conducting them in Rio and across the United States. Villa-Lobos grew to value Marx, dedicating two works to him. Trust to critique each others' compositions evolved, but it was a lopsided friendship, with Marx, younger and less eminent, deferring to Villa-Lobos.

Benefits and Problems in Friendships of Creators

Friends benefit creators not only in sharing new ideas and stretching cognitive growth, but also in validating and sustaining them on a personal level, helping them to overcome self-doubt, a characteristic that creative personality researcher Frank Barron found characterizes creative individuals, expressed as concern about personal adequacy and motivation to prove oneself. Friendship can provide emotional strengthening and a sense of confidence, enhancing the creator's self-esteem. Difficulties also arise, including conflicts and power issues.

Validation

Safety and social validation of creative products are a major function of friends and work place collaborators. They provide creative individuals a safe space where they can break rules without sanctions, as well as offering them a positive perspective on themselves; for instance, that their ideas are not crazy but creative. Friends and colleagues can help foster the courage to test limits, according to psychologist and creativity researcher Arthur Cropley.

David Harrington, known for his work on the ecology of creativity, discussed the role of advocates such as parents, friends, or mentors who champion creative individuals and provide them with help or needed resources. He noted that explicit encouragement is almost always helpful, stating:

Creatively effective people have often described a positive impact which words of encouragement in understanding from credible sources have had upon the creative work, particularly at times of unusual creative challenge and stress.

He observed the importance of feedback that encourages revision without embarrassment or feelings of inadequacy.

Conflicts

But there are also conflicts in friendships and close relationships for creative people, particularly when the friend is not supportive of a creative idea, the creator feels judged or rejected, or power issues arise, such as who gets credit for the new product or idea. Although, as Robert Sternberg and

colleagues noted, "creativity requires a risk-taking personality", the taking of risks by putting a new idea 'out there' can be daunting, especially if not supported by friends, colleagues, or contemporaries.

Although collaboration may lessen the fear of ridicule for innovative work, organizational creativity researcher Teresa Amabile found that when one believes one's work will be judged or evaluated by others, creativity suffers. For example, Howard Gruber, in discussing the risk Darwin felt in expressing new ideas, noted, "Darwin had a real need to ingratiate himself with others to avoid sharp personal controversy, to feel that he'd made the effort to avoid conflict." According to Gruber, although the essence of his understanding of the theory of evolution was complete in his 1837–38 notebooks, it took some 20 years to publish, in part because Darwin was aware of the intellectual and religious forces arrayed against him.

Teresa Amabile also described how peer pressure is an inhibitor of risk taking, which discourages the presentation of new or different ideas. Among school children, John Dacey and Kathleen Lennon found that classmates may negatively impact creativity. They discuss the fourth grade slump described by Paul Torrance, suggesting pressure to conform to peers as a reason.

Twila Tardif and Robert Sternberg noted that in addition to the conflict between criticism and confidence, there is also a conflict or paradox between social withdrawal and social integration tendencies. For creators, there is often both a lack of fit to their environments and the need to maintain distance from peers, avoid interpersonal contact, and resist societal demands. Psychologist Gregory Feist stated that creative people often have the "desire and preference to be somewhat removed from regular social contact" and to focus on their craft. "A unique trait of creative people is their disposition to be autonomous and independent of the influence of the group." They may be introverted and prefer solitude.

Yet there is a drive for accomplishment and recognition, a need to form alliances, a desire for attention, praise, and support, and there may also be an emotional expressiveness, charisma, honesty, and courageousness. These dualities may be temporal aspects, according to Jock Abra and Gordon Abra, who stated that creators have time periods when there is greater need for relationship and feelings of intimacy, and other times for aloneness, although there is considerable individual variation.

Fear of intimacy or rejection can also make for focus on creative work rather than relationships. Gail Lewis reported conflicting studies about peer relationships, speculating that tension develops from the contradictory needs for solitude, working alone, and self discovery and at the same time, for recognition, affirmation, and social support.

Power Differences: Stars, Followers, and Friendship

Stars, whether musicians, scientists, sports heroes, politicians, or eminent creators attract followers, fans, and sometimes sycophants. Highly creative individuals are sought after by such individuals who believe in the greatness of that creator, or may seek favor, affection or even self-aggrandizement, but who often contribute to the creator's success. The follower wants to be a friend of the eminent or potentially eminent

creator and enthusiastically supports the star's growth, sometimes as benefactor, at other times, affirming the creator's ideas. The creator may identify the follower as a friend, but the relationship is often grounded in an imbalance of power, wherein the eminent person gets needs satisfied but does not always give back.

This may be a pattern in friendships among highly creative individuals, the more eminent in the dyad being dominant, wherein the friend is more a support than a beloved person to the dominant creator. In the case of Villa-Lobos, almost all of his friends were musicians or critics who championed Villa-Lobos's career and aspirations. More rarely they were equals, such as the famous pianist, Arthur Rubenstein, who was inspired by Villa-Lobos's music and played it often.

Future Research on Friendship and Creativity

Systematic study of friendships in creative lives is needed. Studies of friendships within particular domains, such as those among mathematicians, or across domains, such as a scientist and a painter, would be valuable, perhaps using cross-case methodology through studies of biographies or among living creators. Friendships that fail but stimulate creative output through criticism, such as that between Van Gogh and Gauguin, as well as friendships that are consistently supportive should be pursued. Friendships that are more equal between the creator and another and those that are less so need to be analyzed. What are the benefits to the friend of the creator, is there satisfaction in supporting creative growth, and is engendering of others' potential a type of creativity are questions to consider. How a friendship can grow out of collaboration or vice-versa needs study. It is not just the work-related collaboration or the intimate connections with spouses or lovers, but the emotionally satisfying,

mutually supportive, power-related, and irrational aspects of friendships that need to be better understood in creative lives.

Mahatma Gandhi

Introduction

Revered in India as 'Mahatma' or 'the great soul,' an epithet conferred upon him by the Nobel Laureate Rabindranath Tagore, Mahatma Gandhi, is internationally famous as the initiator and leading exponent of 'militant nonviolence' against British imperialism in India. Considered one of the 'most ingenious spiritual militants,' he was the product of a critical juncture in the history of the twentieth century (and, arguably, in the history of civilization itself), providing new dimensions to the meaning of concepts such as 'truth,' 'nonviolence,' 'protest,' 'celibacy,' 'struggle,' 'morality,' 'welfare,' 'untouchability' even 'vegetarianism,' 'cooperative farming,' and 'industrialization.' Gandhi was an incessant and tireless reformer through words and, above all, action.

Inherently a dreamer, thinker, and visionary, Gandhi mapped the outlines of a 'free India' by drawing on the rural traditions of its epically rich past to produce the concept of a 'Swaraj.' This 'scrawny little man' developed certain concepts that seem apparently simple yet revolutionary, in a language that itself marked a creative breakthrough of a totally different nature. A source of dissent, as Ashis Nandy noted, he upheld principles in public life. His thoughts (sometimes known as Gandhism) have been influential in one way or another for activists all over the world including some of the great names of our time: Martin Luther King Jr., James Lawson, Steve Biko, Nelson Mandela, Lech Walesa, Khan Abdul Gaffar Khan, The Dalai Lama, Petra Kelly, Benito Aquino, Albert Luthuli, and Aung San Suu Kyi. In the brutally violent world of the 'war on terror,' Gandhi appears more germane than ever. Long ago he asked us to "Imagine the whole nation vivisected and torn to pieces; how could it be made into a nation?" Despite the skepticism of some, who have labeled him as a 'totalitarian' politician of a specialized order or as 'the shrewd Bania' (merchant), Gandhi remains 'a practical idealist' whose creativity goes beyond his own political career (and the Indian context) to have universal significance.

The essential greatness of Mohandas (alias Mahatma) Karamchand Gandhi (known affectionately to Indians as *Bapu* meaning 'Father' in Gujarati), lies in the fact that he did not merely devise principles, he embodied them. Emphasizing that God appears not in person but in action, he claimed: "Action is my domain, it's not what I say but what I do that matters." Becoming a high-stakes performer, "he integrated within himself his life's message of sanity, spirituality, and the eradication of poverty," and in the process "emerging as a personality, a point of hope for the human future in a strife torn world."

Gandhi's life as he described it fell into four main periods, each with its characteristic lessons and experiments with Truth. During the first, from his birth in 1869 to the end of his Indian schooling in 1888, he learned the Hindu Dharma, or way of life, discovering something of its strength and weakness. Next he trained for the English bar in London from 1888 to 1891, where he discovered principles of national greatness, democracy, and of Christianity. Then came the 20 years of struggle in South Africa, from 1894 to 1914, during which he is working out his three fundamental principles of *Satyagraha*, and *Ahimsa*. The last period were from 1914 to 1948, when he was the acknowledged leader of India, and applied his three

principles in working for *Swaraj* and Swadeshi goods, through the boycott of British goods and institutions.

Childhood and Youth

Mohandas Karamchand Gandhi “was born of propitious parents, at the appropriate place, and at the inevitable time” on 2 October 1869, to a Vaisya (merchant) family of Modh Bania subcaste. The respectable traits attributed to the ‘Banias,’ as Erik Erikson described, are enterprise, caution, realism, compromise, and shrewdness. His father was ‘diwan’ (Prime Minister) to the raja of three small city-states annexed to a minor princely state in the Kathiawar Agency of British India. Mohandas perhaps inherited the qualities of truthfulness and leadership potentials from his family. Gandhi’s mother Putlibai, Karamchand’s fourth wife, was an intense believer and he was raised by his deeply religious mother with whom he had a strong emotional attachment. He was also raised in a mixed ‘bhakti’ tradition, and Islamic and Jain ambience. He assimilated quite early many of the influences that would play an important role in his future. Gandhi’s father, apparently indifferent to his son (in accord with the societal norms of his class), was, deep within, fondly affectionate to him, as testified by Gandhi himself in his *Autobiography*. Though biographers generally portray the young Gandhi as a shy, awkward, and, indeed, unimpressive boy who detested sports, other contradictory evidence is also available that attests to his childhood and adolescent mischief – stealing gold, playing truant, and engaging in clandestine practices such as eating meat, visiting a brothel once – all these acts being conscious attempts on his part to reconfigure his character in accord with the perceived ideals of British masculinity, as much as overriding adolescent inclinations and curiosities. Gandhi inevitably confessed all his misdeeds to his father in writing and clearly felt enormous shame and guilt. However, as Raja Rao noted “the father returned the boy’s courage with awesome understanding. . . . This was indeed the beginning of his experiences with truth.” This behavior, is typical of colonial ‘double-think,’ was an inconsistency Gandhi tried to resolve throughout his life.

Education and the Intimate European Contacts

Academically, Gandhi was an average student. His college days were far from pleasant (he dropped out once during the first term and reenrolled in the second). Since his childhood ambition to become a ‘doctor’ was considered ‘unlawful’ for his caste, his father persuaded him to study law instead. We can speculate that he compensated throughout his life by attempting to ‘cure’ humanity metaphorically from every possible ‘disease.’ In May 1883, the 13-year-old Mohandas was married to his 14-year-old neighbor Kasturbai Makhanji in a strict custom-bound child marriage.

On 4 September 1888, Gandhi set out for London, England, to study law and complete his apprenticeship as a barrister at University College, London. Before the voyage, however, he had to swear to his mother, that he would remain faithful to his religious upbringing and abstain from taking meat, alcohol, and sex. However, in England, he dressed in the style of a Victorian dandy, took up dancing and briefly

experimented in creative arts. He adopted ‘English’ customs – learning Latin and the violin and taking a short trip to Paris.

He finally abandoned these customs, and found solace, and a public platform, in vegetarianism. Gandhi believed that a vegetarian diet would satisfy the requirements of the body and serve an economic purpose by being cost-effective: he thus regarded it not only as a spiritual practice but also as a practical one. He wrote *The Moral Basis of Vegetarianism* as well as several papers. In his *Autobiography*, Gandhi noted that vegetarianism was the beginning of his oath to *Brahmacarya chastity or celibacy or sexual abstinence*: to achieve *Brahmacarya*, one should first learn to overpower gastronomic desires. Strangely, at times he indulged in faddish dietetic experiments that sometimes came near to killing him.

Some members of the Vegetarian Society were also members of the Theosophical Society. This Society established in 1875, was dedicated to the study of Buddhist, Christian, and Hindu scriptures. They encouraged Gandhi to join them in reading the *Bhagavad Gita*, both in translation as well as in the original; it is here he first read Edwin Arnold’s translation of the *Bhagavad Gita* that left a permanent impression upon him. Above all, from reading Tolstoy and Ruskin, with their commitment to pacifism and an ethical life, Gandhi began to formulate his own critique of the materialist West. At the same time, he found a way to come to terms with his own heritage. Repudiating the association of ‘feminine’ qualities with weakness, he began to construct a ‘new courage’ in which nonviolence, and passive resistance, were transformed into strength. He would be strong, he proclaimed, as a woman was strong. In fact, he advocated if nonviolence is the law of our being the future is with woman.

As a young law student in England, he looked into the teachings of Christianity: “The Sermon on the Mount, which went straight to my heart. I compared it with the Gita. The verses ‘But I say unto you that you resent not evil, but whosoever shall smite thee on the right cheek, turn to him the other also’ . . . delighted me beyond measure. . . . My young mind tried to unify the teachings of the Gita, the Light of Asia, and the Sermon on the Mount. That renunciation was the highest form of religion appealed to me greatly.”

Gandhi returned to India in 1891 as a Barrister of the Inner Temple only to learn that his mother had died while he was in London, his family concealing the truth from him. An anguished Gandhi received solace from his spiritual teacher Raychandbhai, a highly successful pearl dealer who nevertheless managed to remain completely detached from his activities. Gandhi learned from him the basic lesson that life itself is equivalent to pure meditation: there is no abstract entity such as the inner being – the body and the mind operate in terms of one’s *Karma*, comparable to *Bhagavad Gita*’s – ‘activity in inactivity and inactivity in activity.’ The childhood values embedded in *bhakti* (*devotion*) merged with the doctrine of *Karma* (*selfless deeds*) following the dicta of the *Bhagavad Gita*. The process of the amalgamation of *Bhakti* and *Karma* that began in England reached its culmination at this point.

In the Wilds of Africa

Gandhi remained jobless for a brief spell after his return: he desired to practice law in Mumbai but couldn’t find work.

He applied for a part-time job as a high-school teacher but was rejected there too. Finally, in April 1893 Gandhi accepted an agreement from an Indian firm, to represent them legally in Pretoria, the capital of the Transvaal in the Colony of Natal, Union of South Africa, then a part of the British Empire.

Immediately after his arrival in South Africa, Gandhi was forcibly ejected from a train at Pietermaritzburg after refusing to move from a first-class to a third-class coach. Although he possessed a valid first-class ticket, he was not allowed to travel first class for racial reasons. This brutal incident of racial discrimination intensely affected him and possibly motivated him later to publish and edit a newspaper *Indian Opinion* which reflected the viewpoints of Indians in South Africa. In an indignant letter to the *Natal Advertiser*, he asked: "Is this Christian-like, is this fair play, is this justice, is this civilization? I pause for a reply." In 1894, Gandhi established the Natal Indian Congress and, through this organization, forged the Indian community of South Africa into a coherent sociopolitical force. Raja Rao wrote:

But here in the wilds of Africa . . . (remember it was the time of Kruger and Rhodes, of Smuts and Churchill) Gandhi was only a coolie, a coolie barrister. He was not even a Christian. . . . Thrown out of his compartment, Gandhi sat in a dingy cold room in a vast world of hills and spaces, with no one to turn to. Then he turned into himself, and that was, he says, the most creative experience in his life. (Rao, 2005: 66–67)

However, he again extensively read *Bhagavad Gita*, as well as works by Ralph Waldo Emerson and Henry David Thoreau (in particular, his essay on *Civil Disobedience*). He was also considerably enlightened by his correspondence with Leo Tolstoy and by John Ruskin's *Unto This Last*. As a result of this program of reading, his personal philosophy went through a radical transformation. After reading Ruskin he decided to build a commune called the *Phoenix Settlement*. He also created a cooperative commonwealth for civil resisters on an 1100-acre plot, 20 miles from Johannesburg: the Tolstoy Farm. In addition, he translated Ruskin's work into Gujarati as a draft proposal for his future economic strategies. Gandhi began observing one day each week (generally Monday) as his *day of silence*, when he refused to speak, as he believed that silence leads to inner peace. He drew this idea from the Hindu religious principles of *mauna* (silence) and *shanti* (peace). On that particular day he would communicate with others by writing on paper. From 1906, for three and a half years, Gandhi also refrained from reading newspapers since they did in no way help find creative solutions to his inner conflicts: he felt that the turbulent state of affairs worldwide caused him more chaos than his own inner strife.

In addition, Gandhi began to perform communal prayers for the economically impoverished marginal castes, fasted for self-purification, and dedicated himself to live a life of voluntary poverty. Known for austerity and the eccentricities of his personality, around 1905 he abandoned Western dress and life styles completely (an indirect result of reading John Ruskin's work) and took to the dress he is identified with in history – the loincloth *dhoti*, shawl, and sandals. This earned him the infamous Churchill label of *half-naked fakir, stirring up sedition*. However, Churchill was also conscious of Gandhi's strength – he said Gandhi certainly knew how to fight.

A notoriously paradoxical eccentric, "the flesh-and-blood Gandhi was a most unlikely saint. This was one of the century's great revolutionaries whose strange figure swayed millions with his hypnotic spell. His garb was the perfect uniform for the kind of revolutionary he was, wielding weapons of prayer and nonviolence more powerful than guns." Ultimately, in 1906, he adopted *Brahmacarya the oath of celibacy* as both a means of natural birth control and an approach to divine purity.

At the same time, he was involved in a number of struggles against the British authorities and thus was able to examine the practical value of his principle of nonviolent protest. Influenced by Henry David Thoreau's idea of civil disobedience, it was in Johannesburg that Gandhi first adopted his evolving weapon of *Satyagraha* at a mass protest, on 11 September, 1906. Gandhi wrote: "*Satyagraha is not predominantly civil disobedience, but a quiet and irresistible pursuit of truth.*" It is the practical expression of a higher reality: a moral code and a self-discipline that requires the control of the senses, especially the control of sexuality; the control of anger and violence; and a dedication to the cause of justice and truth. His *Satyagraha* was designed not only for India, but also for the whole world; it could transform relations between individuals as well as between communities and nations.

In 1907 Gandhi petitioned all Indians in South Africa asking them to contravene a law that demanded their registration and fingerprint impressions. Gandhi was imprisoned for some time, handcuffed with a book of Tolstoy between his hands. He was released when he made the rulers agree to voluntary registration. Gandhi's techniques met with further success when the South African government promised to eradicate racial discrimination against Indians; a law was enforced which legalized Indian marriages and the abolition of tax from a certain section of the Indian working-class laborers. This was the blueprint of the 'Gandhian' method of struggle. Gandhi returned to India, in January 1915. Smuts, South African prime minister and one of Gandhi's staunchest enemies and admiring friends, made an exasperated comment on Gandhi's departure. "The saint has left our shores," he said, "I sincerely hope forever."

Back Home to India

The principles that had been applied in expediency for the first time in South Africa were strengthened and sharpened after Gandhi's return to India, where he remained for the rest of his life. On returning to India, Gandhi immediately undertook the mission of laying down the foundations of a new India. As B. R. Nanda noted:

With the genesis of the Gandhian movement for the freedom of India which was based on *Satyagraha* or the holding on to truth, came not just India's independence but also emerged a personality, a point of hope for the human future in a strife torn world. (Nanda, 2002: 54)

Gandhi's first major achievements came in 1918 with the Champaran agitation and *Kheda Satyagraha*. To combat the fraught situation in Kheda in Gujarat, Gandhi established a hermitage, mobilizing his old hands and supporters and bringing in brand new volunteers from the region. He made a

detailed study and survey of the villages, recording the various atrocities and appalling episodes of suffering. Relying on the confident support of the villagers, he began leading the cleaning of the villages, the building of schools and hospitals, while encouraging the village leadership to condemn the various social evils. However, his major impact was felt when he was arrested by police on the charge of instigating unrest and was ordered to leave the province. Several thousand people protested and rallied outside the jail, police stations, and courts demanding his release, which the court reluctantly granted.

In 1919, Gandhi persuaded the Congress Party to launch a Non-Cooperation Movement that snowballed into a countrywide agitation that received widespread participation from all levels of Indian society. During the next five years Gandhi devoted himself to constructive social programs aimed to uplift the subjugated and to build Muslim–Hindu unity. One of his main modus operandi was the *fast*. He undertook a 21-day fast to bring the two communities together and a further fast in support of a strike by mill workers in Ahmedabad. The weapon of the *protest march*, however, gained a much higher prominence than the fast – politically, morally, and historically.

He launched the Civil Disobedience Movement (1930–1933) which began with the famous Dandi March and the Salt *Satyagraha*. The latter was directed against the Salt Law which made it against the law for an Indian to make salt. Gandhi's protest culminated in the famous Salt March to Dandi from 12 March to 6 April 1930. Gandhi marched 400 km from Ahmedabad to Dandi, Gujarat to make salt himself. Thousands of Indians joined him on this march to the sea. This campaign was one of the most successful against British India. The action along with other protests resulted in thousands of arrests, including that of Gandhi himself.

The government, represented by Lord Edward Irwin, decided to negotiate with Gandhi. The Gandhi–Irwin Pact was signed in March 1931. The British Government agreed to free all political prisoners in return for the suspension of the Civil Disobedience Movement. As a result of the pact, Gandhi was also invited to attend the Round Table Conference induced in London as the sole representative of the Indian National Congress. The conference was a disappointment for Gandhi and the nationalists, as it focused on the Indian princes and Indian minorities rather than the transfer of power. The failure of the Round Table Conference induced Gandhi to undertake another fast resulting in the Poona Pact in 1932 by which untouchable leaders renounced separate representation and instead remained within the Hindu fold.

In 1934, Gandhi moved to his ashram in Wardha (his foremost home and hermitage being Sabarmati Ashram in Ahmedabad) and concentrated on the 'constructive program' until 1940 when he briefly resumed leadership of the Congress at a time when India had been at War. In the late 1930s, when the forces of war were gathering momentum in Europe, he reaffirmed his faith in nonviolence. He asserted: "I have nothing new to teach the world. Truth and nonviolence are as old as the hills." Through pages of his weekly paper, *Harijan*, he expounded his approach to political tyranny and military aggression. He advised weaker nations to defend themselves by offering nonviolent resistance to the aggressor. During the early 1940s, he expressed strong antifascist feelings and

condemned Hitler for the genocide of the Jews and for "propounding a new religion of exclusive and militant nationalism in the name of which any inhumanity becomes an act of humanity." "If there ever could be a justifiable war in the name of and for humanity," he wrote, "a war against Germany, to prevent the wanton persecution of a whole race, would be completely justified."

This declaration to support the war effort was provided on the condition that the Congress would receive a firm guarantee of independence. The rejection of such a promise by the colonial government led the Congress to launch a Quit India Movement in 1942. This national movement was ruthlessly suppressed, and Gandhi was kept in detention at the Aga Khan Palace until 1944.

When Gandhi emerged from prison, he sought to forestall the creation of a separate Muslim state of Pakistan that Muhammad Ali Jinnah was demanding. The whole politics of partition and its violent consequence aggrieved Gandhi deeply. He wanted Hindus and Muslims to learn to live together or he would die in the attempt. Gandhi's last major act as a national political leader was to fast for peace amidst the growing sectarian conflict between Hindus and Muslims.

Gandhi's Celibacy and Androgyny

Gandhi's experiments in *Brahmacarya* raised vehement opposition even from his dedicated followers. But he was convinced that sex diffuses human energy, which should be conserved and sublimated. He believed that woman's role in sex was entirely submissive and self-sacrificing, and he assumed that women derived no pleasure from such activity.

When he was 16, Gandhi tending to his father nearing death, engaged in sex:

This shame of my carnal desire even at the critical hour of my father's death ... is a blot I have never been able to efface or forget, and I have always thought that although my devotion to my parents knew no bounds ... yet it was weighed and found unpardonably wanting because my mind was at the same moment in the grip of lust. I have therefore regarded myself as a lustful, though a faithful husband. It took me long to get free from the shackles of lust, and I had to pass through many ordeals before I could overcome it. (Gandhi, 1927: 16)

In comparison to the 'masculinity' of the leaders of the West, Gandhi's image was perceived as 'androgynous.' Androgyny is one of the personality traits of eminent creative people. His 'bisexually-toned passivity' meant that he was unable to overcome his colonial identity. Gandhi's maternal attributes were evident in his assertion that men need to learn to care more the way women do if the human condition is to be improved. Erikson noted: "He undoubtedly saw a kind of sublimated maternalism as part of the positive identity of a whole man, and certainly of a *homo religiosus*." Gandhi's main virtue in his later life was care: an interest in producing life and maintaining it.

Gandhi's Creative Vision

Gandhi wrote *Hind Swaraj* or Indian Home Rule (1938), a booklet which has been dubbed 'the Bible of nonviolent

revolution.’ Yet, it is also an extremely difficult book to stomach, with its uncompromising attacks on the British parliament, on machinery, on railways, doctors, lawyers, and English educated elites. *Hind Swaraj* seems to be a last-ditch stand in favor of a premodern, traditional civilizational ethos, which exalts manual labor, self-restraint, and the pursuit of virtue and sacrifice, instead of pleasure and profit.

This embodied a sharp criticism of Western materialistic preoccupations and the encouragement of fierce competition to fulfill those needs. The *man versus machine controversy*, identifying industrialization with materialism, was what troubled Gandhi most. For him machinery “the chief symbol of modern civilization” represented “a great sin.” The alternative vision he cherished, for the ideal economic independence of the villages, was where the individual, not economic productivity, would be the prime concern. For him, economics and self-reliance were essential to lead a winning campaign. Instead of the ‘aberrant’ mechanized modern civilization of the West, he promoted the ideal of simplicity and innocence rooted in the ancient or traditional village where every member selflessly cares for others.

Gandhi’s goal of *Village – Swaraj* consists of various indispensable stages: his striving to establish the Kingdom of God (*Ram Rajya*, expressed vocally by a musical chanting – *Ramdhun*) through his nonviolent application of Hinduism, following the dictates of the *Bhagavad Gita*, the spiritual backbone of the religion. After its successful deployment against the British, Gandhi’s idea of *Satyagraha* reached a phase of command, insisting that self (*atman*) and truth (*Satya* or God, who is the supreme being *sat*) are identical, and that this unity or oneness ought to lead to harmony and nonviolence (*ahimsa*) and passive resistance against opponents. Most importantly, *Satyagraha* became the ideal way to resolve conflicts, which usually summon an ideological disagreement between two opponents: beneath every struggle lies another clash, a deeper one, an altercation between two views that are each, to some extent, true. Every conflict, to Gandhi, was on some level a battle between differing angles of vision illuminating the same truth. When his wife lay dying, and he was in jail, this is what Gandhi wrote to her: “If you die even that death of yours will be a sacrifice to the cause of *Satyagraha*. My struggle is not merely political. It is religious and therefore pure. It does not matter much whether one dies in it or lives. I hope and expect you will also think likewise and not be unhappy.”

Concept of Truth

Gandhi’s concept of ‘truth’ is multidimensional and often puzzling to comprehend. The essential meaning of truth for Gandhi was loyalty or reliability, and its context, its *Sitz im Leben*, was that of an ideal traditional Indian village where truth is inseparable from community bonds.

Satyagraha, hence, would be the most advanced weapon to fight injustice because it knowingly avoids the drawbacks in other methods and seeks a new position instead, one which is more inclusive than the old ones, and moves into it. The latter, in turn, would result in the welfare of all (*Sarvodaya*) which is the practical expression of a higher reality: a moral code and a self-restraint that requires the control of the senses, especially

the control of sexuality, anger and violence; and a dedication to the cause of justice and truth. *Sarvodaya* – or welfare for all – included the emancipation of the Untouchables, whom Gandhi called Harijans – the ‘children of God/Lord Krishna.’ The plight of the Untouchables could, in Gandhi’s vision, only be alleviated by nonviolence and by holding fast to the truth. To eradicate the plight of the untouchables, he made himself an Untouchable, and he faced ridicule in order to transform his country’s abysmal sanitary conditions. “The bathroom is a temple,” he said, and anyone was welcome to chat with him there. If we closely examine his life, we notice not just how radically Gandhi modified and reformed the Hinduism that he had inherited, but also how deeply he renewed and burnished it. Gandhi’s *Hinduism* signifies a religion of strong ethical commitment to social justice and truth that he identified with God, displaying little interest in ritual or Hindu mythology except as they have bearing on ethical issues he was concerned about. There is little concern for the aesthetic and sensual aspects of Hindu culture – Gandhi has never been referred to as a puritan – but it is the Renaissance Hinduism, of which Gandhi is a part, which has found articulate expression in the modern world. His program was fundamentally focused on a free, united India; and it began with the revival of the spinning wheel, cottage industries, and the production of hand-spun fabrics (*khadi* or *khaddar*).

In 1931, while discoursing with Charlie Chaplin, Gandhi declared that he was not necessarily antitechnology but his priorities were different. His emphasis was on indigenous tradition, naturopathy, artisan and craft-based productions, using low energy and decentralized production system. His *swadeshi* movement had social, cultural, and technological dimensions as well as political objectives. To some extent, this can be seen as a precursor of modern ecological movements. However, his social movement for *swadeshi* did not create a new intellectual breakthrough; it did not direct individual creativity into opening up new areas of research and development.

The Creative Master

The theoretical bases of Gandhi’s vision and most creative actions were that no racial or ethnic group is intrinsically superior to any other, that conflicts need to be settled through nonviolence, and that compromise can strengthen both parties. Reflecting on Gandhi’s political innovation, Gardner noted:

Gandhi is a prototypically creative master ... in his chosen domain (the moral domain) ... he shared fundamental insights that were both simple and revolutionary; no racial or ethnic group is inherently superior to any other, conflicts need not be settled with violence, compromise can strength both parties. Perhaps most revealingly, the experiences surrounding the strikes and fast at Ahmedabad have familiar ring of core components of a creative breakthrough ... the tentative working out of a new language. (Gardner, 2001: 121)

Gandhi was the creator of a radical style of politics that proved effective in fighting against various forms of social division within India and elsewhere in the world. Historians and social scientists, as well as contemporary commentators, have tended to concentrate on Gandhi’s philosophy of life.

However, according to them, his philosophy of life had only a limited impact on the people. It was as a political leader that he was important: through his political strategy and his tactics of struggle he moved millions into political action.

Theorists have emphasized the 'dramatic' or 'performance-oriented' element of Gandhi's political persona through his verbal or linguistic expertise as a kind of comic combination of *folksy* and *canonical* forms of Hinduism. They also noted the *hypocritical blend* of effective protest and the *minimum gesture of protest* in the political style of Gandhi. A veteran Indian leader noticed in Gandhi an even more characteristic trait: "He has in him the marvelous spiritual power to turn ordinary men around him into heroes and martyrs." This was possible primarily through his books and speeches. An example is one of the talismans he gave to the masses:

Whenever you are in doubt, or when the self becomes too much with you, apply the following test. Recall the face of the poorest and the weakest man [woman] whom you may have seen, and ask yourself, if the step you contemplate is going to be of any use to him [her]. Will he [she] gain anything by it? Will it restore him [her] to a control over his [her] own life and destiny? In other words, will it lead to *swaraj* [freedom] for the hungry and spiritually starving millions? Then you will find your doubts and your self melt away. (Nayyar, 1958: 65)

This is so clearly described in his favorite devotional song, 'Vaishnav Jan . . .' (the true man of the Lord is the one who can empathize with the pain of another).

Gandhi's ideas were formulated in terms of a larger vision of an alternative society, one that emphasized mutual respect, resistance to exploitation, nonviolence, and ecological harmony. Politics was only one of the many fields in which Gandhi sought to activate this peculiarly personal vision. Its practice involved experiments in relation to various opponents. From representatives of the British imperialism to Indian advocates of violent resistance; from fundamentalist religious leaders to spokesmen for caste concessions, Gandhi confronted immovable groups and their ingrained ideologies with a deceptively simple ethic of verbal resistance. He even rejected completely and sharply the colonial educational practices that negated truth and nonviolence and put forward a radical alternative called 'basic education' which some classified in the tradition of Western radical humanists like Pestalozzi, Owen, Tolstoy, and Dewey.

Gandhi was a self-described anarchist, and his vision of India meant India without an underlying government. He once said that "the ideally nonviolent state would be an ordered anarchy." While political systems are largely hierarchical, with each layer of authority from the individual to the central government having increasing levels of authority over the layer below, Gandhi believed that society should be the exact opposite, where nothing is done without the consent of anyone, down to the individual. His idea was that true self-rule in a country means that every person rules his or herself and that there is no state that enforces laws upon the people. This would be achieved over time through nonviolent conflict mediation, as power is divested from the layers of hierarchical authorities, ultimately to the individual. This would come to embody the ethic of nonviolence.

A free India for him meant the existence of thousands of self-sufficient small communities (an idea possibly from

Tolstoy) who rule themselves without hindering others. It did not mean merely transferring an established administrative structure derived from the British into Indian hands. This, he said, was just making *Hindustan* into *Englistan*. He was conscious of the limitations of the existing political organizations that he refused to join, reasons explained in his own words:

At my time of life and with views firmly formed on several matters, I could only join an organization to affect its policy and not to be affected by it. This does not mean that I would not now have an open mind to receive new light. I simply wish to emphasize the fact that the new light will have to be specially dazzling in order to entrance me. (Ghose, 1991: 108)

Gandhi in Action: Rise to the Mahatmaship

Gandhi, as Barbara D Metcalf and Thomas R Metcalf noted in 2002, sought a moral, not simply a political transformation of human society. He could not accept the view, common in many nationalist movements, that the end – of freedom – justified whatever means might be necessary to bring it about. He believed that politics in our times yielded *yugadharma* or codes of conduct appropriate for our times. His search for self-realization, as Nandy noted, therefore led him not to mysticism, but to social and political activism. . . . When Gandhi thus defined politics, he had in his mind not so much conventional politics, but the politics of awareness – that liminal world where you create through civil disobedience a space for critical self-awareness, while venturing outer-directed social criticism. You test your categories of knowledge when trying to dismantle the categories of others.

His advocacy of nonviolence was so powerful that at the close of his autobiography he wrote: "In bidding farewell to the reader, I ask him to join with me in prayer to the God of Truth that He may grant me the boon of *Ahimsa* in thought, word and deed."

Similarly, the transformative love that Gandhi held out as the basis of a new India must encompass not only all Indians, from the wealthy zamindar to the despised untouchable, but the British as well. No one, whether Muslim, Hindu, or Christian, was inherently unworthy. If Smuts sent Gandhi to prison, Smuts became a life-long friend. Gandhi was ever a loyal subject. "I implicitly believed," he wrote later, "that the sum total of the activities of the British Empire was good for India, and for humanity."

Gandhi was cited several times in Lord Robert's dispatches. The Queen sent him a medal. His principles in action are reflected practically in all his achievements. Though he "adopted the ascetic mode as the pattern for a great nationalist revival," it was not his philosophy of life that had any major impact on the life of the people but his political strategy and tactics of struggle based on moral principles that moved millions into political action. Gandhi was shocked at the use of the atom bomb by the United States against Japan; he described it "as the most diabolical use of science." Interestingly, Einstein indicated the parallel evolution of the nuclear bomb and Gandhi's nonviolent technique of Satyagraha respectively, almost from decade to decade since the beginning of the twentieth century.

Gandhi and Tagore: Aristocracy of the Sensitive

The two leading Indian thinkers of the twentieth century were Rabindranath Tagore and Mahatma Gandhi. Interestingly, Tagore had anticipated and welcomed the emergence of a figure like Gandhi and when Gandhi entered Indian public life, few gave him such unstinted sanction. However, they had many disagreements on a variety of subjects, including nationalism, patriotism, the importance of cultural exchange, the role of rationality and of science, and the nature of economic and social development. "Tagore did recognize that Gandhi did not have to be the best Gandhian on all issues." Despite differences, Tagore bequeathed his visionary rural university at Shantiniketan to Gandhi. In his moving tribute to this "morally inquiring and unafraid man," Tagore noted:

He stopped at the threshold of the huts of the thousands of the dispossessed, dressed like one of their own. He spoke to them in their own language; here was a living truth at last, and not quotations from the books. For this reason the 'Mahatma', the name given to him by the people of India, is his real name. . . . At Gandhi's call India blossomed forth to new greatness, just as once before in earlier times, when Buddha proclaimed the truth of fellow-feeling and compassion among all living creatures. (Nandy, 2001: 223–224)

Tagore knew that he could not have given India the political leadership that Gandhi provided, and he was never parsimonious in his praise for what Gandhi did for the nation and yet each remained deeply critical of many things that the other stood for. That Gandhi has received incomparably more attention outside India and also within much of India itself makes it important to understand 'Tagore's side' of the Gandhi–Tagore debates. When Tagore breathed his last, Jawaharlal Nehru wrote in his prison diary on 7 August 1941: "It is not so much because of any single virtue but because of the *tout ensemble*, that I felt that among the world's great men today Gandhi and Tagore were supreme as human beings."

Four Gandhis

People can be intimidated and overwhelmed not only by the enormity of Gandhi's accomplishments but also by the complexity, inconsistencies, and eccentricities of his personality and philosophy. He will continue to be analyzed, admired, and deconstructed by people from diverse disciplines. No surprise that according to Nandy there are four Gandhis who have survived Mohandas Karamchand Gandhi's death. It is because of the resilience, force, and potency of Gandhi's ideas, which have the capacity to adapt themselves to unusual circumstances and times, that he is classified as a postmodern thinker and he remains as media-savvy after his death as he was during his life. Both Richard Attenborough's Oscar-winning epic *Gandhi*, and Rajkumar Hirani's *Lage Raho Munna Bhai*, unforgettable motion pictures, celebrate a hero who combined intense spiritual ardor and flawless command of showmanship. One might recall Einstein's comment:

The moral influence which he has exercised upon thinking people through the civilized world may be far more durable than would appear likely in the present age, with its exaggeration

of brute force. For the work of statesmen is permanent only in so far as they arouse and consolidate the moral forces of their peoples through their personal example and educating influence. We are fortunate and should be grateful that fate has bestowed upon us so luminous a contemporary—a beacon to the generation to come. (Einstein, 2007: 71)

Arnold Toynbee predicted:

It can already be forecast with some confidence that Gandhi's effect on human history is going to be greater and more lasting than either Stalin or Hitler's. (Toynbee, 1961: 617)

"Gandhi may have had brilliant or scatterbrained ideas," wrote Howard Gardner, "but in the end it was his capacity to appear credible to his followers, and to the rest of the world, by virtue of his example at specific historical moments, that constituted the central aspects of his creation. . . . In Clifford Geertz's famous phrase. 'It's a form of very 'deep play'.' Further, in search of truth, as Raja Rao noted, Gandhi was ever the pilgrim, which made him surrender himself to truth, to nonviolence, to celibacy, to control of the appetite, to poverty. In fact, he mentioned in his autobiography that "[I]t is not my purpose to attempt a real autobiography. I simply want to tell the story of my numerous experiments with truth, and as my life consists of nothing but those experiments, it is true that the story will take the shape of an autobiography . . .," he adds in the introduction. And hence the title *My Experiments with Truth*. However, he further noted that ". . . [the experiments] will of course include experiments with nonviolence, celibacy, and other principles of conduct believed to be distinct from truth." He dedicated his life to reading religious scriptures, to humility, to honesty, to fearlessness against oppression and against conflict between Hindu and Muslims.

In Gandhi's psyche, political and religious aims, means, and ends became identical. As a "pilgrim on his quest for Truth, quiet, peaceful, determined, and fearless" and as a political leader who, "demonstrated that a powerful human following can be assembled not only through the cunning game of the usual political maneuvers and trickeries but through the cogent example of a morally superior conduct of life," Gandhi compounded "ancient Hindu religion and culture and modern revolutionary ideas about politics and society."

Reviewing his autobiography, Kenneth Saunders noted "Never before in history have these principles of India's ancient Rishis been applied in the sphere of politics, or the Sermon on the Mount been made to work on an imperial scale." Romain Rolland saw him as not merely a revolutionary, but also as a builder of a new humanity. In 1926, Gandhi wrote:

If we are to make progress, we must not repeat history but make new history. We must add to the inheritance left by our ancestors. If we may make new discoveries and inventions in the phenomenal world, must we declare our bankruptcy in the spiritual domain? Is it possible to multiply the exceptions so as to make them the rule? Must man always be brute first and man after, if at all? (Nanda, 2002: 54)

His words, like his visual symbolism, were mesmerizing, his symbolic actions swayed hundreds of millions in India. Through his fasts, protest walks, and acts of passive resistance he also eventually won over the imperialists. Given how

he regarded himself — “My life is my message” – Gandhi invites us to be read in terms of a consistency in his *anubhav*, *vichar*, and *achar*. He was neither God nor ‘Christ reincarnated’: with all his political astuteness, there were also the paradoxes and contradictions, the complexities, incredible contrasts, the inherent moral ambiguities, the tragic and sublimely comic aspects of his existence. Some even talk of a ‘Billion Gandhis.’

It is important to note that Gandhism, as Ashis Nandy pointed out, is greater than Gandhi was. Gandhi himself more or less admitted so, when he gave the entire credit for his ideas to ancient wisdom. In his introduction to autobiography, Gandhi wrote: Tradition declares, he only could be liberated, established in the Truth, who has met his Guru. “I believe in the Hindu theory of the Guru . . . True knowledge is impossible without the Guru.” Gandhi never met his Guru but he had immense ancient wisdom to guide him.

The partition plan that created Pakistan and Kashmir was approved by the Congress leadership as the only way to prevent a wide-scale Hindu–Muslim civil war. A devastated Gandhi gave his consent. After partition in August 1947, Gandhi returned to Delhi to help restore harmony among Hindus and Muslims. In the process, Gandhi’s activities aroused much hostility among Hindu extremists: his moral and physical resistance appeared to the fundamentalists as a pro-Muslim stance. This culminated in Mahatma’s assassination on 30 January 1948, approximately six months after India achieved freedom. He was going for a prayer-meeting, by the 35-year-old editor of a Hindu extremist weekly, who admired Gandhi but thought of him no politician. On his death Raja Rao reflects: “He died as he would have wanted, the last gesture of Gandhi was blessing his own assassin.” When Gandhi died, Smuts his old adversary said: “A Prince among men is dead.” And Einstein remarked: “It is hard to believe such a one has walked the earth in our time.”

Glossary

'Big C' creativity Creative performances or products of a grand scale, which are socially judged to merit recognition and approval.

Creative performance The actual transformation of creative abilities into a measurable achievement or product.

Creative potential The likelihood of an individual to produce creative acts, thoughts, or products.

Criterion problem The difficulty of identifying an appropriate criterion to be measured when attempting to assess creative ability.

Divergent thinking One's ability or capacity for original thought when presented with a stimulus or initial idea.

'Little c' creativity Creative performances and products which are developed to address everyday problems or tasks and do not typically receive social recognition.

Nature or nurture The classic question of whether biological factors or environmental factors play more of a role in shaping an individual.

Psychological androgyny A personality trait describing individuals who possess equal levels of traditionally masculine and feminine psychological characteristics.

Psychometrics The scientific measurement of personality, abilities, aptitudes, attitudes and knowledge.

Introduction

Throughout human history, and continuing even to the present day, gender roles and expectations have continuously defined much of what individuals are expected and able to accomplish. Cultures and societies have often pushed males to excel, create, and take risks, while encouraging females to maintain a focus on the family and fulfill more domestic obligations. These rigid expectations have historically influenced every facet of cultural life, typically funneling resources and support to young men while adding barriers and obstacles in the paths of career-minded young women. As a result, females with great potential were often kept from the education and materials necessary to nurture their abilities, resulting in wide gaps between the visible accomplishments of men and women in terms of both popular history and creative endeavors. In recent decades, progress toward equality between the sexes has made great strides around the globe, and a substantial amount of academic research has been conducted regarding the root causes and ultimate effects of the persisting differences. Significant work has been conducted specifically in the creativity field as well, exploring the questions of whether males and females differ creatively and why this may or may not be the case.

Much of the research concerning gender and creativity has revolved around two intriguing questions worthy of such scrutiny: how gender impacts creative potential and creative performance, and why a gap between the two should even exist. Creative potential, typically measured in this case through tests of divergent thinking ability, attempts to quantify an individual's likelihood to produce creative acts, thoughts, or products. Creative performance, on the other hand, refers to the actual manifestation of those abilities, measuring the quality and significance of the resultant creative achievement. Understanding this distinction is of great importance to comprehending the body of research concerning gender differences in creativity, as demonstrating creative potential does not

necessarily imply that meaningful creative performance will result. For any number of reasons, countless individuals have shown creative promise yet failed to develop their skills, and for many women through history a specific lack of support, education, and resources likely deprived their potential of nurturance. In spite of this however, some eminent women did manage to achieve great creative accomplishments, yet the number of females historically recognized for such talents has been small when compared the long lists of famous male scientists, artists, and thinkers.

One additional reason for this historical disparity stems from what is known in creativity research as the criterion problem – the difficulty of identifying what exactly should constitute and define a creative act. While nearly everyone can agree that painting the Mona Lisa was a creative act, it becomes more difficult to reach consensus when we consider that not every creative act need appear monumental or grandiose. If it was creative for da Vinci to paint, is it creative for a child to do the same with his fingers? If the famous chefs of Paris are being creative when they combine exotic ingredients to prepare new and exciting gourmet banquets, is it creative for a hurried mother to rush home and quickly prepare her children dinner from what has been sitting in the refrigerator? In each of these examples, the complexity of selecting and evaluating creative criteria becomes evident, and historically this difficulty has greatly affected the recognition of women's creative contributions. Modern creativity theorists often distinguish between what is known as 'Big C' creativity (socially lauded creative acts, such as the Mona Lisa or invention of the light bulb) from 'little c' creativity (creative acts to address everyday challenges, such as quickly preparing a nutritious dinner), but all too often the public retains an outdated notion that creativity need be spectacular. This common mistake can cause one to overlook the creative contributions of females through history, in that a person may stretch the observation that most historically eminent creators have been men to a faulty assumption that only men are capable of such work.

Having introduced the historical creative inequalities between the genders and explained the foundational concepts central to the debate, we now turn to an exploration of modern research concerning the topic. This article will first examine the question of what creative differences do and do not exist between the sexes, through examining both data concerning creative performance and creative potential. In recent decades almost 100 published studies have searched for differences in potential between males and females, with almost all of them testing schoolchildren, and the mounting data have steadily built to a number of generally agreed upon findings. The article will then attempt to explain any differences between the sexes' creativity through detailing both relevant biological and socio-cultural theories. Included in this portion will be discussions on biological factors such as prenatal hormone exposure and the effects of psychological androgyny on creative performance, in addition to socio-cultural theories regarding historical resource allocation and complexities regarding the evaluation of creativity. Finally, a brief examination of the interplay among gender, creativity, and personality traits will follow, as personality is shaped both by biology and society and plays a crucial role in many creative arenas and endeavors.

Do Differences Exist?

The topic of differences between the sexes can be difficult to discuss, due to its controversial nature and tendency to stir the passions. On one hand, differences between males and females has been painfully obvious on a historical and cultural level, with centuries of overrepresentation of males in nearly every creative field, from the sciences to the arts. On the other hand however, little credence can be given to traditional interpretations that this disparity was the result of mere biological factors alone, as creative women were so often denied the social support and resource level necessary to transform potential to reality. Modern creativity researchers have instead attempted to approach the gender gap from a psychometric perspective, administering tests of divergent thinking in the hopes of finding, or not finding, a significant difference between the creative abilities of males and females that could explain the historical divergence. We now turn to a more in-depth discussion of gender differences in creative performance and creative potential, outlining what such researchers have come to learn.

Creative Performance

Historically, pronounced differences have certainly existed between the sexes in terms of creative accomplishment and achievement, even if the past 100 years saw a great leap forward in terms of gender equality and fairness of opportunity. For many centuries men were overrepresented in nearly all creative endeavors and fields, and in almost all cultures and geographic regions. Not only did this inequality exist at the basic levels of creative production and involvement, such as the question of who was provided with training, time, or opportunities to engage in creative activities, but the historical trend is even more undeniable when one considers groupings of historically eminent figures through time. Male composers, painters, sculptors, musicians, scientists, and philosophers all

earned celebration and fame at a much higher degree than their female counterparts, who were often few and far between. Even more so, those creative women who were able to break through social expectations and generate opportunities to hone their creative craft usually met with fierce resistance, if not from their families then from their compatriots in the field. Consider for example that many famous and highly creative women even went to great lengths to obscure their identities as females, such as the acclaimed writer 'George Sand,' who adopted a masculine pseudonym and quickly gained widespread renown for 'his' literary ability.

Fortunately, the past century has done much to correct these cultural double standards and advocate a higher degree of gender equality throughout much of the world. That is not to say, however, that legacies of creative difference between the sexes no longer exist. Recent research into male/female participation rates throughout the creative domains has consistently found lasting patterns of gender specific overrepresentation by field, even though these trends do in some cases seem to be slowly lessening in severity. Males, for instance, are still found in significantly greater numbers throughout the fields of scientific publishing, engineering, mathematics, mechanics, musical composition, and painting. Females, however, have come to numerically dominate in certain other creative endeavors, including those of literature, musical performance, dance, and the dramatic arts. While decades of increased support and access to creative fields has helped to mitigate the gender gap and propel greater numbers of females to develop their creative potential, it is important to note that stark differences still do remain at the highest levels of eminence. Male scientists continue to publish scholarly work at a rate over double that of their female counterparts, and earn tenured professorships at a much higher rate as a result. Female artists now garner social support, fame, and recognition at levels previously unseen in western history, yet males continue to be overrepresented as art critics – a powerful fact that some have surmised continues to work against creative females' potential for success.

Additionally, momentum for equality-minded change has not spread evenly among the globe, and creative women in various cultures continue to receive distinctly uneven levels of support and nurturance. As a result, even greater levels of disparity continue to exist between creative women and men internationally, with several studies having shown that the gender gap widens and constricts according to a culture's level of gender equality and modernization. Compounding this effect are the impacts of regional economics and social class structures, as poorer regions and those with more traditional and rigid social class hierarchies also display heightened differences between males' and females' levels of participation and degrees of success across the spectrum of creative endeavors. Regardless of which nation one examines however, at least some gender gap may be easily observed in creative performance and accomplishment, even if the overall trend is one of gradual improvements toward equality.

Creative Potential

While examinations of creative performance between the genders are forced to deal with a lasting legacy of stark differences, modern creativity researchers have been free to investigate

creative potentials from a more empirical and data driven perspective. Academic interest in the topic has ebbed and flowed over the past five decades, but a large number of studies have in fact been conducted to quantify and compare the creative potential of males and females, in the hopes of explaining the real-world effects previously discussed. Almost 100 published studies have collected comparative data on the genders, and when taken together they provide adequate evidence to support some basic conclusions. It is important to note, however, that the vast majority of these studies have utilized only assessments of divergent thinking capability as their indicator of creative potential, in contrast to other forms of creativity assessment instruments that might quantify or measure differing aspects of the creative process. Over 80% of the published studies chose to adopt such an assessment measure, and while evaluating divergent thinking capability has long been regarded as an important and reasonable method of creativity assessment, future researchers investigating this topic may wish to adopt an alternate approach. Additionally, a second caveat worth mentioning pertains to the fact that almost all of these studies have utilized samples of school-age children, with very few actually searching for differences among a sample of adult men and women. Considering that creativity requires nurturance to develop and bloom, this lack of a temporal dimension may be concerning to some, and the potential for gender differences to change or develop over time certainly stands as an area in need of much further research. Finally, it is also crucial to understand that while divergent thinking tests have been shown to be reasonably reliable predictors of creative production, divergent thinking is not in itself creativity *per se*. These tests are thus valuable indicators of creative potential and creative individuals have been shown to score higher on such tests than less creative individuals, but we cannot claim that an individual subject who scores highly on these tests is necessarily more creative as a matter of fact. In other words, divergent thinking assessments provide valuable information, but this information is only one piece of the creativity puzzle.

Of the approximately 100 published studies regarding gender differences in creative potential, roughly one half found there to be no observable gender effect. The remaining studies were typically mixed, with studies finding small degrees of advantage by female test-takers actually outnumbering those finding an advantage for the males by a 2-1 margin. Most of these differences were not statistically significant however, and a growing consensus thus argues for the position that a reliably measurable gender difference in creative potential does not appear to exist. This conclusion is of great academic importance for a number of reasons, first and foremost in that it raises serious questions as to the root causes behind the gender gap in creative performance. Historical explanations for differences between the sexes in terms of socially recognized creative accomplishment were often centered on biological explanations alone, a position that now seems more tenuous in light of the recent data. More likely, a combination of biological and socio-cultural factors, or socio-cultural factors primarily, is responsible for perpetuating the gender gap. These potential explanations will be more thoroughly discussed in the following portion, including both the biological and socio-cultural theories. Additionally, the gendered disparity between creative

potential and creative performance also hints at meaningful revelations concerning the environment creativity requires to blossom. If both genders truly begin with an even skill set yet arrive at predictably distinct results, much information may be inferred as to how creativity in an individual of any gender may best be nurtured and encouraged. Finally, while very few studies have searched for a difference in creative potential between working-age men and women, it is heartening to see that consistent conclusions can be drawn from both studies involving young children and studies involving adolescents. This stability of results throughout the early years of the lifespan acts to support the overall findings, even if the literature would surely benefit from more dedicated research involving the adult population.

Explaining the Differences

Research on gender differences in creative process and production has seemingly brought to light a major conundrum: If no significant difference between males and females can be found in terms of creative potential, how can the historical and modern creative performance gap between men and women best be explained? This question, like so many others in the social sciences, has attracted theories from both biological and socio-cultural viewpoints. In these offered explanations, the age-old question of 'nature or nurture' constantly presents itself, asking whether genetics and natural gendered physiology and psychology differences are more responsible for the gap or whether males' and females' destinies are more meaningfully shaped by their environment and cultural influences. Theorists from both camps have presented rational arguments and chains of evidence, advocating for their positions and rebutting alternate views. Ultimately, it is likely that both biological and socio-cultural factors may play a substantial role.

This section of the article will attempt to present some of the major arguments, both biological and socio-cultural, that have been advanced to explain the cause of the creative performance gender gap. It will begin by examining the major biological arguments, before exploring the major socio-cultural theories. In recent years biological arguments have somewhat slipped in favor and support, partly for evidence-based reasons and partly for political rationales as well, yet they remain worthy of serious consideration and contemplation. It should be understood however that with fewer researchers being interested in the biological perspective, as compared to the social viewpoint, more of the biological position remains theoretical in nature and still requires a greater degree of future empirical research. The socio-cultural positions, in contrast, have seen a greater number of relevant research studies conducted and thus have more data-driven evidence to support their claims. Raising this distinction is not meant to cast one side in a more favorable light, but rather to make clear that a great deal of potential research still remains ripe in this field.

Biological Arguments

Biological theories regarding gendered differences in creative performance have tended to cluster along four main groupings:

Family-focus arguments, field-difference arguments, hormone-based arguments, and inquiries into the effects of psychological androgyny. The first of these refers to a collection of traditionalist viewpoints that women are inherently more focused on family life and/or interpersonal relationships than men may be, possibly as a result of evolutionary processes. As a result, the argument continues, greater proclivity to a domestic focus would complicate (but certainly not preclude) creative achievement. These claims have been almost entirely theoretical in nature, with no empirical foundations, yet point to anecdotes that females may be more apt in interpersonal situations than males on average and may even benefit from increased instinctual knowledge regarding childcare. The viewpoints are however somewhat based in cultural frameworks on their own, and thus find difficulty in deflecting criticisms that social influences could equally have shaped such a family orientation mindset in females (if it does exist). Additionally, such claims overlook the serious possibility that interpersonal relationships and family life may carry additional opportunities for creativity as well, even if these opportunities are more likely of the 'little c' creative variety. Finally, these arguments are not generally popular among academic theorists, and clearly do not fit well into the prevailing social and political mindsets of our day.

A second class of biological argument regarding the creative performance gender gap is that of field-specific differences, in the sense that certain claims have been drawn from the fact that males and females tend to predictably outperform each other in particular creative endeavors but not in others. For example, males have long been overrepresented in most creative fields, but significant evidence does exist that females' work quality in certain creative activities has outperformed that of males for possibly even centuries. Consider the case of creative writing: Males undoubtedly were overrepresented among Europe's lists of lauded authors throughout the centuries, but historical evidence that females' reading and writing abilities on average outpaced those of males has existed since at least the time of John Locke (1632–1704), who once wrote that he had cause for great concern regarding boys' comparatively poor performance in the language arts. This concern is still very much alive today, as a significant gender gap in reading and writing exists in nearly every modern nation in the world, with young women clearly outpacing their male counterparts. As a result of such long histories of evidence, theories have been advanced that females and males may actually possess biological advantages in various creative fields which could make them more likely to succeed by virtue of their gender and the compatibility of their chosen domain. Contrarily, rebuttals have also been offered that these distinction may have less to do with genetics or innate biological predispositions however, and may have more to do with questions of resources and historical mores regarding the 'appropriateness' of certain fields of interest for young men or young women.

A third category of biological arguments has emerged in recent years from research conducted on the effects of prenatal hormone exposure to developing fetuses. To some extent it is shocking to think that major elements of our personality and destiny are shaped months before we take our first breath, but growing evidence from the fields of neuroscience and human development routinely illustrate just how true this is.

The presence of androgens such as testosterone (which are present at higher levels when a male fetus is *in utero*) are believed to have many significant effects upon brain development, distinct from that which occurs within female fetuses. The hormones signal changes of both a structural and functional nature, and their continued presence is thought to contribute to everything from increased aggression in males to increased anxiety in females. It is important to note however that hormone-driven, gender-based differences in brain size, shape, and development do not carry a connotation of superiority in either direction – but they are thought to have predictable effects upon the personality, aptitudes, and possibly even the preferences of the individual in question. Consider, for example, that in cases where female fetuses are exposed *in utero* to androgens (as in the case of different-gender fraternal twins), they have been found on average to display more traditionally 'masculine' traits and behaviors later in life, including even a higher rate of incarceration for violent crime. Controversial arguments have been put forth that gender-distinct hormone differences may be responsible for changes in hemispheric lateralization and dominance as well, a factor that could potentially help to explain some portion of differences in creative accomplishment. If, as postulated, hemispheres develop at differing rates and females rely more strongly on their 'verbal' left hemisphere while males rely more heavily on their 'spatial' right hemisphere, this could shed light on observable gender patterns in linguistic and mathematical creative performance. Although this line of research is empirically driven and scientific however, it is deeply contested among scholars and will require more investigation before its claims should be taken more seriously.

Finally, a fourth strand of biological argument hypothesizes that creative accomplishment must be at least partially biological due to substantial evidence that 'psychologically androgynous' females may possess more potential for advanced creative performance. Psychologically androgynous individuals, who possess both traditionally masculine and feminine psychological attributes equally, have been found to benefit from a wide range of positive adaptations in psychological health and well-being, including both social and intellectual advantages. They are known to possess higher levels of cognitive flexibility on average, with the ability to quickly shift viewpoints and approaches, and generally report higher degrees of self-esteem, achievement orientation, and personal satisfaction. They tend to resist entrenchment in any one manner of thinking, and remain open to new ideas and concepts more so than peers with a traditionally masculine or feminine personality. As might be expected, these traits lend themselves well to creative problem solving tasks, and several research studies have found evidence to support the notion that psychologically androgynous individuals may perform more creatively in certain endeavors. Interestingly, the prevailing methods of identifying androgynous individuals have begun to include salivary hormone level testing – with some evidence suggesting that females with higher levels of testosterone do potentially achieve at higher creative performance levels. Limiting this argument however is evidence that androgyny is not only beneficial to the creativity of women, but is an equally positive trait for males as well. If both genders are equally able to benefit from thinking more like the other, less can be inferred

about why a gender gap in creative performance currently exists. Additionally, while unambiguously creative women have been shown to refute gendered stereotypes on average, no study of creatively eminent women and psychological androgyny has yet been conducted, mainly due to difficulty of getting eminent individuals to participate in academic research. Further work will be necessary to explore these issues, but recent advancements in hormone testing may at least provide a more reliable method of conducting empirical studies of biological factors influencing creative accomplishment.

Socio-Cultural Arguments

Contrary to biological theories regarding creative performance, socio-cultural arguments choose instead to focus on the environmental and culturally-guided developmental influences that shape young women and men and the ways in which they behave. These theories find serious flaw in the biological assumption that humans exist independently from one another and can be studied in a cultural vacuum, claiming instead that people are greatly shaped by their culture and social expectations and cannot be easily torn or examined apart from this interconnected fabric of being. To illustrate, while researchers advocating a biological examination of hormone influences might discover that creative career women have increased levels of testosterone and conclude that these hormones have led to increased achievement orientation and career focus, socio-cultural theorists would dispute the chain of causation. Instead of concluding that the hormones have led to greater creative success, they might ask, might it be that increased social participation and creative work led these women to experience higher levels of stress, ultimately resulting in increased levels of testosterone production? Androgens are generated in higher quantities at times of intense stress in both males and females, making this flip of causality appear plausible.

This section of the article will examine three major clusters of socio-cultural arguments regarding the creative performance gender gap, each of which offers possible explanations as to how social forces and expectations may contribute to the problem at hand. These three categories of arguments each revolve around the importance and effects of human interaction upon an individual, framing the person's behavioral choices as the result of external pressures and shaping agents. First, we will examine arguments involving historical patterns of resource denial and inequality of support between the genders. Next, arguments that social forces have led males and females to show interest in different elements of the creative process will be considered. Third, questions concerning product evaluation and a creative performance 'glass ceiling' will be offered, before moving on to a discussion of the biological and social interplay among gender, creativity, and personality factors.

The most commonly repeated and well supported of the socio-cultural arguments is one which explains the modern creative performance gap as the result of centuries of unequal treatment of males and females, including marked differences in levels of social support, encouragement, educational and training opportunities, financial backing, and other resources. Nearly all worldly cultures traditionally considered the workplace and public domain as exclusive arenas of male

participation, while females were expected to remain domestic and look after the home, children, and family affairs. Such expectations were typically quite rigid, often with religious or philosophical arguments underpinning and validating their existence. More so, social structures worked to promote and maintain these gendered expectations, and women who dared to become too involved in public affairs or socially recognized creative endeavors were treated very harshly indeed, resulting in scorn, ridicule, punishment, and in some cases much worse.

Several socio-cultural theorists have offered evidence linking this historic denial of resources to present day gender gap effects, including examinations of various world nations that compare their degrees of modernization and social support for females to women's level of active public participation in the creative fields. Taken collectively, these studies have offered a number of similar conclusions. First, it has been well established that prevailing social, political, religious, and philosophic currents do have a substantial effect on the level of cultural and creative participation that women have been able to experience. Second, it has been clearly documented that financial support and increased access also plays a role, as higher numbers of women in modernized wealthy nations are apt to participate in creative sciences and arts while countries with fewer resources and more traditional gender role expectations predictably see lower levels of involvement. Third, it has been shown that even in the most modern of nations levels of support for women's public participation in creative avenues can vary throughout the lifespan, as gender gap effects still exist but have begun to emerge at later stages of life. This subtle trend most likely occurs as a result of generational changes regarding the average age of first marriage, as modern women now expect full participation in public and creative life yet begin to experience a greater degree of tension once they have started a family of their own.

A second socio-cultural argument that is commonly advanced also stems from the effects of historical inequalities, but focuses more clearly on the adaptive effects that these stringent restrictions have led many women to undertake as a result. Social rules and expectations do not only act upon individuals, these researchers argue, but cause behavioral changes and modifications that later impact society as a result. Each step causes further effects, like a chain of falling dominos, except that later results curl back and help to create the next generation of environmental expectations and influences. In the case of expectations regarding creative participation and performance, it is thus argued that centuries of domestic expectations have forced generations of women not to refuse participation in creative endeavors, but rather to modify the ways and means by which they satisfy their creativity and find socially appropriate outlets. In doing so, they modify the environment and expectations provided to them, creating pockets of 'socially acceptable' creative activities for females. These alternate ways of being creative – such as cooking, gardening, and even focusing on growth in interpersonal relationships – have become viewed as feminine in nature, and while they certainly are creative in their own right society has gradually devalued them and failed to recognize the degree of creativity which they can inspire. Additionally, because most creative avenues that generated publicly shared creative products were closed to women for so long, most of these pockets of acceptable activity

are either private and domestic, or more process-oriented rather than product-oriented. This distinction harkens back to the difference between 'Big C' creativity and 'little c' creativity previously discussed, as most people imagine grandiose products when they think of creativity, while overlooking the less obvious and typically more process-concerned avenues of creative participation and expression that have seen higher degrees of female involvement.

A third explanation for the creative performance gender gap has only recently begun to gain empirical support, but presents a series of intriguing questions regarding the effects of gender on the evaluation of creative products. It has long been recognized that even in creative fields where women are numerically overrepresented, male participants typically receive greater recognition as experts along with higher levels of status. For example, while painting is believed to be a field of numeric gender equality or female overrepresentation, a majority of professional art critics are actually men. Some evidence has been presented to show that males and females may possibly prefer different shape and color schemes on average, potentially leading to a disadvantage for female artists when their work is evaluated by a male critic. Additionally, studies have shown that males are more likely to take creative risks while females are more likely to stifle originality in order to conform to an evaluator's expectations, potentially placing them at an additional disadvantage. Finally, a growing body of sociology and psychology research has strongly demonstrated that individuals typically under-perform or over-perform to meet expectations if they believe a stereotype to exist about their identity group's aptitude for the task at hand. While these studies have not specifically addressed the issue of creativity related stereotypes, their conclusions do strongly suggest that if young women perceive their gender as being less creative than men, their performance would subconsciously suffer as a result. This is a worrisome idea, as some published evidence does purport that a majority of school-age females do believe that males are naturally more creative, even if their teachers disagree.

Personality Factors

One further area in need of discussion, whose potential explanations regarding the creative performance gender gap lie theoretically between the biological and socio-cultural camps, is that of personality differences. Gender, creativity, and personality share a number of meaningful interplays and associations, and the resulting effects may greatly impact an individual's creative potential and performance. Gender has long been known to affect personality, and seemingly influences creativity, while certain personality traits are highly correlated with creative potential and also appear more regularly in individuals of either a certain gender and/or of specific creative interests. To illustrate, consider both the personality traits of psychological androgyny and males' increased frequency of creative risk taking, each of which has already been discussed. In each case, personality, gender, and creativity are so intertwined that it is difficult to guess as to which is more responsible for the final behavioral pattern. Are androgynous people more creative because of their personalities, or are their personalities being shaped by their creativity? Do males prefer to take risks because they are creative, or are they considered creative because they

prefer to take risks? Similarly, these complex three-way interactions are also impossible to classify as strictly biological or socio-cultural in nature, as both nature and nurture weigh heavily on the construction of each.

Regardless of the circular interplays however, psychologists and sociologists have in fact conducted hundreds of studies examining gender and personality, and several conclusions have been reasonably established. Although not universally accepted, significant empirical data suggest that males are more aggressive, ambitious, willing to take risks, assertive, and confident on average than their female peers. On the other hand, the data suggest that females on average possess greater degrees of interpersonal ability, self-awareness, communicative expression, cautiousness, anxiety, and modesty. These gendered differences in personality are likely to have sizable effects upon an individual's creative performance, as many of these personality traits (among others) have also been shown to correlate with creative ability within specific domains. Artistic creativity, for example, appears well connected to emotional instability, nonconforming tendencies, anxiety, and imagination among others. Scientific creativity, on the other hand, seems more closely tied to personality traits such as introversion, independence, and aloofness to emotions. It is important however to note that the personalities of artists and scientists share much more in common than they have in difference, but these differences certainly must play a role in making specific creative endeavors more or less appealing to particular individuals. As a result, it is possible that men or women (on average) may find their equally creative personalities pulling them toward different domains of creative expression.

Conclusions

The ultimate question of gender differences in creativity quickly splits into two distinct inquiries, with one examining creative potential and the other creative performance. Decades of research has firmly established that no meaningful difference exists between the sexes in terms of potential, but centuries of history clearly illustrate that differences in performance have and do exist. As such, we are left with an intriguing question: if indicators of potential tell us that no difference should exist, how can we best explain why one actually does? Psychometricians, psychologists, and sociologists have long struggled with this problem, and their proffered theories have largely come from biological or socio-cultural viewpoints. For some, it is the fault of nature, and men and women were simply created to be distinct. For others, it is the fault of society, and men and women have been taught and shaped to make different choices in creative expression. In all likelihood however, the truth may lie somewhere between the two, incorporating both biological and socio-cultural elements.

Continued research to address these questions is of great value and importance, because of the real-world nature of the problems being discussed. If men and women should be achieving on an equally creative level, yet are not, one reasonable inference is that a great degree of creative talent is being neglected and going to waste. Creativity in any domain is a valuable and precious resource, and finding ways to maximize its development and application in both males and females carries meaningful implications for individuals and society as a whole.

Glossary

Allele Alleles are alternative DNA sequences at the same gene locus.

Heterozygous Having different alleles at a certain gene locus. This is only possible if the gene locus is polymorphic.

Homozygous Having the same alleles at a certain gene locus.

Polymerase chain reaction (PCR) Molecular genetic technique invented by Kary Mullis in 1983 for which he was awarded the Nobel prize in chemistry ten years later.

Mullis work has revolutionized the field of molecular genetics. PCR allows quantification of DNA fragments without cloning.

Polymorphism A polymorphism is a mutation that occurs in more than 1% of the population.

Single nucleotide polymorphism (SNP) A SNP is a polymorphism that is defined by an exchange or a deletion of a single nucleotide/base at a distinct locus in the genome.

An Introduction into Behavioral Genetics

The question whether cognitive abilities are heritable has concerned mankind constantly and is still a matter for debate. During the last decades the public opinion on this issue has changed due to unequivocal evidence from scientific studies demonstrating strong genetic effects on general cognitive ability. However, the downright importance of cognitive abilities especially for job performance, as described by Schmidt and Hunter in 1981, makes it difficult to accept that environmental influences (e.g., training, education, upbringing) can only boost cognitive functioning within a certain framework determined by our genes. The scientific discipline that addresses this issue, behavioral genetics, has a long tradition starting in the nineteenth century when Francis Galton, a first cousin of Charles Darwin, published a two-article series on high intelligence and other abilities, which he later expanded into the first book on heredity and cognitive ability, *Hereditary Genius: An Enquiry into Its Laws and Consequences*, published in 1869.

Behavioral genetics can be divided into two subdisciplines: quantitative genetics addressing the question whether a certain phenotype is heritable and how large the genetic effects are, and molecular genetics, a very young discipline that tries to identify those gene loci that constitute the molecular basis of individual differences in behavior. Interestingly, quantitative genetics has nothing to do with the molecules that form our genome. It is a discipline that applies quantitative statistical models to decompose the variance of a given phenotype into proportions of variance accounted for by genes, environment, and gene–environment interactions. With respect to the genetic effects, additive and nonadditive gene effects are distinguished. ‘Additive’ means that small effects of single gene loci are numerically summed up whereas ‘nonadditive’ refers to gene–gene interactions, so-called epistasis effects. On the side of environmental influences, shared and nonshared environmental effects are separated (see below). Methods by which the phenotype is assessed often lack reliability. Therefore, measurement error needs to be considered along with environmental and genetic effects when heritability estimates are calculated.

In humans, quantitative genetics uses twin and adoption studies to disentangle genetic and environmental effects. The first study addressing the heritability of cognitive abilities was published in 1924. The method using twins was applied to find out whether identical twins were markedly more similar with respect to IQ than fraternal twins, a result suggesting a strong genetic influence on general cognitive ability. The rationale behind these findings is as follows: in twin studies, heritability is estimated by comparing correlation coefficients between mono- and dizygotic twins. Due to the fact that monozygotic twins share 100% of the same genome and dizygotic twins have only 50% of the genetic material in common, a simple formula which estimates heritability (h^2) of a given phenotype is twice the difference of the intrapair correlation coefficients of mono- and dizygotic twins ($h^2 = 2(r_{MZ} - r_{DZ})$). However, this Falconer formula is only precise under the prerequisite of the ‘equal environment assumption’ that assumes that environmental influences are equally strong for monozygotic and dizygotic twins. In practice, this assumption cannot hold due to the higher similarity of monozygotic twins as compared to dizygotic twins; monozygotic twins are more likely to be treated the same by their surroundings. Then later in life, the greater genetic overlap between pairs of monozygotic twins will increase the possibility that these twins actively choose the same environments with the consequence of decreasing the effects of nonshared environments. Another popular strategy to estimate heritability in humans is the combination of adoption and twin studies. In such designs, monozygotic twins separated by birth and reared apart are investigated. The intra-class correlation over pairs of monozygotic twins is a direct measure of heritability because the genes are identical and the environment is assumed to be different. However, the latter assumption certainly cannot hold because of selective adoption strategies of the public authorities, placing children only in adoption families with a certain socioeconomic status. Therefore, these combination designs result in an overestimate of heritability. Moreover, these samples of monozygotic twins separated by birth and reared in different environments are extremely rare.

Studies from Quantitative Genetics

Findings from quantitative genetics indicate that Intelligence (also referred to as IQ or general cognitive ability (g)) is the most heritable psychological phenotype known. Heritability estimates from twin and adoption studies indicate that up to 70% of the variance in intelligence is determined by genes. Many studies from applied psychology have demonstrated the importance of intelligence for academic achievement and job performance. The influence of creativity on scientific and industrial progress, inventions, and on the creation of outstanding art and music has been widely acknowledged. However, this had no salient impact on creativity research. In comparison to intelligence, research on creativity is rather orphaned. According to Sternberg, creativity research has "taken on the role of a prodigal stepbrother to research on intelligence." Obviously the neglect of creativity research is mainly due to methodological problems concerning reliability and validity of creativity measures and also due to disagreements in the definition of creativity. Some researchers preferred the *product*, others the *process* criterion to investigate creativity. The *process* approach assumes that creativity is a trait that is normally distributed in the general population, whereas the *product* approach defines creativity in terms of exceptional real-world creative production, which very few individuals manage to achieve. Therefore, supporters of the process/trait approach – like Guilford who followed the assumption that components of divergent thinking, namely originality, flexibility, and elaboration are at the core of creativity, and that these components are also manifest in a normal population – attempted to discover the underlying processes of creativity and tried to develop appropriate instruments to measure it.

Both intelligence and creativity are broad constructs of higher cognitive abilities but where are the differences or similarities? Getzels and Jackson stated that there is no relationship between intelligence and creativity. This view was criticized by several investigators and studies that found pronounced correlations between intelligence and creativity in unselected populations of school children. To account for these discrepancies a threshold model has been suggested that there is a relationship between IQ and creativity up to a level of about 120 IQ points but that above this level creativity is not necessarily correlated with intelligence. Guilford postulated that intelligence is a mandatory prerequisite for creativity but that not all intelligent people are necessarily creative. Items in intelligence tests always have one distinct solution whereas the achievement in creativity tests is defined by the originality and the number of diverse answers to a given problem. It is obvious that the criteria diversity and originality depend on the subjective views of the different raters resulting in poor reliability estimates. This lack of reliability in addition to different conceptualizations (process versus product approach) has made creativity research less popular than research on intelligence. Interestingly, in some intelligence models creativity or divergent thinking are facets of intelligence. Therefore, creativity should also have a strong genetic basis and should be – in a similar way as intelligence – normally distributed in the population. This assumption is in line with the process/trait approach. However, little is known about the genetic basis of

creativity and its heritability. A first seminal twin study of creativity in 1973 yielded an average correlation of 0.43 for identical twins and 0.31 for fraternal twins across different measures of creativity. Here, significant differences between MZ and DZ twins were only detected in the Word Association Test. A review of ten twin studies on creativity originating from the 1970s yielded an average correlation of 0.61 for identical twins and 0.50 for fraternal twins. According to this study the genetic influence of about 20% (Falconer formula: see above $H^2 = 2(0.61 - 0.50)$) is primarily due to the correlation between creativity and IQ. When IQ is controlled, identical and fraternal twin correlations for creativity tests were scarcely different. However, some of these studies deal with methodological problems concerning the reliable measurement of creativity and therefore, results are difficult to compare across studies. Unfortunately, no recent studies from quantitative genetics are available. Obviously the small effects and the above discussed problems in creativity research have discouraged scientists to carry on with this interesting research.

Short Introduction into Molecular Genetics

Molecular genetics is a very young discipline. The biggest milestone here was the invention of the polymerase chain reaction (PCR) technique by Kary Mullis in 1983 for which he was awarded the Nobel prize in chemistry ten years later. The work of Mullis has revolutionized molecular genetics and from there on it has become one of the most technical, industrialized, and fast developing disciplines in science. The progress in this field is breathtaking. Shortly after the mouse genome was decoded in 2002, the human genome was completely sequenced. Every few months new machines are introduced that allow an even faster genotyping or sequencing of the genome.

Molecular genetics directly ties into the results of quantitative genetics. It tries to answer the question of which genes make up the genetic basis of heritability. As outlined above, heritability is assessed by means of correlations. However, the size of a correlation is determined by the variance of the phenotype under investigation and variability accounted for by genes is caused by genetic diversity. Interestingly the overlap between the mouse genome and the human genome is tremendous: 99% of the mouse genome has an analogon in the human genome and 96% of the human genome has an analogon in the mouse. Consequently the overlap between the genes of two unrelated humans is >99%. Therefore, tiny differences in the human genome must have huge effects on the phenotypes. These differences in the genome across individuals are called polymorphisms if they occur in more than 1% of the population. In other words, polymorphisms are common mutations in a given population that constitute the genetic basis of variability in the phenotypes (e.g., behavior). The most frequent sort of polymorphisms are single nucleotide polymorphisms (SNPs) that are caused by an exchange of a single base (nucleotide) in the genetic sequence. The human genome comprises three billion base pairs (pairs due to its helix character), whereas the genetic code only consists of four different bases; arginine, cytosine, guanine and thymine.

Therefore, a SNP is a very small alteration in the human genome that in some cases can have a strong effect on the gene product encoded in our DNA. A polymorphism that leads to alterations in the gene product is labeled functional. Such functional polymorphisms are most likely located in the coding region of our DNA, that is, in an exonic region, or if it is located in the so-called promotor region of a gene that initiates its transcription. SNPs occur every 100–300 bases along the three-billion-base human genome. The information representing our genome is located in nearly every cell of our body, to be more precise in the nucleus of our cells. Therefore, a geneticist is confronted with the problem of making a bit of information, a SNP, visible. Similar to other techniques from the neurosciences, for example EEG, this is achieved by amplifying the raw signal of the data. It is here that the PCR comes into play. A PCR machine is nothing but a copy machine for DNA without cloning. In three steps defined by different temperature conditions the process of DNA self-duplication that takes place in the living organism at any time is imitated by PCR in a test tube. The first step is the denaturation of the DNA at 95 °C. Denaturation means that by simply heating the DNA the double-helix is disentangled with the result of having two single strands of the original DNA. Only single strands can be read or duplicated. The second step, called the annealing phase, starts by lowering the temperature in the reagent tube to 53–65 °C depending on the respective base sequence. Here the region under investigation (i.e., the region of the DNA where the SNP of interest is located) is marked by oligonucleotides (a series of about 20 nucleotides/bases), the so-called primers. Primers are synthetically designed and produced in a way that they complementarily bind to the original DNA strand and are unique in the genome. Complementary means that an adenine binds selectively to a thymine and a guanine to a cytosine. The actual duplication process takes place in the third step, the elongation. At 72 °C a thermo-stable enzyme, the Taq polymerase, elongates the simple DNA strand starting at the position of the primer. At the end of the first PCR cycle consisting of the three phases denaturation, annealing, and elongation we have two double stranded DNA molecules. These three steps are repeated for at least 35 cycles. During the reiterations the amount of DNA copies in the test tube follows an exponential growth function: After the second cycle we have four copies and after the third cycle we have eight copies and so on. The number of DNA copies is defined by 2^n where n denotes the number of the PCR cycles. After 30 PCR cycles we have over one billion copies. Besides DNA and the Taq polymerase the investigator has to add synthetic nucleotides into the reagent tube and dependent on the protocol other chemicals like Mg^{2+} fine tune the pH-value. At the end of a PCR run our tiny signal, the DNA region where the SNP is located, has been amplified in order to make the signal strong enough to find out if a base exchange has occurred or not. The latter is the process of genotyping that follows the amplification process. It is important to know that we have a diploide chromosome set, that is, every chromosome is present twice in our organism. From each pair of chromosomes one stems from our mother and the other one from our father. Therefore, the information on any gene locus is available twice. The genotype refers to both pieces of information at a distinct gene locus, the paternal and the maternal.

As a result our genotype at a certain SNP locus (the SNP may be defined by a base exchange from A → G) can be AA, AG, or GG. The base exchange resulting in the SNP occurred somewhere during evolution by chance and was transferred from generation to generation if this spontaneous mutation turned out to be beneficial. The ancestral allele is called the wildtype and the new allele is named the mutant. Thus, in our example we have the homozygous wildtype AA, the heterozygous AG genotype and the homozygous mutant GG. Genotyping is conducted by means of gel-electrophoresis or real-time-PCR. The latter technique uses fluorescence dyes to identify both alleles.

I will not go into further detail. What I intended to explain by this brief introduction into molecular genetics is that small variants (different alleles) in the genetic code build the basis for individual differences in behavior. The basis for genetic association studies are the allele frequencies or the genotype frequencies in distinct groups differing with respect to a certain phenotype. To obtain information on alleles/genotypes fragments of the genetic code the DNA strands have to be amplified first by means of PCR to get a signal that is strong enough for further analysis. I hope that the reader can now better understand the ensuing review of empirical studies from molecular genetics trying to identify those gene variants relevant for creativity.

Association Studies from Molecular Genetics

The number of genetic association studies on creativity is very small until now. The main reason for this is that creativity is a construct that is mainly studied by psychologists and psychologists normally are not familiar with molecular genetic techniques. However, if psychologists do not want to learn these techniques by themselves, they at least have the possibility to analyze their samples in cooperation with scientists from other disciplines who run a genetic laboratory. A similar development of interdisciplinary collaborations can be observed with respect to functional imaging studies. Nowadays, many psychologists use MRI techniques to investigate the biological basis of cognitive or emotional processes. Functional imaging with EEG has a long research tradition in psychology and the adoption of MR imaging was the straightforward next step. With respect to molecular genetics, however, psychologists seem to enter a completely new field.

In 2006 the first molecular genetic study on creativity was published by Reuter and colleagues. We investigated three polymorphisms on candidate genes for cognitive functioning, the COMT VAL158MET, the DRD2 TAQ IA, and the TPH1 A779C SNPs with respect to creativity. The COMT gene had especially been successfully related to cognitive functioning before. There is mounting evidence from the literature that unequivocally relates the MET allele or the homozygous MET/MET genotype of the COMT VAL158MET polymorphism to higher performance in prefrontal executive functions like working memory and executive control as measured by the Wisconsin Card Sorting Test. Functional studies have demonstrated that the MET allele of the COMT gene is characterized by a three- to four-fold reduction in COMT enzyme activity. The COMT enzyme's primary function in the human brain is the degradation of the neurotransmitter dopamine in the

prefrontal cortex. The authors conclude that the molecular genetic findings support the assumption that high dopamine levels in the prefrontal cortex are associated with higher cognitive abilities. However, it has to be mentioned that the total dopamine activity is not only influenced by the dopamine catabolism but also by the synthesis rate of dopamine in the presynapse, the activity of the dopamine transporter, the receptor density, and the receptor affinity. DRD2 TAQ IA, the second polymorphism under investigation, has been studied with respect to intelligence but the results were heterogeneous. One study reported a higher IQ in carriers of the A1A1 genotype in a female Taiwanese sample, Berman and Noble found a significant reduction in visuospatial performance in a sample of Caucasian children and Petrill et al. found no association between IQ and the DRD2 gene in an adult Caucasian sample. The rationale for investigating the TPH A779C polymorphism, a serotonergic SNP, with respect to creativity is based on evidence that the serotonergic (5-HT) system is also involved in cognitive functioning. The mechanisms of how the 5-HT system influences cognitive functions is less understood and support from the literature is scarcer than for dopamine. For example Coccaro et al. found a significantly negative correlation between whole blood 5-HT and cognitive-intellectual abilities in a sample of autistic patients and their first-degree relatives. By means of tryptophan depletion (reducing the food intake including the amino acid tryptophan), an elegant method to investigate the involvement of 5-HT in brain functions, impairment in cognitive functioning could be demonstrated in both animal studies and studies on healthy human subjects. Further evidence stems from clinical studies showing the beneficial effects of substances increasing central 5-HT activity. All these findings underline the role of the 5-HT system in cognitive functioning, although the role of the dopaminergic system seems to be more salient. Also it cannot be excluded that some of the 5-HT effects on cognitive functioning are mediated via an indirect pathway by influencing the activity of the dopaminergic system. It is known that the 5-HT system exerts an inhibitory effect on DA release. In its function as the rate-limiting enzyme of 5-HT synthesis, the tryptophan hydroxylase 1 gene (TPH1) is a promising candidate gene for cognitive functioning. However, previous positive association studies investigating the TPH1 gene have been criticized because the TPH1 gene is primarily expressed in the periphery and not in the brain. A recent finding by Nakamura et al. reporting a specific role of the TPH1 gene for the central 5-HT synthesis in a late developmental stage underlines that the TPH1 gene could indeed have an impact on cognitive functions. Recently another TPH isoform has been identified, the TPH2 gene that is responsible in central 5-HT synthesis. Recently, a promising functional candidate SNP on TPH2, the TPH2-703 G/T, has been related to executive control functions and altered brain metabolism during a working memory task by our group. Unfortunately this SNP was not available for our 2006 study on the genetics of creativity. In this study creativity and intelligence as a control variable were measured in analogy with a previous study by our group in which we investigated the influence of testosterone and personality on creativity. Creativity was assessed by the test battery 'inventiveness' of the *Berlin Intelligence Structure Test* (BIS). The BIS defines creativity as a subcomponent of intelligence. The inventiveness

tests challenge the flexible production of ideas, the power of imagination, and the skill to consider many possible ways and solutions to solve a problem. They measure figural, verbal, and numeric creativity and have very good psychometric properties. In order to control for the influence of intelligence on the association between gene loci and creativity, fluid and crystallized intelligence were also tested and served as covariates.

The results obtained in a sample of $N=92$ Caucasian subjects showed that the DRD2-gene and the TPH1-gene were both associated with total creativity with a combined 9% of the variance while COMT was not related to creativity at all. With respect to the subcomponents of creativity, the A1+ allele (carriers of the A1/A1 and A1/A2 genotype) of DRD2 was related to higher verbal creativity as compared to the A1- allele (carriers of the A2/A2 genotype) and carriers of the A allele of TPH1 showed significantly higher scores in both figural and numeric creativity.

Recalling that verbal tasks are assumed to be processed in the left hemisphere and numeric and figural tasks in the right hemisphere, the findings suggest that the two gene loci discriminate between higher cortical functions, according to the organization of cognitive functions in the respective hemispheres. Moreover, the results indirectly support Eysenck's hypothesis on creativity suggesting higher creativity in subjects scoring high on the psychoticism dimension. Psychoticism is related to aggressiveness and there is evidence in the literature that the A allele of the TPH1 A779C which was linked to higher creativity scores in our study is also related to high aggression.

A second study from Finland investigating musical aptitude as a form of artistic creativity directly refers to the first genetic association study on creativity by Reuter et al. by adding TPH1 A779C, COMT Val158Met, and DRD2 Taq Ia, plus three additional polymorphisms, the serotonin transporter polymorphism (5-HTTLPR) and two variable microsatellites located in the promoter region of the vasopressin receptor 1a gene (AVPR1a). The authors combined a quantitative genetic and a molecular genetic approach by testing musical creativity in 19 Finnish families with at least some professional musicians and/or active music amateurs. The heritability estimates for creative functions in music were very strong ($h^2 = 0.84$; composing $h^2 = 0.40$; arranging $h^2 = 0.46$; improvising $h^2 = 0.62$). The authors reported an overall haplotype association between the microsatellite markers RS1 and RS3 of AVPR1a and musical creativity. While the effects of the gene variants of AVPR1a on all dependent variables were very strong, weak associations between the three previous candidate SNPs suggested by Reuter et al. and musical creativity could also be detected. The TPH1 A779C A allele that was related to figural and numeric creativity in the Reuter et al. study showed an association with composing. The Finnish authors argue that figural and numerical abilities are skills that are required for composing. The COMT Val158Met Val-allele was weakly associated with pitch recognition and improvising. The Taq Ia allele of DRD2 was suggestively related to Seashorers test score of time perception. The authors see a relation between the findings of Reuter et al. who reported higher verbal creativity in carriers of the A1 allele because there seems to be a common evolutionary background of music and language based on overlapping brain regions. It can be assumed that the rather weak effects of COMT, DRD2, and TPH1 may be

caused by the small study sample. However, the strong effects of AVPR1a, a gene related to prosocial behaviour, indicates that the neurobiology of music perception is likely to be related to the pathways affecting intrinsic attachment behavior.

Another molecular genetic study by Volf et al. tried to extend the role of the serotonergic system on creativity suggested earlier by also using an approach from molecular genetics. They chose the serotonin transporter polymorphism 5-HTTLPR that was also used in the Finnish study but showed no association with musical creativity. In this study on 62 Russian students the authors found higher verbal and higher figural creativity scores in carriers of the S-allele (genotypes SS and SL) as compared to homozygous LL subjects. Verbal creativity was assessed with one of the scales of the BIS that was also applied to the Reuter et al. study and figural creativity was measured by means of the figural tasks of the Torrance Tests of creative thinking. The S-allele of 5-HTTLPR has been reported to be associated with lower mRNA levels, decreased 5-HT transporter density, and 5-HT uptake as compared with carriers of the LL genotype. The findings are contrainuitive because the S-allele whose carriers exhibited higher creativity scores has been related to neuroticism and depression. It is known that creativity is associated with positive rather than negative emotionality.

In a recently published study, Kéri investigated a prominent SNP (rs6994992) on a candidate gene for psychosis, neuregulin 1, for its relevance for creativity. The starting point for his study was the suggested association between psychotic features and creativity. Neuregulin 1 has an influence on neuronal development, synaptic plasticity, glutamatergic neurotransmission, and glial functioning. In previous studies the TT genotype of rs6994992 was related to an increased risk of psychosis and lower premorbid IQ, to lower working memory capacity, to higher sensitivity to harsh criticism during interpersonal interactions (Kéri et al., 2009), to decreased activation of the frontal and temporal cortex during cognitive tasks, and to reduced white-matter density.

In a sample of 200 healthy subjects with high academic and intellectual performance Kéri found a significant allele load effect of rs6994992 on all three scales (originality, fluency, flexibility) of the *Creative Achievement Questionnaire* and on the test score in the 'Just Suppose' subtest of the *Torrance Test of Creative Thinking*. Carriers of the TT genotype had highest scores, heterozygous CT carriers intermediate, and homozygous CC carriers lowest levels of creativity. The effects hold even after correction for gender, socioeconomic status, or IQ. With his study Kéri showed that a polymorphism that increases the risk for psychosis has also a positive effect on creativity. According to the author, the link between psychosis and creativity is mediated by neuregulin 1 that reduces cognitive inhibition in the prefrontal cortex. Neuregulin has been related to this brain region and it is also known that the prefrontal cortex has a prominent role for cognitive inhibition and creativity. One limitation of the study is that the association between the neuregulin 1 SNP and creativity was found in a sample with high intellectual achievement. Further studies need to show if this findings can be extrapolated to the general population.

Finally, a recent study by Marc Runco and colleagues investigated five candidate genes for creativity and their effects on ideational fluency, originality, and flexibility. Besides the three known SNPs used in the study by Reuter et al. two repeat

polymorphisms – one on the dopamine D4 receptor gene (DRD4) and one on the dopamine transporter gene (DAT) – were also analyzed. Runco et al. applied tests of creativity that provide measures of fluency as well as measures of originality and flexibility. The authors have criticized previous studies for merely focusing on the fluency concept of creativity rather than on originality and flexibility. They argue that fluency only represents productivity but that it is not nearly as closely tied to creativity as is originality. Originality can be defined in terms of the uniqueness or unusualness of ideas. Results showed that all four dopaminergic candidate genes were associated with fluency. In contrast none of the five polymorphisms alone was significantly related to either originality or flexibility. When controlling the significant effects on fluency for intelligence, the effects became even stronger. Therefore, the study by Runco and colleagues supports previous findings that dopaminergic genes are relevant for fluency. Negative findings with respect to measures of flexibility and originality do not exclude that other gene variants are relevant for these phenotypes.

Problems and Perspectives

Genetic research on creativity is absolutely scarce. The reasons for this are manifold. First of all the construct of creativity is investigated by two different approaches, the process and the product approach which promotes inconsistencies in research findings. Second, creativity tests using the process approach are dependent on independent raters when trying to assess the component of originality. A lack of reliability in turn is related to a pronounced measurement error rendering heritability estimates low and increasing the risk of nonfindings in genetic association studies. Third, creativity is a construct stemming from psychology and psychologists do not have a long tradition in genetics especially not in molecular genetics. The first quantitative genetic studies originating from the 1970s produced small heritability estimates that may have discouraged further research in this field. However, these twin studies had mostly small sample sizes so that the question as to what extent creativity is heritable is still open. On the other side molecular genetic studies on creativity seem to become *en vogue*. After the first pilot study in 2006 three new studies were published in 2009. Of course, the proportions of variance that can be explained by some singular SNPs are very limited. Traits that are normally distributed in the population like creativity are caused by a large number of polymorphisms. Genome-wide association studies (GWAS) that are already applied in the field of psychiatric genetics may be a solution. This new technique allows investigating more than 1 000 000 SNPs at a time by placing specific hybridization probes on a microchip. At the moment the costs are very expensive but it is a question of time until this technique becomes affordable. At the moment GWAS are used in research addressing pathologies (e.g., schizophrenia), and psychological phenotypes like creativity seem to be lower in priority ranking. Despite the chances offered by GWAS there are also problems related to this technique. We are confronted with multiple testing and are at risk to commit type I errors. GWAS demand independent replication and corroboration of the candidate SNPs by ensuring high-throughput-sequencing or -hyphenotyping. Another

promising pathway is the strategy used by Ukkola et al. (2009) who combined a twin study with a molecular genetic approach. Although their sample size was small their strategy is promising in order to learn also about gene–environment interactions and gene loci that are related to them.

Recent molecular genetic studies make me confident that we will learn much more about the genetics of creativity in the next few years. Other approaches from the neurosciences that investigate brain activity or brain architecture related to creativity by means of EEG or MRI are other promising strategies worth mentioning. As already done with respect to other research topics the combination of MRI data with molecular genetics will be also very fruitful to understand the biological basis of creativity.

Glossary

Anthropometric measures Instruments developed by Francis Galton that he claimed to measure what he called 'natural ability.'

'Great man' theory of history A theory proposed by Thomas Carlyle and others that maintains that history is made by a relatively small number of great creators and leaders.

Historiometric genius Genius defined according to an individual's impact on history, using historiometric measures, like the amount of space the person receives in reference books.

Multiple intelligences The theory proposed by Howard Gardner that there are seven or more distinct intelligences with divergent consequences for outstanding achievement.

Psychometric genius Genius defined according to an individual having received a very high score on a psychometric measure, most commonly an IQ test.

Serendipity When a person accidentally discovers something that he or she was not originally seeking.

10-year rule The empirical generalization that, on average, it requires about a decade of intense study and practice to acquire world-class expertise in most domains of achievement.

Introduction

Consider the following historical personalities: Napoleon Bonaparte, Abraham Lincoln, Isaac Newton, Marie Curie, Leo Tolstoy, Leonardo da Vinci, and Ludwig van Beethoven. What do they have in common that sets them apart from the rest of us? Several answers are possible, but two perhaps stand out. First, all can be considered geniuses of some kind, whether military, political, scientific, or artistic. Second, all can be said to display greatness in their chosen domain of achievement. Thus, Napoleon was a great general, Lincoln a great president, Newton a great scientist, and so forth. In these examples, genius and greatness appear to go together. Yet do they always have to correspond? Can genius exist without greatness or greatness without genius? It is the purpose of this entry to examine the conceptual connection between these two constructs. Discussion begins with their respective definitions, and then examines the convergences and divergences implied by these definitions. Although often used interchangeably, the two terms are by no means equivalent.

Genius

The concept of genius has undergone a substantial change over the course of history. The word originated in Roman times. According to Roman mythology, each man was born with a genius that represented a kind of guiding spirit or guardian angel. A man's genius is what made him distinctive – and exerted some influence over his fate. Although the parallel tutelary spirit for women was a 'juno,' this gender-differentiated usage did not survive to modern times. Interestingly, not just individuals had a genius. Particular places might have genius loci that served as protective spirits. And a Roman clan, caste, or group of families could also have a genius. Although the connection is not completely secure, the Latin word may be related to the Arabic 'jinn,' often translated into English as 'genie.'

Over time, genius became dissociated from the spiritual world. Instead, it became something highly characteristic of a given person, especially with respect to some unusual ability or inclination. Someone could have a genius for making friends, for example. In line with this usage, anyone could have a genius because genius is what defined one's individuality. But since the Renaissance, genius began to acquire a more restrictive meaning. As a result, only an elite subset of the human population could be said to have genius. In particular, a person could only be considered a genius if he or she exhibited exceptional intellectual or creative power. Uniqueness or individuality was insufficient.

At first, the emphasis seemed to have been placed on the creative powers. For this reason, perhaps, genius was initially confined to artistic domains of achievement. William Shakespeare and Michelangelo Buonarroti could thus be considered geniuses. Scientific creativity, by comparison, required no genius because science relied solely on a method that could be taught or imitated. For instance, Immanuel Kant argued, in his *Critique of Judgment*, that even a scientist as great as Newton could not be considered a genius because someone could theoretically learn to do what he did. Artistic geniuses, in contrast, invent their own rules, unconstrained by logic and fact. Nonetheless, eventually genius came to be found outside of the arts, including in the sciences. Indeed, after a while it became reasonable to speak of military genius, political genius, and the like. Sometimes the term even became overextended. Galton's 1869 *Hereditary Genius* includes athletes along with generals, scientists, philosophers, artists, and composers.

These etymological developments lead to the most critical question: How can genius be given a definition suitable for scientific research? Stated differently, is it possible to devise a definition of genius that supports precise measurement? The answer is affirmative but plural. Researchers have tended to use two rather divergent definitions of genius, namely, the historiometric and the psychometric.

Historiometric Definition

Galton was the first to define genius in terms of historical impact. A genius was someone who had acquired an extraordinary reputation for culturally valued achievements. This reputation was first established with contemporaries but was later consolidated by the posthumous appraisals of posterity. Given sufficient time, the judgment of an individual's contributions to civilization should become reasonably stable. Certain reputations will have withstood the 'test of time' whereas others will have 'fallen by the wayside.' The question was then how to assess whether or not a particular individual could claim sufficient reputation to be counted as a genius.

Galton's solution to this problem was to adopt a crude eminence measure. A person who was featured in a major biographical dictionary had a *prima facie* justification for being considered a genius. An alternative solution was proposed by Galton's contemporary Alphonse de Candolle, who introduced awards or honors as the criterion of distinction. More specifically, Candolle studied scientists who were sufficiently illustrious to earn election to a prestigious scientific society. Galton later endorsed this criterion as a reasonable alternative to his original measurement strategy.

Even so, both of these measures had a drawback: They did not admit of degree. Geniuses can differ in the magnitude of their genius. Not all persons with entries in a biographical dictionary are equally eminent. Galileo Galilei certainly surpasses Evangelista Torricelli, just as Fyodor Dostoyevsky outshines Aleksandr Kuprin. Similarly, not all recipients of a given honor or award are of equal standing as geniuses. Albert Einstein received the Nobel Prize for Physics one year after the same award was bestowed on Charles Edouard Guillaume. Whereas the former laureate revolutionized our conceptions of matter, light, space, time, and gravity, the latter laureate merely discovered some anomalies in nickel steel alloys.

The first researcher to offer a quantitative rather than qualitative measure of genius was James McKeen Cattell. In 1903, he ranked the 1000 most eminent creators and leaders of Western history based on the amount of space devoted to each luminary in standard reference books. According to his sources, the most space was devoted to Napoleon and Shakespeare, the least to Barthélemy Prosper Enfantin and François-Noël Babeuf. Later investigators refined this approach, especially Frederick Woods, who was the first to refer to such measures as historiometric.

Cattell also introduced an alternative method for the historiometric definition of genius: expert surveys. He would ask experts to evaluate the relative impact of eminent scientists. This approach has also been used frequently to assess the differential influence of achievers in a variety of domains, including classical composers and US presidents.

The above two historiometric definitions are not equivalent. Space measures tend to have much more skewed distributions than do expert evaluations. Even so, they correlate very highly, the top figures by one assessment tending to be pretty much the same as the top figures by another assessment. Just as important, historiometric judgments tend to be highly stable across historical time, even after the passage of a century or more.

Psychometric Definition

The historiometric definition of genius is clearly sociocultural rather than psychological. Reputation is irretrievably contingent on the opinions of others. Scholars have to decide how much space to assign entries in biographical dictionaries, and experts have to assess the relative impact of various contributions. Nevertheless, Galton believed that an achiever's reputation was directly related to his or her personal qualities. In particular, he attributed genius to high natural ability. The latter was a complex concept that included intelligence, energy, and motivation. Even so, it is clear that Galton viewed intellect as primary. Human beings varied greatly in natural ability, and this variation was quantitative rather than qualitative. That is, each individual could be placed on a continuous scale with the least able at the bottom and the most able at the top. In addition, Galton introduced an important innovation: the concept of the normal distribution, as described by the 'bell curve.' Although Adolphe Quételet had shown that many physical characteristics, such as weight and height, were normally distributed, it was not until Galton that psychological attributes were said to have the same distribution. He went even further by specifying that geniuses represent the upper tail of this normal distribution. That is why geniuses are so rare.

Unfortunately, at the time that Galton advanced this concept of genius, no instruments existed by which he could directly measure natural ability. So he was obliged to devise his own instruments, eventually producing a large number of 'anthropometric' measures. These assessed individuals on visual and auditory acuity, reaction times, breathing power, strength, height, and weight – attributes that do not seem to have an obvious link to natural ability. In fact, these measures were later shown not to correlate with anything that would be associated with intelligence, even less with genius. For instance, a student of Cattell found that they did not correlate with college grades. As a consequence, Galton's instruments could not provide the basis for a psychometric definition of genius.

The needed measures came from an unexpected quarter. In the early twentieth century, Alfred Binet and Théodore Simon devised an intelligence scale that assessed a child's mental age. William Stern later conceived the idea of dividing the mental age by the chronological age and then multiplying the result by 100 to yield an intelligence quotient, or IQ. Not long after, Lewis M. Terman adapted the Binet–Simon for use with English participants, implementing Stern's concept of the IQ. In the early 1920s Terman applied the resulting Stanford–Binet Intelligence Scale to a large sample of young children. Those with IQs of 140 or more were then subjected to an intensive longitudinal investigation. The study was published in a series of volumes under the title *Genetic Studies of Genius*. The criterion of IQ 140 thus became the psychometric definition of genius. This cut-off even found its way into some standard dictionaries.

Of course, such a threshold is necessarily arbitrary. It defines those individuals whose IQs are in the top 1 percent of the general population. Certainly alternative cut-offs might also be justified. Mensa, the organization for high-IQ people, requires that a member only be in the top 2% of the population, whereas membership in the Triple Nine Society demands a score in the 99.9th percentile. Even more extreme, the Mega

Society sets the IQ requirement at the 99.9999th percentile! Because standard intelligence tests do not yield scores high enough, candidates for membership must take specially designed tests.

Given the psychometric definition of genius, the person with the highest recorded IQ would be considered the world's greatest genius. Marilyn vos Savant was once listed in the *Guinness Book of World Records* as having that distinction, with a putative score of 228. Although both the claim and the score are controversial, she does illustrate an important point: psychometric genius does not always correspond to historiometric genius. Since 1986, her chief claim to fame has been the column 'Ask Marilyn' that appears each Sunday in *Parade* magazine. Here she answers questions and solves puzzles posed to her by the column's readers. She has not yet made a single contribution that would make her eligible for the distinction of being called a genius in the historiometric sense. Her situation can be contrasted with that of her husband Robert Jarvik, who attained some degree of eminence as the inventor of the Jarvik artificial heart. Stated differently, Jarvik's claim to greatness is probably higher than vos Savant's even if the latter has the higher IQ.

Greatness

The concept of greatness is strongly associated with what was once called the Great Man Theory of History. In this view, history is essentially equivalent to the biography of a few 'great men' or 'heroes.' This theory is often credited to the British historian Thomas Carlyle, who expounded the position in his 1842 book *On Heroes, Hero-Worship and the Heroic in History*. He devotes considerable attention to such historic figures as Napoleon, Muhammad, Martin Luther, Jean-Jacques Rousseau, and Shakespeare, seeing them as decisive agents of civilization. Supposedly, the world we live in would be decidedly different if these individuals had died in the crib. A more recent illustration of this theory can be found in Hart's book *The 100*, which purports to rank 'the most influential persons in history.' The top figures on his list are Muhammad, Newton, Jesus Christ, Buddha, and Confucius. A glance of the complete 100 reveals that every one of these influential figures can be assigned to one of two categories of greatness: outstanding leadership and exceptional creativity. However, it must be recognized that another guise of greatness exists that cannot be included in either of these two categories, namely, prodigious performance. Below we examine all three forms.

Outstanding Leadership

Leadership has been defined many different ways. Some of these definitions have greater scientific utility than others do. On the one hand, we might identify leadership with some mysterious property that only certain great persons possess, such as charisma, dynamism, or magnetism. These highly romantic conceptions of leadership have immediate appeal, capturing as they do some popular myths about great leaders. However, such notions do not have much precision. Accordingly, these ideas do not lend themselves to measurement, and if scientists cannot measure an attribute, they cannot really study it.

Hence, leadership researchers tend to adopt a much less romantic conception of the phenomenon. Given a group of individuals, leadership is defined according to the magnitude of influence a given group member exerts over group problem solving, decision making, or cohesiveness. Although the person who displays the most impact is often called the group leader, groups can have more than one leader, and often do. For instance, one leader might be a 'task specialist' while another would serve as the 'social-emotional specialist.' Where the former would focus on group decision making or problem solving, the latter would concentrate on maintaining group morale or cohesiveness. Naturally, the best leaders would exhibit the capacity to accomplish both ends.

Defining leadership in this way leads quite naturally to a definition of 'great leaders.' The groups over which great leaders exert their influence are much larger, and the magnitude of that influence is much greater. The groups are whole nations, even civilizations, and the influence takes the form of new religions, laws, reforms, institutions, military victories, or territorial conquests. It is no accident that some of the highest ranked luminaries in *The 100* are religious leaders: Their impact often affected millions of people not only in their own time but also for centuries after their death.

Exceptional Creativity

The creative individual is usually defined as someone who can generate ideas that are both original and adaptive. However, both criteria are quantitative rather than qualitative variables. There are degrees of originality and degrees of adaptiveness. An idea might seem original to a person even if it is not original to others. And an idea might work for a person without working for others. For this reason, it has become standard practice among researchers to distinguish between 'little-c' and 'Big-C' creativity. The former involves the low levels of originality and adaptiveness that are sufficient for everyday life. An example might be a new recipe in response to some missing spices. The latter entails high levels of both factors. The levels may be so high that the ideas are deemed original and adaptive by many others, and perhaps even by a whole discipline, society, or civilization. Big-C creativity almost invariably results in the creation of a specific product, such as a poem, play, novel, painting, sculpture, design, composition, patent, monograph, or journal article. Furthermore, it is not enough to create a concrete product; it also must have impact. For example, a poem must be frequently anthologized, a composition must be often performed and recorded, and a scientific article must be cited by many other scientists. Indeed, at the highest level of creativity the product may become labeled as a masterwork or masterpiece.

It should be evident by now that Big-C creativity bears a striking conceptual relation with leadership. Such creators are in effect leaders, and the greatest creators are the greatest leaders. The main difference is the 'group' that is the object of influence. A great film maker exerts influence over movie audiences and critics – and over fellow film makers as well. Moreover, the impact of the greatest creators, like that of the greatest leaders, withstands the test of time. Newton was listed among the most influential creators because his contributions to mathematics and physics shaped the course of history.

Even Einstein was profoundly influenced by Newtonian physics. Einstein's special and general theories of relativity only acquire importance in the context of Newton's mechanics. One cannot launch a scientific revolution without having an established paradigm against which to revolt.

Notice that Newton and Einstein exemplify another feature of truly great creators: their impact extends beyond the specific domains to which they contributed. Both have produced ideas that became part not just of the larger intellectual community but also popular culture. The story of Newton discovering gravity while sitting under an apple tree and Einstein's famous equation $E=mc^2$ are known to people who might never have had a course in physics.

Prodigious Performance

It was mentioned earlier that Galton included athletes among the 'geniuses' in his 1869 *Hereditary Genius*. Specifically, he examined both oarsmen and wrestlers! Although it seems to be stretching the concept of genius to apply it this way, no reservations are required when we speak of greatness in sports. Athletes who receive Olympic gold medals, win world championships, or hold world records can certainly earn this status. Thus, in this sense, we can say that Michael Jordan was a great basketball player or that Joe Montana was a great quarterback. Furthermore, it is obvious that the epithet 'great' can be legitimately assigned to other exemplars of prodigious performance. For example, we certainly speak of greatness in chess, and the term is no less applicable in the performing arts, including acting, dancing, singing, and instrumental performance. In general terms, if supreme performance in a given talent domain is recognized with trophies, prizes, or awards, it becomes appropriate to view the achievements as signs of greatness.

In the case of outstanding leadership and exceptional creativity we add the proviso that the person must exert sufficient influence to earn the ascription of greatness. The same requirement might be attached to prodigious performance as well. To be great, the individual must inspire others in the same talent domain. For example, many violin and piano virtuosos have been inspired by the great Jascha Heifetz and Vladimir Horowitz, respectively. In sports, certain world records set by earlier great athletes can inspire their successors to strive to attain an even more impressive greatness. With the advent of audio and video recordings, it has become possible for somewhat ephemeral forms of achievement to provide inspiration for subsequent generations.

But must we consider all forms of prodigious performance to count as instances of greatness? There are certainly cases where we might wish to withhold the appellation. Should we count serial killers? Should greatness be ascribed to individuals who manage to make it into the *Guinness Book of Records* for feats such as stringing together the longest chain of paperclips in a 24-hour period?

Convergence

It is possible to provide a convergent definition that combines the concepts of genius and greatness. The best place to begin is Kant's definition of genius, which combines some of the

features of the earlier definition of creativity with some of the aspects of Galton's historiometric definition of genius. Kant said that geniuses must generate a product that is both original and exemplary. A product is *original* if it does not depend on the *imitation* of others, and it is *exemplary* if the product is so striking that it becomes an object of imitation by others. Although Kant confined his definition to artistic creativity, the restriction can be relaxed. Contrary to what Kant argued, Newton's *Principia Mathematica* can be considered both original and exemplary. The work provided a new model for doing physics that dominated the field until the early twentieth century. Even if Newton had to learn a lot of mathematics and science to conceive his masterpiece, the resulting product was by no means imitative. The work advanced well beyond its influences. At the same time, Kant underestimated the role of 'imitation' in artistic creativity. Contrary to what he maintained, talent alone does not suffice to produce works that are both original and exemplary. Even artistic creators have to devote a considerable amount of time to mastering the necessary knowledge and skills. In fact, research has shown that it normally takes about ten years of extensive learning and practice before anyone acquires sufficient domain-specific expertise to make superb contributions to a given domain. This ten year rule even applies to child prodigies like Wolfgang Amadeus Mozart.

Indeed, we can contend that a product cannot be viewed as a work of genius unless that product represents a domain in which the ten year rule applies, at least as an approximation. This requirement then rules out many of the achievements that populate the *Guinness Book of Records*. Whoever first came up with the task of stringing paperclips together in a 24-hour period was certainly original, and the task later became exemplary, at least in the sense that the accomplishment inspired imitators who hoped to get their names in the record books. Yet it is patently true that the ten year rule does not apply. It does not take a decade to learn how to form paperclip chains. Ten minutes is more than enough practice. Hence, even the originator of the Guinness category cannot be identified as a genius.

The preceding stipulation suggests another useful requirement. It is not just a matter that chaining paper clips requires no vast domain-specific expertise. It is also the case that it requires no exceptional intelligence to acquire and manifest that expertise. Many of the unusual feats in the record books do not require any more than an average intelligence even if they require more expertise than paperclip chaining. This observation certainly holds for most of the events that earn Olympic medals. To become a champion in shot put no doubt demands tremendous skill that is contingent on considerable practice and dedication. Still, it is unlikely that shot putters must be extremely intelligent to attain mastery of the sport.

Therefore, we may add the requisite that genius can only be displayed in a domain in which expertise acquisition and manifestation presume an intellectual power far above average. This intellectual power does not have to be of the variety assessed in the typical IQ test. It could even represent a more specialized ability, as represented by one of Howard Gardner's multiple intelligences. Einstein's expertise acquisition would then have a different intellectual foundation than Pablo Picasso's or Martha Graham's. Yet the fact would remain that the

domain-specific expertise that they acquired could not be attained and demonstrated by the average person on the street. Not everyone has the intellectual wherewithal to acquire and exhibit superlative mastery of physics, painting, or choreography.

By this point, we have said that genius requires the generation of original and exemplary products within a domain that presupposes the acquisition and manifestation of an intellectually demanding expertise. Such a conception would definitely apply to every major domain of exceptional creativity, whether scientific or artistic. Moreover, if the concept of products is broadened to encompass the principal acts of generals, politicians, diplomats, legislators, judges, and the like, then the same definition works for extraordinary leadership. As a case in point, Napoleon's battlefield tactics can be judged as both original and exemplary – to such a degree that his tactics became the objects of study in military science. The definition can also be extended to certain types of prodigious performance. Undoubtedly, chess champions who devise original and exemplary tactics would be considered geniuses. The same might hold for violin virtuosos who come up with original and exemplary interpretations of masterworks in the classical repertoire. Athletes in certain sports may also qualify if (a) their skills required a high degree of intellectual power and (b) their accomplishments proved both original and exemplary. An example might be a player in a team sport whose prodigious performance permanently changed the nature of the game.

Nonetheless, this inclusive definition might seem too inclusive. After all, might not a 'criminal mastermind' count as a genius if the crimes displayed domain-specific expertise, intelligence, originality, and inspired numerous imitators? Although the answer would have to be affirmative, given the conditions, the criminal would be considered a genius of a special type, namely an 'evil genius.' More critically, we would not assert that the hypothetical individual exhibited greatness. That ascription cannot be applied because greatness presumes that the products of genius fulfil widely shared values. That is, the achievements represent contributions to society to a whole and not to some small group or individual that has what might be deemed a parasitic relationship with the larger society. Accordingly, the person credited with the accomplishment can be broadly taken as a role model for many others to follow. Stated differently, the genius who attains genuine greatness can be proclaimed as a sociocultural paragon – a person who exemplifies what is commonly taken as the best and the brightest. He or she inspires nearly universal admiration. Consequently, their portraits or images of their accomplishments more often end up on postage stamps, T-shirts, and even cartoons. The cream of the cream will have monuments built in their memory, such as the Washington, Jefferson, Lincoln, and Roosevelt memorials in Washington DC.

In the earlier discussions of genius and greatness, it was noted that these are quantitative variables rather than qualitative attributes. The same observation applies to the convergence of genius and greatness. The greatest geniuses are those who generate the largest number of original and exemplary products or acts that are widely admired as lasting contributions to civilization. For this reason, one-shot or one-idea achievers receive much less acclaim than those whose lifetime of notable achievements cannot help but provoke awe.

Pachelbel's Canon in D is certainly a very pleasant work, but it is a rather small peg to hang a reputation on in comparison to all the masterworks generated by Johann Sebastian Bach. Worse yet, Pachelbel's best cannot really compare with Bach's best, so the former is overwhelmed by both quantity and quality. Necessarily, then, Bach must be credited with more genius and greatness than Pachelbel. This same contrast is applicable to great leadership and performance as well. Union General George Meade established his reputation for his defeat of Confederate General Richard E. Lee at Gettysburg, yet Meade's lone achievement pales in comparison to the multiple Union victories under General US Grant.

Divergence

The previous section just outlined how genius and greatness might be viewed as converging on the same exemplars of exceptional creativity, outstanding leadership, or prodigious performance. This integration began with Kant's assertion that genius produces works that are original and exemplary, and from there added domain-specific expertise, high intelligence, productivity, and sociocultural value. Yet it must be recognized that this synthesis came with a price: unlike the psychometric and historiometric definitions of genius, the convergent definition of genius and greatness does not lend itself to direct measurement. Some of the components of the definition are too elusive or vague, such as sociocultural value. For that reason, we have to ask how psychometric and historiometric genius compare with greatness.

Psychometric Genius Versus Greatness

We have put forward that bona fide genius demands sufficient intelligence to enable a person to acquire and manifest domain-specific expertise. So what is the minimum level of intelligence that would suffice? Creativity research has often suggested a threshold IQ of 120. If we take this figure to apply to various intelligences rather than just that intelligence tapped by IQ tests, then it should be apparent that a genius-level psychometric IQ is not necessary. Being intellectually gifted should be sufficient. Even so, this threshold must undergo two reservations.

First, different domains of achievement seem to have distinct lower bounds to the amount of intelligence required. Among leaders, military leaders appear to require less raw intellectual power than do political leaders, and less intellect is demanded to become a poet than a philosopher.

Second, whatever the threshold level required for a particular domain of achievement, higher levels of appropriate intelligence are associated with higher levels of greatness. This positive relation was first demonstrated in Catharine Cox's classic 1926 historiometric study of 301 geniuses. After a team of independent raters assessed the individuals on IQ using developmental data, the resulting scores were shown to correlate positively with eminence. Moreover, the association has been replicated in several subsequent studies. For instance, it has been shown to hold for United States presidents, European monarchs, and eminent African American creators and leaders.

The upshot is that psychometric genius has a weak but positive connection with greatness.

Historiometric Genius Versus Greatness

One would think that historiometric genius would come much closer to greatness than does psychometric genius. Where the latter is predicated on a test score of some kind, the former is based on actual achieved eminence, as gauged by historiometric measures. In addition, it would seem that a luminary cannot attain eminence without producing something that satisfies the criteria that we have laid out for greatness. However, various other factors can undermine the degree of correspondence between historiometric genius and authentic greatness.

In the first place, individuals sometimes attain not fame but infamy. Not every person who makes it into the history texts, biographical dictionaries, or encyclopedias is placed there because they affirm certain sociocultural values. On the contrary, they are included as examples of what not to do – individuals to be eternally derided and damned. Benedict Arnold, John Wilkes Booth and Grigori Rasputin are illustrations. Significantly, one empirical study of 342 European monarchs looked at the relation between a ruler's eminence and his or her assessed morality or virtue. The relation was defined by a U-shaped curve. The most eminent were either highly moral or virtuous (the famous) or highly immoral (the infamous). In the history of England, a 'bad king' like Richard III is about as well known as a 'good king' like Henry V. A parallel pattern is seen in the United States presidency. Both good and bad presidents are better known than run-of-the-mill chief executives are, particularly when the failed administration resulted from a major scandal. Richard M. Nixon attracts more attention in the archival records than does Jimmy Carter.

Even worse, sometimes a person may attain distinction for reasons that have nothing to do with their actual achievements, good or bad. Shakespeare once wrote, "Some are born great, some achieve greatness and some have greatness thrust upon them." The first and last of these three alternatives present the biggest concern. A significant proportion of eminent personalities born prior to the twentieth century were members of royal or aristocratic families. Even if some of these 'blue bloods' eventually ended up being the agents of worthy deeds, and perhaps even works of genius, a large proportion entered the history books through an accident of birth. Even if royalty and the aristocracy are on the wane, that is no longer the only biological route to fame and fortune. One wonders what would be the celebrity status of Paris Hilton were she not the privileged heir to the Hilton hotel empire.

The third of Shakespeare's three alternatives is perhaps the most interesting. Sometimes people do score high on historiometric genius because of events or circumstances that thrust greatness upon them in adulthood rather than at birth. To illustrate, United States presidents who are assassinated in office are more likely to go down in history as great presidents – despite the fact that there is absolutely no evidence that they are better leaders. Similarly, European monarchs who suffer a violent death – by whatever means – are more eminent than those who die peacefully. Although such arbitrary influences are most conspicuous in leadership domains, they appear in

creativity as well. Sometimes it is just a matter of being at the right place at the right time. Karl Guthe Jansky, an engineer for Bell Labs, was assigned the task of investigating the source of static that disrupted transatlantic voice communications via short-wave frequencies. Having shown that that source of interference came from the center of the galaxy, he inadvertently became the founder of radio astronomy. Had his employers assigned him a different job, he would have been denied the opportunity to make the discovery, and someone else might have become the field's founder. Instances of utterly capricious serendipity are all too common, introducing an element of luck in historiometric indicators of genius.

Hence, once more, the association between historiometric genius and greatness is positive but weak.

Conclusion

Genius and greatness are both highly praiseworthy and intimately linked concepts. And both are closely connected with creativity. When we speak of creative geniuses and great creators, the distinction between the two becomes imperceptible. At that convergence, we can talk of individuals who generate works both original and exemplary in domains that presume that exceptional intelligence had been relegated to the acquisition of domain-specific expertise. Even though both constructs are also related to eminence, the relationship has some unpredictable ingredients that render it more ambiguous. Eminent creators need not be identical to creative geniuses or great creators. When we choose to incorporate psychometric IQ into the mix of concepts, the result is even more complex and ill defined. At present, it is impossible to determine whether the ambiguities can be resolved with additional empirical research. Perhaps the problem is more logical than empirical. The concepts of creativity, intelligence, eminence, genius, and greatness may need analyses that are more refined before their overlapping meanings can be precisely delineated.

Glossary

B-cognition Maslow's conception of love for the being of the other person or object, the highest fulfillment of which is represented in certain "peak-experiences."

Divergent thinking Thinking that results in many possible ideas as opposed to convergent thinking, which emphasizes finding the one right idea.

Flow Csikszentmihalyi's description of a state in which the individual is totally immersed in an intrinsically enjoyable experience.

IQ Intelligent quotient, originally expressed as a quotient of a measure of intellectual age divided by chronological age,

but now expressed according to deviation from the average. 100 is typically set as average with numbers above 100 representing measured intelligence above average and numbers below 100 representing measured intelligence below average.

Peak experience An experience of revelations or illuminations accompanied by a feeling of euphoria.

Zen A school of Buddhism that emphasizes the attainment of wisdom through meditation in the search for enlightenment.

What is giftedness? What is creativity? And, how are they related? There are many answers to these questions. Some view them as separate constructs, others see them as overlapping, and, still others see one subsumed under the other. Also, the views vary with time, culture, and philosophical orientation. This article will examine some of the theoretical views and relationships that are proposed.

Traditional and Untraditional Views

Early definitions usually equated giftedness with intelligence as measured by standardized intelligence tests. Therefore, giftedness was not only assessed by, but also defined by, the intelligence quotient (IQ). Lewis Terman's interpretation and use of Alfred Binet's intelligence test in the United States in the 1920s enabled the study and classification of individuals according to a measure of mental ability. Further development of intelligence tests that allowed for group administration and efficient scoring enabled wider use of these tests by schools and businesses. However, concerns about equity in the 1930s and 1940s resulted in a decline in the use of IQ tests to classify students for special classes in the United States.

There is some form of gifted education in most countries, but the ways giftedness is defined and students are identified and served vary widely. A major difference is that psychometric testing has never become as prominent in other countries as it is in the United States. In fact, the Soviet Union forbade psychological tests because they were seen as supportive of the idea of innate abilities, and thus, counter to the Soviet ideals of a classless society. Though not as extreme as in the former Soviet Union, many nations struggle to balance excellence and equity, causing their educational systems to walk a fine line in providing for gifted students.

In spite of these differences, many countries still use US models for identification and service, but with a cultural flavor of their own. For example, in much of Asia, where effort is emphasized over ability, students are not labeled as gifted for their aptitude, but rather for their achievement.

Creativity is generally defined according to the parameters of novelty and value. Dean Keith Simonton called it adaptive originality. Thus, a creative product is one that has at least some element of novelty and is of value in some domain. A creative process results in such a product, and a creative person is one who regularly produces such products. Yet, this simple definition begs the questions: "novel to whom? of value according to whose criteria?" The answers are not simple. Mark Runco discussed the complexity of defining creativity when he explained that the multidimensional construct is comprised of a constellation of abilities, some of which may be developed and some that are evident in early childhood, and incorporates intentionality, motivation, choice, strategy, and evaluation of the products in addition to other processes.

E. Paul Torrance offered three different definitions of creativity, his research definition, artistic definition, and survival definition. His research definition explains creativity as:

the process of sensing difficulties, problems, gaps in information, missing elements, something askew; making guesses and formulating hypotheses about these deficiencies; evaluating and testing these guesses and hypotheses; possibly revising and retesting them; and finally communicating the results. (1988: p. 47)

This definition, so reminiscent of the scientific process, seems less applicable to artistic creativity than problem solving or scientific creativity.

According to Torrance, his artistic definition was more helpful to him in his own creative thinking. The artistic definition is composed of a sequence of metaphors with corresponding pictures, which a former student, Karl Anderson, gave him in 1964. These metaphors are:

Creativity is ... wanting to know; digging deeper; looking twice; listening for smells; listening to a cat crossing out mistakes; getting in; getting out; having a ball; cutting holes to see through; cutting corners; plugging into the sun; building sand castles; singing in your own key; shaking hands with tomorrow. (1988: p. 49-55)

Finally, Torrance's survival definition is the most basic, and according to him, the most satisfactory.

When a person has no learned or practiced solution to a problem, some degree of creativity is required. (1988: p. 57)

There are two major differences in the issues of defining giftedness and creativity. First, the definitions for creativity are less fraught with the need for legal specifications than are definitions of giftedness because creativity in itself is not a formally identified area of educational need, except where it is part of giftedness. Second, the popular belief is that an individual can be gifted in many spheres of human endeavor, although the emphasis is usually on academics. On the other hand, creativity most often conjures images of the arts, and many lay people have trouble envisioning creativity as part of higher-level mathematics or science.

In 1950, J. P. Guilford delivered a very influential speech to the American Psychological Association emphasizing the importance of creativity. In his address, Guilford decried the fact that only 186 out of 121 000 entries in Psychological Abstracts were concerned with creativity. As the then-president of the APA, his words were given great weight, and six years later, when the first national research conference on creativity was held, the number of entries had doubled. By 1965, of 4176 references found for a cumulative bibliography on creativity, 3000 were dated after 1950.

Psychologists had been looking at conceptions of intelligence that widened the view beyond that of a unitary ability that could be designated by a single number. Although not the first to conceptualize intelligence as having more than one dimension, Guilford created a complex model of intelligence, *The Structure of the Intellect*, which included many creative abilities, including divergent thinking and transformations. This model impacted the view of intelligence, and thus, giftedness.

However, the launching of Sputnik in 1957 caused great concern in the United States about the nation's competitiveness, resulting in a renewed emphasis on giftedness, particularly in science and mathematics. It was not until the first national definition of giftedness was formulated and published in a 1972 report to the United States Congress that the broadened view of giftedness was made official. It included six areas through which a child could show outstanding potential or achievement indicative of giftedness:

1. general intellectual ability,
2. creative or productive thinking,
3. specific academic aptitude,
4. leadership,
5. visual or performing arts, and
6. psychomotor.

With this definition, creativity was subsumed under the umbrella term of giftedness as one manner in which students might show their gifts.

In the educational Amendment of 1978, the last category was deleted to prevent sports programs from diverting the money allocated for the gifted. Then, in 1988, the latest version of the US federal definition was amended to emphasize that "Outstanding talents are present in children and youth from all cultural groups, across all economic strata, and in all areas of human endeavor."

Also in 1978, Joseph Renzulli published a paper that featured a definition of giftedness that would become very popular and prominent in the field of gifted education. The Three-Ring Conception of Giftedness illustrated giftedness at the intersection of above average ability, creativity, and task commitment. He explained:

Gifted and talented children are those possessing or capable of developing this composite set of traits and applying them to any potentially valuable area of human performance. (p. 261)

Thus, creativity is seen as an important component of giftedness.

In 1986, Robert Siegler and Kenneth Kotovsky differentiated the traditional view of giftedness, one in which children are identified for school programs, usually by tests, from the type of giftedness exhibited by eminent adults who contribute to their fields. They termed the first *Schoolhouse Gifted* and the second *Creative-Productive Giftedness*, to emphasize a key difference in these two conceptions – creativity. This conceptualization implied that the addition of creativity is needed to lift giftedness to eminence.

In 1993, Robert Sternberg and Todd Lubart proposed an alternative relationship between creativity and giftedness by defining creative giftedness as composed of six resources: intelligence, knowledge, styles of thinking, personality, motivation, and environment. In this conceptualization, intelligence is subsumed under the term creative giftedness. It is a separate type of giftedness, not a part of giftedness nor a type of intelligence that makes up giftedness.

Francois Gagné's view of giftedness, as delineated in his *Differentiated Model of Giftedness and Talent (DMGT)*, differentiates between giftedness as potential and talent as developed abilities. So, according to this model, one can possess gifts in intellectual, creative, socioaffective, and sensorimotor domains, but it takes a developmental process of formal and informal learning influenced by interpersonal characteristics, environmental properties, and chance to develop into talent in specific fields. Thus, creativity can be a part of giftedness that develops into talent.

These changes in views over time are listed chronologically, but they do not represent an evolutionary change in commonly held views. The greatest changes in the definitions have been the broadening of the concept of giftedness beyond IQ, and the corresponding broadening of the concept of intelligence to incorporate more abilities. Also, the greatest change in the view of creativity has been to incorporate levels of creativity, which recognize everyday creativity as well as that of the eminent, such as in the conceptualization of little *c* and big *C*, respectively. James Kaufman and Ron Beghetto have suggested two additional levels and *Cs* – mini-*c*, which is personal and inherent in the learning process, and Pro-*c*, which represents professional-level expertise that is not eminent.

Cultural Views

No matter how we conceptualize the definitions and relationship between giftedness and creativity, cultural and socioeconomic factors will continue to impact the way different groups operationalize the concepts. A good example of this cultural

relativism can be seen in the eighteenth century response of a confederacy of six tribes of indigenous North American people, called the Six Nations, to an offer from the government of Virginia to educate the Native American youth at the college in Williamsburg. The Native Americans declined, albeit with gratitude for the offer, citing past experience with their young men being educated in such colleges:

... when they came back to us, they were bad runners, ignorant of every means of living in the woods, unable to bear either cold or hunger, knew neither how to build a cabin, take a deer [sic], nor kill an enemy, spoke our language imperfectly, were therefore neither fit for hunters, warriors, nor counselors: they were totally good for nothing.

However, to show their appreciation, the Six Nations offered to take a dozen of the young men from Virginia, educate them, and "make men of them."

In more modern examples, Ernesto Bernal found that Mexican-Americans did not give much importance to grades, a large vocabulary, and good grammar as indicative of giftedness. Instead, they valued things like liveliness and being able to make it in the Anglo world. Jean Peterson found that Latino, African American, Native American, immigrant Asian, and low-income Anglo groups viewed giftedness differently from each other and differently from mainstream teachers. Although each group differed in its focus, she found some common themes in the language of these groups when describing gifted people. They tended to put more emphasis on helping in the family and community, including leadership, building and art skills, and nonbook knowledge. Two of the groups valued not displaying what one knows, with the Native American group refusing to identify anyone as gifted. Likewise, in Asia, the proverb, "The nail that sticks up will be hammered down," reflects a view that one should try to blend in with the crowd.

In the Scandinavian countries, where the ideal of egalitarianism is especially strong, there has also been reluctance to identify any students as gifted. Yet, in much of Europe, and in countries that have modeled their education system from European systems, there has been a tradition of testing and separating students in the upper grades according to academic ability. For example, the gymnasium is the term given to selective secondary schools in German-speaking countries, as well as in the Nordic, the Benelux (Netherlands, Belgium, Luxemburg), and the Baltic countries. Likewise, the British and French, and their former colonies and commonwealths, have traditionally had systems that have attempted to separate students to prepare for the university or a trade. The tension between promoting excellence and equity has impacted schools systems all over the world.

So, too, views of creativity differ. For example, there is a difference in the way that people in western cultures view creativity as compared to the way people in eastern cultures do. In the West, creativity is usually defined as the ability to produce work that is novel, original or unexpected, appropriate, useful, or adaptive concerning task constraints. In contrast, in the East there is a focus on personal expression or understanding of an inner sense of ultimate reality. This includes a focus on meditation as a method to achieve these goals.

Yet, the experiences of creating in the East and West are undoubtedly very similar. The work of Abraham Maslow in describing B-Cognition in Peak Experiences and Mihalyi

Csikszentmihalyi in describing Flow are very reminiscent of the Zen Buddhist state when turning inward in the search for higher consciousness.

Philosophical Orientations

In a series of experiments designed to measure people's implicit conceptions of the constructs of intelligence, creativity, and wisdom, Robert Sternberg found that both professors of art, business, philosophy, and physics, as well as laypersons had systematic implicit theories of each of these psychological constructs. They had a more difficult time separating intelligence and wisdom from each other, but their conceptions of these two constructs correlated well with measures of intelligence and social intelligence/competence respectively. No measure of creativity was used.

Professors' and laypersons' implicit conceptions of creativity were highly overlapping, including an emphasis on freedom of spirit and unconventionality, aesthetic taste and imagination, inquisitiveness, and intuitiveness. Yet, they differed according to the specialized fields of the professors in expected ways. For example, art professors emphasized originality and imagination, while the physicists emphasized aspects of problem solving. This may also have been partially a function of the design in which the questions of the experts were field related: "Thus, physicists, for example, were not asked their conceptions of intelligence or creativity as they apply to philosophers, or vice versa." Another important caveat is that the respondents were all from New Haven, thus not representative of the multicultural views as discussed above. It is likely, given the research on culturally mitigated views of giftedness, that a more diverse group of participants would have used a wider variety of conceptions of these constructs.

Implications

The definitions of giftedness and creativity might not be important to individuals other than researchers who work in these areas if it were not for the practical implications. Whether creativity is considered a part of giftedness determines who is identified for gifted programs and what kinds of curriculum modifications are made for a student. In addition, the relative importance that a society places on giftedness or creativity determines central values that impact, among other things, allocation of resources, hiring, business conduct, immigration policies, evaluation of quality, and self regard.

Traditionally, giftedness as defined by intelligence has been valued more than creativity. There is evidence that teachers value gifted students more than creative students, and a look at entrance exams to colleges or the professions shows that they test academic aptitude, not creativity. However, there has been a change in recent years with more emphasis on creativity as a valued ability. This may be, as Keith Sawyer claims, because the last several decades have seen the most developed countries move away from an industrial economy and toward a knowledge economy. Recent economic reports have indicated the value of creativity for the well-being of a nation, and especially the economy. It remains to be seen whether the current worldwide economic crisis will be the catalyst for creativity that

Sputnik was for giftedness. If so, we may see an increased explosion of definitions of creativity aimed at operationalizing the construct for identification and development, and the hierarchical relationship between giftedness and creativity may be reversed.

Glossary

Brainstorming A technique for increasing idea generation that emphasizes quantity of ideas and deferred judgment.

Competition Working for individual goals or to surpass the performance of others in a group.

Cooperation Working together collaboratively toward a common goal.

Cross-functional teams Work teams that involve individuals with different job skills or expertise.

Divergent thinking style A way of thinking that emphasizes the generation of unusual or atypical responses to problems.

Electronic brainstorming Generating ideas as a group on a local computer network.

Intrinsic motivation A strong interest in an activity for its own sake rather than for external rewards such as praise or money.

Leadership style An approach to leadership that is typical of certain individuals, such as directive or participative.

Prevention focus A self-regulatory tendency in some individuals to focus on security and safety, resulting in a focus on responsibilities and avoidance of risk.

Promotion focus The tendency of some individuals to have a self-regulation system that focuses on approaching opportunities and accomplishments.

Teamwork The organization of work in terms of groups that collaborate in performing work tasks.

Transformational leadership style A type of leadership enacted by one who has charisma, is inspiring, encourages innovation, and is sensitive to the needs of individuals.

Creativity

Creativity is generally considered to involve the generation of novel but useful ideas that gain widespread acceptance. The development of novel ideas requires a certain degree of knowledge and experience, a willingness to take risks or take unique perspectives, and a style of bringing together diverse or previously unconnected domains. From the various ideas that are generated, the most useful ones must be selected and then promoted to gain social acceptance. Creativity involves some important processes such as preparation, incubation, illumination, and verification.

Most research and theory on these creativity processes focuses on individual creativity, the 'lone genius.' The classic perspective is that creativity requires certain individual characteristics and our culture tends to focus on individual geniuses. Yet creativity is essentially a social phenomenon and almost all creativity involves group processes. Geniuses such as Einstein and Freud were greatly influenced by the scholarship and mentorship of others. The development of novel ideas requires some basic knowledge in a variety of areas. This knowledge is often attained in group contexts through the role of teachers, mentors, and colleagues. These individuals may directly provide information or direct or motivate the knowledge acquisition process. Individuals may also learn to model the work and creative styles of key individuals in their group or social context. Colleagues and peers are used to obtain feedback on novel ideas or discoveries. Creative geniuses often encounter considerable resistance to their ideas but eventually their novel ideas may gain much acceptance and acclaim. Creative processes

need to successfully go through the phases of generation, incubation, evaluation, and promotion to gain widespread acceptance for novel ideas. Only a small percentage do so successfully.

Group Processes

Group interaction provides a basis for the exchange of information among group members. This information can be in the form of knowledge, skills, or new perspectives. Effective groups should have individuals with a diversity of knowledge and skills and be motivated for a full exchange of ideas. However, a number of factors inhibit groups from attaining this ideal. In their discussions, group members tend to focus on information and ideas they have in common rather than ideas that are unique to a particular individual. They also tend to evaluate ideas as they are presented and this may inhibit group members from presenting novel or unusual ideas that may receive critical reactions. In particular, group members may be hesitant to share ideas or perspectives that are contrary to the shared beliefs, values, or norms of the group. Groups tend to react negatively to those who deviate from their norms or values and often enforce conformity to norms. If group members share responsibility for a group product, some members may loaf or reduce their efforts and let others do most of the work. Unless group members are already strongly motivated to work on a particular task or project, the group context may lead to reduced motivation. If these various negative group factors are counteracted, groups have much potential to facilitate creativity.

Group Idea Generation

Creativity requires that individuals take new or unusual approaches to problems. This is sometimes called a divergent style in which there is an emphasis on unique or atypical responses. This may require a somewhat random association of different domains, sets of knowledge, or ideas. Group interaction should be ideal for such a process. One can bring together people with diverse knowledge and skills and allow them to combine these in unique ways. Certainly such a group has a greater potential for developing unique conceptual combinations than a similar group of individuals working in isolation. However, experimental studies have demonstrated that groups generate fewer ideas and fewer high quality of ideas than do similar numbers of individuals performing in isolation.

One problem with groups is the tendency toward conformity. Groups often have a strong tendency to seek consensus or agreement. Individuals who deviate from a group consensus or norm often receive negative reactions from group members. They may be criticized and rejected if they do not conform their ideas to those consistent with the group consensus. This type of reaction can be observed in creative and scientific domains as well as in areas of values and opinions. However, if conformity is the dominant force, how can innovation ever occur? Fortunately, highly motivated individuals who persist in promoting their novel ideas or perspectives may eventually gain group acceptance. Research on the influence of minority opinions in groups indicates that persistent minorities can have an impact on the beliefs of those holding the majority perspective. Furthermore, new generations that are not as committed to older paradigms are more likely to appreciate or accept these novel perspectives. Exposure to minority perspectives can even increase divergent thinking. Thus a critical factor in creative innovation is the persistent efforts by the creator to promote his or her ideas.

Another way to increase novel perspectives in the group is to encourage some degree of turnover in membership. New members will not have been involved in prior interactions with the group and thus will not have acquired some of the group biases or conclusions. The additional input from new members may stimulate additional ideas or reevaluations. However, groups may not appreciate new ideas when they have already developed some degree of consensus. Yet, new members may be useful in overcoming the tendency of the group to develop a consensus before they have fully examined all of the relevant issues (sometimes called groupthink).

Heterogeneity

A major benefit of group interaction is that it allows individuals with different educational backgrounds and expertise to exchange information and ideas. With the increasing complexity of different disciplines and areas of expertise, it is difficult for an individual to develop significant expertise in more than one area. As a result, creative advances that require the combination of information from different domains of expertise will require some form of group interaction or exchange process. Cross-functional teams in business and industry involve individuals with different job skills or expertise. Scientific research also often requires this type of diversity. Intellectually diverse

groups should be more likely to develop unique or creative ideas because they have the ability to combine many different sets of knowledge. However, such an outcome is not inevitable. Unstructured groups tend to focus on areas of expertise or knowledge that they have in common. Group members may have difficulty understanding ideas from an area where they do not have a grasp of some of the basic concepts or language. Group members often express some discomfort in groups that are diverse in cultural characteristics or backgrounds such as race, ethnicity, or language.

Individuals from different backgrounds may also have different value systems. As a result, conflicts or disagreements in diverse groups are likely. Although both emotional and intellectual conflicts can inhibit group productivity, under the right conditions cognitive conflicts can increase creativity. If conflicts stimulate individuals to reevaluate their assumptions or perspectives, group members may experience some intellectual growth. This is evident from studies where the majority viewpoint is challenged by a minority perspective. The group member presenting the conflicting perspective tends to produce negative reactions from other group members. However, if the group deviant persists in making a strong case for his or her point of view, the other group members may think more deeply about the issue and experience some degree of cognitive change. Exposure to minority perspectives in groups may even stimulate group members to take a more creative or divergent approach on other tasks or projects.

The research literature thus far has not found overwhelming support for the creative potential of diverse or heterogeneous groups, whether the diversity is based on cultural, personality, expertise, or other differences. It is presumed that groups need to overcome some of the inhibitory factors and learn how to take advantage of their diverse perspectives. It appears that positive feelings about diversity, a positive group climate, some experience as a group, and effective group sharing techniques are required to enable groups to fully tap their diversity potential.

One possible reason for the mixed results for diversity in enhancing creativity might be the role that mood plays. Both positive and negative moods have been shown to have an impact on creativity, but their effects depend on a complex mix of factors. Positive moods appear to be related to increased flexibility or divergent thinking, especially if individuals have a focus on accomplishment (promotion focus) and they involve some level of activation or arousal (such as happiness). In contrast negative mood states may increase task persistence if there is some level of activation (e.g., anger) and there is some prevention focus (a concern for safety and tendency to avoidance). These individuals may not take the 'risks' involved in divergent thinking but may be highly motivated to persist on the task and possibly come up with novel insights in that way. From this vantage point, when diverse groups are associated with activating positive feelings and a promotion focus, these factors may lead to greater creativity due to increased flexibility in the thinking process. However, when diverse groups produce some strong negative feelings and a prevention focus, these factors may lead individuals to greater creativity through increased persistence. So it will depend on what type of creative performance one is measuring to determine more precisely the potential benefits of diversity on creativity.

Group Brainstorming

Even though groups have much creative potential, they often do not attain it. In a desire to get along and please others, group members may avoid disagreements or self-censor any thoughts or ideas they feel might receive negative reactions. Groups are often formed on the basis of similarity of values, interests, or purpose. Individuals whose words or deeds conflict with the general group consensus are likely to elicit negative reactions from other group members, who will try to move the deviant member back into the group mainstream. However, conflict, disagreement, and exposure to disconfirmation of one's ideas are the seed of creativity in groups. Therefore, it is important to structure groups so that there is much tolerance of disagreement or deviant perspectives. This is the philosophy behind the brainstorming procedures developed by Alex Osborn. He noted that premature judgment of ideas shared in groups is a major inhibitor of creativity. He developed a set of rules and procedures to facilitate the exchange of ideas in groups. Groups are instructed to defer judgment of ideas in intensive idea-generation sessions. They are to express all ideas that come to mind, not to criticize ideas presented, to generate as many ideas as possible, and to build on the ideas of others. Thus there is an emphasis on the full and nonjudgmental exchange of ideas or information in a group. Only after such an exchange process will the group members or outsiders begin the task of evaluating the value or utility of the ideas generated. The brainstorming rules do seem to increase idea generation in groups, but groups often still generate fewer ideas than a comparable group of solitary brainstormers.

Why do these groups underperform? It may be hard for group members to overcome a natural tendency to self-censor unusual or unique ideas, even in groups where there may be no overt negative evaluations. Even though no negative feedback may occur, individuals still do not want to make negative impressions. Individuals in groups may also tend to reduce their efforts or loaf if there is no individual accountability for the group's performance. This is most likely if other group members appear willing to take up the slack. The group interaction process also may inhibit one's ability to generate novel ideas. When others are talking, one cannot present ideas and it may be difficult to think of new ones. Groups may also get off on tangents or elaborations that limit the time available to generate new ideas.

These various problems can be counteracted in various ways. When groups use a writing or computer-based exchange process, their performance improves significantly. Various forms of electronic brainstorming are now available to facilitate the idea-exchange process. In electronic brainstorming individuals type ideas on computers and these ideas are shared with others who are typing their ideas at the same time. At the end of the brainstorming session, the ideas are often summarized and evaluated by means of computer voting. Conventional face-to-face groups can also significantly improve their performance if they receive some training in the efficient sharing of ideas. Groups composed of members who are positively disposed to social interaction (e.g., low social anxiety or high sociability) tend to be more productive in the generation of ideas in groups.

The major benefits of group interaction for creativity may come after the interaction process is completed. When individuals have some time to reflect or let the ideas incubate, additional creative insights may occur. Thus the most beneficial pattern may be one in which group interaction and solitary reflection are interspersed. This is, of course, typical of the ways many scientific and work teams function. There are also benefits of group brainstorming experiences beyond the ideas that are generated. Participants enjoy the experience and may use it to practice or develop their intellectual skills. Group brainstorming may also be viewed positively as means of impressing others and developing appropriate organizational norms such as openness to the ideas of others.

Models of the Group Creative Process

There have been several comprehensive models of the group creative process. These models have primarily focused on the cognitive processes involved in searching one's memory for relevant information, the effects of ideas shared by others on this process, and the motivational and social factors that influence these processes. These models can account both for the negative effects of group interaction and the conditions under which one can obtain benefits of group interaction. When one member of the group is exposed to ideas from others, this may stimulate additional associations and allow individuals to build on these shared ideas. Shared ideas may also remind participants of other relevant domains or categories of knowledge and may stimulate a search of these domains. However, if individuals do not pay careful attention and process the shared ideas they will not benefit. Moreover, if the ideas shared by others limit their ability to share ideas because of time competition or because they are irrelevant to the task or distracting, the sharing process may inhibit group creativity. Benefits of shared ideas are most likely when group members have an opportunity to process ideas or rehearse and reflect upon them. This should enhance the potential associative impact. It is also important that group members are highly motivated to attend to and process the shared ideas. This motivation can come from internal factors such as a strong interest in the topic, the interaction process or external factors such as incentives for performance or valued goals. Shared ideas can also serve as a motivational factor because high levels of shared ideas by one member may motivate a high level of performance by other group members. Group members who share similar personal and performance relevant characteristics may be more likely to be a source of influence. However, group members may also pay attention to those who are very different in personal characteristics since such individuals may have unique expertise or perspectives on the issue or problem at hand.

Leadership

An important factor in group effectiveness is leadership. Most groups have either an appointed or an informal leader. A major function of the leader is to motivate each group member to contribute effectively to the group. The style of the leader has a strong impact on group functioning. Some leaders tend to be

very directive or production oriented. Their major concern is that the job gets done or the goal is achieved. Other leaders are more nondirective or person oriented. They are concerned with the personal well-being of the group members as well as goal achievement. The nondirective/person oriented style is consistent with a teamwork culture of participative management. Recent trends in teamwork have emphasized the importance of teams being autonomous or self-directed. This involves having team members with much freedom in the choice and conduct of their tasks. There is some evidence that these types of teams are most productive. Team autonomy should also be related to team creativity. Team members are more likely to be intrinsically motivated when they have a lot of choice in the conduct of their work. Intrinsic motivation exists when individuals have a strong interest in an activity for its own sake rather than as a means for external rewards such as praise or financial gain. Intrinsic motivation appears to be an important factor in the generation of creative products. A highly directive or authoritarian leadership style may inhibit or reduce such intrinsic motivation.

Participative or nondirective leadership is not inevitably better than directive leadership in enhancing group creativity. People can be motivated to work hard for both intrinsic and extrinsic reasons. Many artists and scientists reap significant financial rewards and worldly acclaim and continue to make creative contributions. Extrinsic rewards that reflect positively on one's competence may, in fact, increase the sense of efficacy that is required to take on the unusual challenges or risks that lead to significant creative accomplishments. Thus directive leaders who set high standards or goals and provide significant rewards for creative successes may significantly enhance the creative efforts of group members. Teams that experience a strong sense of challenge as well as intellectual stimulation tend to be most creative.

What then are the critical features of leader or supervisory behavior? Many of the important components are part of a transformational style of leadership, which motivates individuals to perform beyond expectations. Transformational leaders have charisma in the sense of being strong role models in terms of ability, standards, persistence, values, and willingness to take risks. They inspire by motivating followers to a shared vision, high goals, and a sense of optimism. They encourage innovation and creativity and refrain from public criticism. They are sensitive to the unique characteristics and needs of each group member and provide the appropriate level of directive or nondirective support.

Which of these styles is best for creative groups or teams? A plausible answer for this question is that different styles of leadership are needed in different phases of the group processes. A more directive or transactional style may be most helpful in leading to the production of a high quantity of ideas in a limited period of time. However, the inspirational and intellectual stimulating aspects of transformational style may be most helpful in making decisions concerning which ideas should be implemented. Thus it is clear that creativity in groups requires some degree of task and interaction structure. The leader needs to insure that the appropriate level of structure is in place, such as appropriately alternating individual and group interaction. The type of leadership or management that is likely to inhibit creativity would be characterized by

high levels of control, emphasis on external evaluation and criticism, lack of clear direction or vision, and lack of support for innovation.

Cooperation and Competition

When people work together in groups there are tendencies for competitive or cooperative relationships to develop. Some group members or groups may emphasize the need for cooperating or working with one another to achieve their common goals. Cooperation may be the only way to function effectively when the unique skills of all group members are required for success. This would be the case for many complex scientific and technological enterprises. However, cooperation is also emphasized as a generally positive orientation by those who espouse the benefits of teamwork and collaborative learning. Participants in research and development teams cite a cooperative and collaborative corporate climate as being conducive for creativity. A cooperative atmosphere should enhance the willingness to take risks, to share ideas and information with others, and to compensate for the inadequacies of some group members. However, a system that ignores individual differences in the quality of contributions is not likely to motivate group members to optimum levels of performance.

Any system of reward that is sensitive to differences in contributions to the group may induce some sense of competition among group members. In competition the goal achievement of one group member may reduce the chance of goal attainment of other group members. In competitive situations, one group member's gain is another's loss, as when only one can win a prize or get a big raise. Competition can be healthy in motivating group members to perform at a high level, but it can also lead to conflicts and a reduced willingness to work cooperatively. This problem does not occur when competition is between groups, teams, or organizations. Fierce competition among top scientific teams to be the first with a certain discovery is quite common and provides strong additional motivation for creative efforts. Effective group leadership is required to develop the appropriate balance of cooperation and competition in groups. This is likely to vary with the phase of the innovation processes. In the discovery or generation phase, cooperation may be critical for a full exchange of information and views. Once a range of ideas has been proposed, there could be some healthy competition in the development and promotion of different alternatives.

Team Innovation

Today is the era of teamwork. Most organizations have structured their work so that individuals work together as a team on a particular project. Team members are often trained in multiple skills so that they can perform a range of tasks. It is presumed that teamwork will lead to higher job satisfaction and productivity. Teamwork is also common in scientific enterprises because the complexity of most scientific problems requires individuals with a variety of skills. So much of the creative work that occurs in the business and research enterprises occurs in a group context. Researchers have only recently begun to study creative processes in these types of groups.

Studies of scientific research laboratories have shown that group interactions are important in facilitating important discoveries. These interactions often occur during regular laboratory meetings in which research findings are discussed. Creative laboratory groups are led by researchers who are willing to take risks and set challenging but realistic goals. They often may work simultaneously on a set of high- and low-risk problems to ensure that they will have some degree of success. They pay particular attention to unexpected or inconsistent results and use analogies to understand the implications of these and other findings. These analogies focus on the similarity between the ongoing research and prior research or research and concepts in other domains. Conceptual or creative change often involves the use of these types of analogies by highly expert researchers. Other important factors in the creative success of research laboratories are a diversity of expertise among the group members, a willingness to challenge one another's interpretations, and the posing of questions that stimulate group members to think about an issue in different ways.

Research on team innovation in organizations has led to a similar perspective. Innovation or development of new ideas in teams requires a supportive organizational context. Some important features of this context are explicit support by the organization of innovation, a positive interpersonal atmosphere, and an intellectually stimulating and challenging environment. It is important for the team to be committed to a clear set of goals or objectives. There is some research evidence that groups or teams striving for a specific, difficult group goal outperform those that did not have specific, difficult goals. Teams also need diversity and differences of opinion but they need to handle emotional and intellectual conflicts effectively. In addition, teams in which there is a high level of participation or communication, an open and frank exchange of conflicting ideas or opinions, and support for innovative ideas are most likely to develop innovations. Moreover, clarity of team goals and commitment to their accomplishment is associated with high levels of team innovation. Finally, high reflexive teams who have a hierarchical ordering of plans as well as both long and short range planning are more creative than low reflexive teams who do not have such plans. It is important for the organization to support these innovative efforts and to provide training for effective teamwork.

Phases of Group Creativity

Creative processes tend to go through a series of stages. A preparation stage involves the acquisition of knowledge, information, or ideas. It may take some time to digest these and to come up with some novel perspectives. This period of incubation often involves being focused on other activities. Most creative people are engaged in a variety of activities that allow for multiple incubation opportunities and potential combination of ideas from different domains. The incubation period may be followed by an experience of insight or discovery. After new ideas have been generated they have to go through a promotion or elaboration process. The creator needs to persuade colleagues and other consumers of ideas or products of the value or utility of the new ideas. This may involve considerable feedback from peers and experts in relevant domains as

ideas are sharpened or elaborated. The social judgment process can be influenced by a variety of factors. Groups may not be particularly objective in this process. The prior reputation of the innovator, the apparent novelty of the ideas, and the consistency of the ideas with prior conceptual systems will likely influence this judgment process. Groups may be wrong in their judgments if they simply focus on developing a consensus. However, if there is a full exchange of perspectives, group interaction may increase the likelihood of making correct decisions. Groups can be helpful in catching logical or conceptual mistakes, especially if these can be clearly demonstrated.

One phase of the group creative process is the selection of the best ideas from among the pool of available ideas for further evaluation and possible implementation. It appears that groups are not particularly good at picking the most novel ideas, focusing instead on the more feasible ones. Although it makes sense to focus on feasibility, it is important for groups and their leaders to make sure that the most novel or creative ideas get full consideration. Although they may not be feasible at present, they might be in the future. There are a number of guidelines that appear to enhance the effectiveness of the group decision processes. Groups should have sufficient time to evaluate all of the alternatives adequately. They should also have multiple meetings that may allow for the occurrence of unconscious processes, which may lead to better decisions in the case of type of complex issues that groups often face. Outside evaluators or experts should be consulted to make sure that group has considered all of the relevant issues.

H

Joseph Haydn 1732–1809

R J Bathurst, Massey University, Auckland, New Zealand

In our search for exemplars of creativity, we often turn to men and women of international renown. This is especially the case in the arts where names from the past and more recent times like Rembrandt, Michelangelo, Picasso, Shakespeare, Brecht, Warhol, Mozart, and Beethoven texture our landscape. These people, above others, have through their art, significantly shaped the ways in which we view the world and have added much to our notions of what it means to be creative. Not often mentioned in this list is the name Franz Joseph Haydn (1732–1809); and yet it was Haydn who reshaped the musical world so profoundly that he prepared the way for the genius of Mozart and the audacity of Beethoven.

It was Haydn, who not only enabled the flowering of the Viennese classical style, but who also set the stage for the expansive romanticism that shook the very foundations of society. It is in the life and work of Haydn that this interconnection of art, social development and politics found an expression, all accomplished by a congenial man who was able to mix easily with commoners and the aristocracy. That a medal was struck in his honor and a statue erected to celebrate his life, tributes usually reserved for monarchs and noblemen, demonstrates the great esteem he was held in his lifetime. It was not, however, his demeanor alone that saw him gain this recognition, though he was demonstrably diplomatic in his dealings with his musical peers and patrons; his obvious ability to stretch boundaries and to use his creative genius to continually challenge and recast the musical forms of his time that makes him an exemplary creator. It is not without significance, therefore, that his moniker 'Papa Haydn' still has currency today.

Haydn left very little correspondence and wrote no treatises that could offer insights into his creativity. Furthermore three early biographers – Griesinger, Dies and Carpani – relied on anecdotes, and in Dies' case, interviews with an aging Haydn, whose memory was fading, to create a picture of this man who dominated musical Europe in the late eighteenth century. All three biographies were published after Haydn's death and lack first-hand accounts of his thought processes as they developed over time. We do, though, have an extensive repertoire of extant compositions which, under any measure, represent a large and productive creative career. His works include two oratorios, 14 masses, 15 operas, more than 69 string quartets, and 104 symphonies. This record of Haydn's life preserved in his compositions demonstrate a man continually inspired by a creative energy that remained with him even in his declining years.

By way of brief biographical summary, Haydn was born in Rohrau, Austria, and at the age of six, and on recognition that he had musical talents, was sent by his parents to live with a relative Johann Matthias Frankh who lived and worked in Hainburg as a schoolmaster and choir director. Here Haydn learned the violin and harpsichord and sang treble in the church choir. At this young age his talent for singing was noted by the director of music at St Stephens Cathedral in Vienna, where he moved as an eight year old in 1740. Nine years later when his voice had fully broken and he was unable to sing the treble parts, he was dismissed. For several years he worked as a musician, busker and accompanist to the Italian composer Nicola Porpora, from whom he learned musical composition. Following a number of years of financial and employment insecurity working freelance in the court of Vienna and in various aristocratic houses, Haydn eventually in 1761 gained the position of Vice-Kapellmeister to the one of the wealthiest and politically powerful families in the Austrian Empire, the Esterházy family. In 1766 and following the death of his predecessor, Haydn became Kapellmeister. Haydn worked with the Esterházy family for 30 years first under the patronage of Prince Paul Anton Esterházy and then his successor in 1762 Prince Nikolaus.

Following this long tenure and after Prince Nikolaus' death in 1790, Haydn traveled twice to London in 1791–1792 and 1794–1795 under the auspices of J. P. Salomon. He finally settled in Vienna where he lived out his final days dying on 31 May 1809.

Once his compositional talents became fully known, Haydn lived and worked within the security of the patronage system that the Court of Eszterháza offered. Only later in his life was he able to live comfortably off the income he derived from manuscript subscriptions as the music publishing business began to thrive. The apparent ease of his financial circumstances lacks the potent narrative of an artist who kicked against the pricks of institutionalism and aristocratic control to ultimately triumph. Instead, Haydn's creative genius was enacted through his subordinate social position marked by the 'Esterhazy uniform' worn by court servants, and by the fact that much of his work was achieved in physical isolation in Esterháza.

The palace that Prince Nikolaus Esterházy constructed in 1766 to rival the Palace of Versailles was built on swampland. Although it soon became the Prince's preferred residence, especially during the summer months, for Haydn it was a barren

'wasteland' far from the bustle and musical life of Vienna. And yet it was in this isolation that Haydn's creativity found expression. Here he developed instrumental music from the old Baroque Suite – a collection of short mainly dance pieces – to what we now know as the Classical string quartet and symphony.

Under Haydn, the string quartet and symphony developed into a standard four-movement work which can be summarized as a first *allegro* movement with perhaps an introduction, a second slow movement, a third *minuet and trio* movement retained from the Baroque Suite, and a final movement which completes the set with a dramatic flourish.

However, it was not just the sheer enormity of his output nor his role in establishing the formal arrangements that developed into the Classical style that warrant focusing on Haydn. Rather it was his ability to work productively within his social context and the audacious nature of his musical innovations that make him a fascinating study of creativity. Thus with the freedom of hindsight and in recognition of the global celebrations of the bicentenary of his death, it comes as no surprise that Haydn is called "the most dangerous man in musical history" by *Kansas City Performing Arts Examiner* journalist Erick Klackner. In his 2009 article he writes that:

The most ruthless among us will stab a person in the back. The most cold and calculated among us will stab a person in the front. But it takes the most creative among us to stab a person in the front without them even knowing it. This is Joseph Haydn (n.p.).

Klackner observes that Haydn was such an unremarkable a person that today he has been overshadowed by composers with surnames beginning with 'B' (including Beethoven, Bach and perhaps even the Beatles!). And yet Klackner goes on to quote Sir Simon Rattle who announced at the BBC Proms in 2008 "probably to the surprise of many" that "there is no greater composer than Joseph Haydn" (ibid.).

What, then, are the hallmarks of his greatness and how did he express his creativity? To make these assessments I will examine his creative work from five perspectives: politics, diplomacy, motivation, musical structure, and spirituality. I will conclude with some comments that links Haydn with the contemporary quest for understanding the development of artistic creativity.

Creativity and Politics

Notwithstanding the isolation of Esterházy, Haydn did not write in a social or political vacuum. Haydn created his works during a period of scientific and political change and revolution. The industrial revolution and the changes to the civic landscape that came in its wake, along with the advances in scientific inquiry that accompanied the Enlightenment formed the backdrop of Haydn's world. Several events helped shape his musical development and creativity.

First, as a young man Haydn would have been aware of the disastrous effects for the Lisbon earthquake that occurred at 9:55 on the morning of 1 November 1755, devastating much of the city. Geologists looking back believe it to be about magnitude 9.0 on the Richter scale and the death toll was

60 000–100 000 people, making it probably the most destructive earthquake in recorded human history. The tragedy occurred on All Saints Day, an important festival and holiday in the Christian Church's calendar giving rise to questions of God's immanence and ability to protect the innocent. The necessary theodic revisions resulting from the chaos brought into question ecclesiastical authority and a consequent loss of faith of the populace in their pastors. Ultimately the effects of these revisions informed the Austrian Enlightenment and its influence on religious music which will be addressed later in this article.

The earthquake also rocked the scientific community resulting in reconsiderations of Enlightenment certainty. The need to cope with indeterminate character of such natural disasters raised questions about the ability of scientific inquiry to solve humanity's problems. Similarly scientific revisions came in the form of global exploration and in particular Lieutenant James Cook's journey on the *Endeavour* to Tahiti to observe the 1769 transit of Venus. Cook's mission in itself is unremarkable in that he was to observe the transit as one of 76 places around the earth and from these calculations extrapolate the scale of the solar system. What is remarkable, however, were the secret orders from the British Admiralty that Cook was to open once he reached Tahiti. He was ordered to travel south into uncharted waters and locate the supposed 'Great Southern Land,' a continent to balance the landmass of the Northern Hemisphere. Instead of finding another America, Cook discovered and mapped a series of small islands including New Zealand, and continental Australia. The certainties that the scientific community had claimed concerning the nature of the globe were shattered with Cook's travels.

The theological and scientific certainties that began to be undermined in the eighteenth century also spread to the political arena. Across the Atlantic, the American War of Independence 1775–1783 and in Europe the French Revolution in 1789 destabilized traditional political arrangements resulting in the rise of democratic governments in the Western Hemisphere.

This shift in power and responsibility from leaders born to their position, to democratically elected officials delegated authority by their constituents is prefigured in the Romantic turn in the arts. For Haydn this found expression in what we now term his *Sturm und Drang* (storm and stress) works composed 1767–1773, compositions that gave rise to emotional expressions that burst through the strictures of Enlightenment rationality.

For the older Haydn in London, his knowledge of changes in the political and social landscape, along with his freedom to work through compositional problems as they arose, gave him an ease with the English aristocracy. For example, as Griesinger reported:

The King and the Queen wished to keep him in England. "You shall have a place in Windsor in the summers," said the Queen, "and then," she added with an arch look toward the King, "we shall sometimes make music tete a tete." "Oh!" replied the King, "I am not worked up over Haydn, he is a good honest German gentleman." "To keep that reputation" answered Haydn, "is my greatest pride" (p. 34).

Thus, underpinning Haydn's creativity was a diplomatic ability that enabled him to work with people of varying ability and

status. His early years of working as a freelance musician in Vienna's aristocratic houses taught him valuable lessons that he was able to draw on at the Court of Eszterháza and in London.

Creativity and Diplomacy

Rather than stifling his creative drive, his many years working to please his patron and to accommodate the Esterházy's musical tastes, provided Haydn with lessons in the art of diplomacy. Haydn's first patron, Prince Paul Anton Esterházy, was a well known music lover but died after Haydn had served him for just 1 year. Paul Anton was succeeded by his brother Nikolaus in 1762 and he was equally fond of music. Thus Haydn regularly accompanied the Prince on his favorite instrument the baryton, a now extinct part of the viol family of fretted, bowed instruments played in a similar manner to the modern-day cello. It was during these extended periods of almost daily music-making with the Prince that Haydn learned how to cater for the Prince's musical preferences while experimenting with harmony and form.

Haydn's role of Kappelmeister made him responsible not only for composing new music, but also ensuring that the instruments were in constant working order. Here, then, was a man equally comfortable in the company of the aristocracy and his musical peers as well as developing his musical vocabulary through experimentation and plying his craft as instrumental repairer. In this manner he worked for 30 years gradually building his reputation across Europe.

But this reputation could have been ruined in 1772 if Haydn had not developed the necessary diplomatic skills to address a deep concern among his musicians. During the autumn of that year the Prince delayed his return to Vienna. The servants, including the musicians, being obliged to pander to their master's whims, remained at Eszterháza absent from their loved ones. They were growing restless, wanting to return home. Haydn too was suffering by being so long away from home but his status as just another contracted servant did not grant him direct access to the Prince to plead on behalf of himself and his musicians. The only tool he had at his disposal was his pen.

Haydn set about writing a symphony that would startle the Prince and encourage him to bring his long summer's holiday to a close. On that evening in 1772 Haydn produced a symphony that was radical by any measure. Now known as Symphony No 45 'Farewell' Haydn had set this symphony in the distinctive and unusual key of F sharp minor, and although to us in the twenty-first century this is not particularly striking, back then on that balmy autumn evening this would have shocked the audience. The beginning theme is an unmelodic descending triad in the violins underneath pulsating cellos and basses. The score requires the violinists to play with a harsh, short, almost hammered style that is all but impossible to perform sweetly; and by the third measure, the audience had been assaulted with clashing chords and confronted with the most unusual tonalities.

Haydn had a reputation as a musical ironist, often using unconventional harmonies and unexpected surprises to startle his listeners. On this night, though, Haydn was in the process of rearranging not only the ways his symphonies were structured

but also the natural order of this little aristocratic community. With the audience now fully awake and alert to the not-so-subtle twists and turns of this new work, the symphony continued through its four standard movements. By the final movement the feathers he had ruffled at the start of the work were now beginning to settle. This last movement began in Haydn's usual style with a spritely *allegro*. It seemed that the aristocrats' universe had returned to normalcy. But Haydn had another surprise in store. About half way into the movement, the activity suddenly stopped and the orchestra started playing a mournful *adagio*. As the music continued, one-by-one the musicians blew out the candle lighting their music and quietly shuffled off stage eventually leaving Haydn and his concertmaster Alois Luisgi Tomasini softly finishing the symphony as a duet.

For Haydn, his 45th symphony was both a creative and diplomatic triumph. Not only was he able to quell the growing anger of his musicians, he was also able to direct his employer to take remedial action while at the same time preserving the Prince's dignity. The elegant industrial action where the musicians artistically withdraw their labor by quitting the stage, signaled a new style of leadership where creativity and organizational activity merge together under the notion of 'principled infidelity' (see Hoyle and Wallace, 2008). Hence, here is Haydn the prudent leader using all his wisdom and creativity to secure a positive outcome for both his staff and employer, all the while helping change the social order *and* the aesthetic direction of Western music.

Further evidences of Haydn's diplomatic skills are evident after Prince Nikolaus died in September 1790. Immediately on hearing of the Prince's death, the impresario J. P. Salomon met with Haydn and persuaded him to visit London, at that time Europe's cultural capital. Although initially reluctant because of his poor English language ability, Haydn agreed, and during his two visits there in 1791–1792 and 1794–1795 he composed 12 symphonies, an opera and a number of works for chamber ensembles. However, although Haydn was feted by the English aristocracy and music-loving populace alike, his presence was not without controversy.

It was Haydn's *savoir-faire* that made him a great success in London. He was required to use the orchestra of the musical entrepreneur Giovanni Gallini, a group with whom he had no history or working relationship. Yet despite this presenting an opportunity for disaster, Haydn worked with the musicians in such a way that they became willing to meet his requirements. For, as Griesinger reports:

Through long practice he had learned in general how musicians must be handled and thus succeeded by much modesty, by appropriate praise and careful indulgence of artistic pride so to win over Callini's orchestra that his compositions were always well performed (p. 36).

However problems arose in 1792 when he discovered that a rival group, the Professional Concert, had invited one of Haydn's former pupils, Ignace Pleyel, to compose music for their annual subscription series. The Professional Concert's commercial viability was threatened by Haydn's work with Salomon. Arthur Searle writes that Haydn was wary of the potential for destructive acrimony to break out sought for appeasement. In a letter he wrote:

So now a bloody harmonious war will commence between master and pupil. The newspapers are full of it, but it seems to me that there will soon be an armistice because my reputation is firmly established here (in Searle, p. 231).

Notwithstanding that it appeared as though Pleyel was unwittingly set up by the Professional Concert to act as a foil for Haydn's popularity, Haydn sensed the potential for catastrophe. This only served to spur his creative endeavors and he deliberately set about to upstage Pleyel by further experimenting with the orchestral sound. Griesinger writes:

I asked him once in jest whether it was true that he had composed the Andante with the Drum Stroke [Symphony No. 94] to waken the English who fell asleep at his concert. "No," came the answer, "but I was interested in surprising the public with something new, and in making a brilliant debut, so that my student Pleyel, who was at that time engaged by an orchestra in London (in 1792) and whose concerts had opened a week before mine, should not outdo me" (p. 33).

The English were impressed by Haydn's versatility and, again as Griesinger reports:

Clippings from English newspapers of the year 1792, which Haydn had kept in his diary, are full of the highest praise for the originality, versatility, and productiveness of his talent (p. 28).

This penchant for dealing with warring factions and for seeking peaceful solutions arose again in 1795. With all his practical wisdom and years of experience in dealing with contrary people, Haydn offered a solution to an impasse among several musical luminaries.

On 21, January 1795, I dined at Dr Parsons', where a quarrel arose as to which of the three doctors, Parsons, Dupuis, or Arnold, should direct in the orchestra the Handel anthem at the marriage of the Prince of Wales. Dr Parsons is Kapellmeister of the Royal Chapel, the other two are Court Organists. But in England it is the organist who is chief director in all churches, and the singers are under him. Each of the three wished to conduct. As I was pressed to give my opinion, I said, "Let the junior organist play the organ, the other direct his choir, and Dr Parsons the *Instrumental Performers*; and because the singer always takes precedence over the instrumentalist, let him stand with his choir on the right, the other on the left" (p. 29).

Although Haydn's advice was rejected, nonetheless he had learned the important art of diplomacy and this was crucial to his success as a composer. Besides diplomacy, though, Haydn's biographers offer some insights into his personal drive and inner motivation.

Creativity and Motivation

Contemporary scholar Teresa Amabile ruminates on the motivations that underpin creative endeavors. Although much of her research has been conducted among research and development scientists, the essence of her ideas applies to Haydn. Amabile argues that creativity occurs under conditions when the creator is intrinsically motivated and who has a deep love for their work. This is certainly true of Haydn even to his final years. J. C. Hadden records that Haydn wrote in 1802 of his pride of knowing that his music continued to give people pleasure.

Often when contending with the obstacles of every sort opposed to my work, often when my powers both of body and mind failed, and I felt it a hard matter to persevere in the course I had entered on, a secret feeling within me whispered, "There are but few contented and happy men here below; everywhere grief and care prevail, perhaps your labors may one day be the source from which the weary and worn or the man burdened with affairs may derive a few moments' rest and refreshment." What a powerful motive to press onwards! And this is why I now look back with heartfelt, cheerful satisfaction on the work to which I have devoted such a long succession of years with such persevering efforts and exertions (p. 103).

For Haydn, composition was not an exercise in self-aggrandizement where he sought to garner both his reputation and financial reward. He was not just driven by the desire for extrinsic recognition but, rather, a desire to offer his talents for the betterment of mankind. This desire perhaps even intensified as he aged, with his mind fully engaged in compositional ideas until his death. Biographer Griesinger noted that "ideas oftentimes came to him whereby his art might still be carried much further, but his physical powers no longer permitted him to put them into execution" (p. 8). Haydn's life is testament to the creative spirit that impels people beyond accepting the *status quo* and urges them to continually experiment, even though physical powers may wane.

So far in this article I have placed Haydn within his political, scientific, and social context and have explored his penchant for diplomacy and his inner motivation to perform a social good. But what of his musical contribution and in what ways does his work offer insights into the creative process? Perhaps his primary contribution in this regard is the development he made in musical structures.

Creativity and Musical Structure

As mentioned, Haydn played a primary role in the development of the string quartet and symphonic forms that grew out of Viennese classicism. It was in this environment that he worked alongside other composers, notably his friend Wolfgang Amadeus Mozart, who as Griesinger reports, warned him against traveling to England because of his advanced age, to which Haydn retorted, "but I am still vigorous and in good health" (p. 23). Furthermore, it was to Haydn in Vienna that the young Ludwig van Beethoven came for lessons in composition. In recognition of Haydn's influence, Beethoven dedicated his first set of piano sonatas to his teacher (Opus 2 nos 1–3, 1795) along with his first String Trio (Opus 3, 1794) and first String Quintet (Opus 4, 1795).

Within this environment and using both chamber and symphonic ensembles, Haydn participated in creating what is now termed 'sonata form' or sometimes 'first movement form.' Sonata form takes on oxymoronic and paradoxical binary-ternary shape. It has two major sections, namely the beginning Exposition, where generally two themes are stated, and a concluding Recapitulation where these themes are restated, thereby giving it a binary shape. What sets sonata form apart from other binary forms, however, is a middle section between the Exposition and Recapitulation known as the Development (hence its ternary element). Although this middle section is marked by thematic (melodic) development, of more

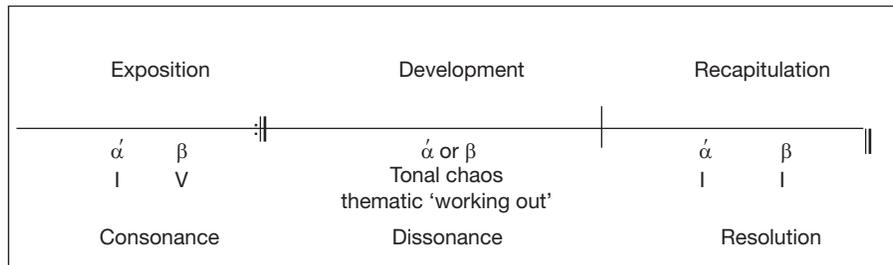

Figure 1 A synthesised plan of sonata form.

importance are the harmonic twists and turns it contains. Tonal dissonance is pushed to a point where any sense of *home* is lost to the listener. Hence this middle space of tonal and thematic ‘working out’ creates numerous possibilities for the composer to exploit. For instance, the Development opens the possibility for harmonic chaos which then challenges the composer with a problem of timing. How far can listeners be pushed before they are alienated from the purpose of the movement outlined in the Exposition? When should listeners be offered an escape route from feelings of collapse and disorientation by the Recapitulation and the safe return of the main themes and reestablishment of the home (tonic) key?

Figure 1, a synthesised plan of sonata form, shows the progression between the three sections. The melodic themes are indicated with the α and β nomenclatures. Below these are numbers in Roman numerals I and V and, following musicological convention, these numbers represent harmonic relationships of the tonic and dominant and give meaning to the structure. (There are other harmonic possibilities such as the second theme in IV the subdominant or even vi the relative minor, but in order to present a stylized image, the dominant V is chosen.) There are no such numbers in the Development section because this is marked by the collapse of tonality.

It was this musical structure of sonata form that provided Haydn with the vehicle to play with his audiences, to toy with them through wit and irony, and to surprise them with sudden changes in dramatic intensity. Thus sonata form as it morphed and evolved under Haydn’s tenure provided him with the license to experiment both with instrumentation and tonality. Although his sometimes radical compositions startled his audiences, he rarely estranged them.

Even as early as 1761 as Vice Kappelmeister, Haydn was carrying out daring musical experiments. For example, in Symphony No. 6 in D ‘Le matin,’ instead of having the bassoon and double bass playing in unison, thereby reinforcing the bass line, he gives the bassoon an independent line, an innovation that was revolutionary for the time. Similarly, Haydn experiments in this symphony with sudden and dramatic changes from *forte* to *piano*, a technique that became a signature effect for his later works.

These experiments marked an even deeper development that Haydn explored, that of harmony. The generation prior to Haydn culminated in the works of Handel and J. S. Bach. Under these latter composers, musical compositions were set within stable keys. Thus a contrapuntal work of Bach may traverse through a number of different tonalities, but always the tonic home key is present, even in its absence. Thus the tensions caused as a result of these tonal excursions are kept

manageable by the certain return to the tonic. However, under Haydn this sense of tonal predictability changed and key centers were set against each other within a movement thereby increasing the dramatic intensity of the music. Thus in Haydn’s work there is a constant pull between different tonal centers each competing with the other.

The freedom to explore musical antipathy, most notably in his *Sturm und Drang* works referred to above, is expressed in works that are at once both witty and humorous as well as tempestuous and dramatic. These works mark a reinvention of himself as an impassioned composer. Many of the works of this period are characterized by the use of the minor key (e.g., String Quartet Op 20 No 5 in F minor and Symphony No 50 in C minor), and the often use of playful false endings and deferments designed to keep the listener fully attentive.

Following this period of angst and development Haydn continued to draw on his creative talents to refine the symphonic and string quartet forms. Ultimately it was Haydn’s spirituality which reveals a paradoxical mix of outward cheerfulness and an inner restlessness that characterizes his music. Hence, it is to the inner spiritual life of Joseph Haydn that we turn and examine the music that reveals this deeper purpose.

Creativity and Spirituality

Haydn’s final years perhaps mark him as the consummate creator. Rather than living of the spoils of his fame, on his return to Vienna Haydn set about creating and solving further musical problems. During these years from his return from London until his death, he wrote six masses and two oratorios, works which form an important part of the canon of Western music.

In his last six masses (Numbers 9–14) Haydn merges the four-movement form of the symphony with the parts of the Mass Ordinary: the *Kyrie*, *Gloria*, *Credo*, *Sanctus*, and *Agnus Dei*. These two forms are contradictory. Where the symphony contains its primary intellectual content in the first movement and ends in the fourth movement with an explosive flourish, the Mass Ordinary works in reverse, with the congregation gradually moving emotionally beyond the opening *Kyrie* and the *Gloria* and *Credo* narratives to the much more contemplative and sober *Sanctus* and *Agnus Dei*. For Haydn this posed numerous compositional problems especially how to end the mass in a celebratory mode while at the same time leading the congregation into quiet reflection. However, working within the strictures of the two forms saw Haydn at his most creative,

for his solution was to superimpose three repetitions of the symphonic form over the five movements of the Mass Ordinary.

Perhaps it was Haydn's sincere yet simple spirituality that provided him with the tools to solve these compositional problems. Rosen writes that Haydn's religious faith was "simple, direct, and popular in character" (p. 368), and yet he appears to have grappled with the liturgical form in profound ways. Rosen acknowledges that the later masses are "full of admirable details and contain writing of great power" he also argues that "they remain, however, uncomfortable compromises" (ibid., p. 369). It is Haydn's ability to embrace complexity and to creatively work with the structural challenges and limitations within the mass that demonstrate a deeper spirituality that Rosen misses.

Therefore it appears as though Haydn was a deeply religious man and his turn to composing masses in the final years of his life is testament to his lifelong commitment to Catholicism and his quest for an authentic spirituality. Griesinger writes that "Haydn was very religiously inclined, and was loyally devoted to the faith in which he was raised" and notes that "All his larger scores begin with the words *In nomine Domini* and end with *Laus Deo* or *Soli Deo gloria* (In the name of the Lord, Praise to God, To God alone the glory)." He also claims Haydn "was very strongly convinced in his heart that all human destiny is under God's guiding hand, that God rewards the good and the evil, that all talents come from above" (pp. 53–54).

In Austria under the reign of Emperor Joseph II (1780–1790) Catholicism became simplified and liberal. Joseph introduced a number of reforms that saw religious practices transform from their former highly ritualized and even superstitious tenor to more simplified forms in the vernacular. These developments provided the context for Haydn to write the final two oratorios *The Creation* (1798) and *The Seasons* (1801). In particular *The Creation* demonstrates the essence of Haydn's creativity. The libretto was originally in English and tells the story of the creation of the Earth from the biblical *Genesis* narrative. Although the work ends with a hint of the Fall, it shows Adam and Eve in a state of spiritual bliss. Contrasting this oratorio with Bach's Passions (*St Matthew* and *St John*) which shows humanity imprisoned in the consequences of Adam's sin, Haydn's libretto derives more from ancient Greek optimism and respect for the body. In *The Creation*, Adam is a virtuous character rather than man whose self-will was the cause of human suffering.

This optimistic view of humanity and the creative essence that Haydn believed is derived from the Divine is expressed most profoundly in the opening section of *The Creation*. The chaotic opening is a slow *Largo* in C minor which moves to its conventional relative major E flat with shifts to the flat side of E flat minor, in bars 16–19 and 32–35, and again to D flat major, in 21–25. The melodic motifs of the opening are mere punctuating dynamic fragments rather than melodic phrases.

All these fragmentary elements ultimately lead to the entrance of the chorus singing "And the spirit of God moved upon the waters" with the tonality descending to the home key of C minor moving then to the explosion of 'Light' in bar 78 in C major offer a clue to Haydn's spirituality. The movement is both profoundly simple and yet complex. A paradoxical mix of

a shortened conventional sonata form mixed with tonalities that prefigure that of the romantics and even anticipates the miniaturist Anton Webern (1883–1945).

Musically Haydn follows a principle established in the symphonic form of putting most of the intellectual content in the first movement. The opening of *The Creation* is no exception. The sudden harmonic shift from C minor to C major depicting the creation of light is not only programmatically determined, but also contains the essence of a theology of presence, an agenda explored more recently by phenomenologist Merleau-Ponty, who writes of an 'empirical pregnancy' (p. 207) that begins an artist's work. Although not the silence of the painter's line, for Haydn the bursting forth of light is the moment of empirical pregnancy. It is this sweeping brush stroke of light that enables the becoming of being as the 'spirit of God' continues to hover and move. Thus it is Haydn's theological optimism that is not only the hallmark of his last works but is characteristic of his entire oeuvre.

Haydn the Consummate Creator

There are, therefore, many sides to Joseph Haydn. His abiding reputation is of a man of wit, a trickster with a magician's sleight of hand who leads listeners toward an expected close, all the while plotting for ways of robbing them of the satisfaction of final resolution. And yet to dismiss him as the joker in the pack is to miss the essence of his creative genius. Beneath his evident jocularity lies a darker, more angst-ridden struggle.

Nicolas Rothwell reflects on the Op 50 Prussian Quartets which Haydn wrote in his mature years in 1787. He notes that they are "contained, unyielding pieces – works that strain against the cage of form and elegance, and only at rare instants break through to resolution, and allow their themes a semblance of fluency and flow" (p. 44). And this is the mystery that is Joseph Haydn; for he was no revolutionary in the sense that he swept away all that had gone before. Rather, with the patience of a master he gradually reformed existing structures and crafted new directions that were realized by Mozart and Beethoven and later into the Romantics.

The kind of creativity that is expressed in Haydn's compositions is deeply connected with his predecessors and yet breaks through into something new. It is this that is the essence of Haydn's creative process. He did not work in a vacuum but rather used the materials available to him at the time and stretched them into previously unknown directions. Indeed the political, scientific, social, and theological environment within which he worked provided him with a context for his creative expression, enabling him to shape the direction of Western music towards the romantic revolution.

Rather than offering a simple template, Haydn continually wrestled with structural dimensions never settling into what today's business-speak could call strategic 'best practice.' On the contrary, it is the ways in which Haydn continually contested the forms within which he worked that makes him a fascinating study. He continually builds up and tears down in order to avoid finality and closure; and all done with the congenial demeanor of a man who is both comfortable and discontented; settled yet ever-reaching for transformed structures and new tonal vistas.

Glossary

Creative aspirations The interest in, and the desire for, the realization of a creation. Graphologically, creative aspirations are reflected in the height and elaboration of the upper zone of letters such as t, f, h, k, and l, and in many capitalized letters. It is the expressiveness of writing, or the totality of graphic movements, that is sufficient to differentiate one writer from another.

Creative organization The deliberate and systematic production of ideas and methods that result in creation. Graphologically, the creatively organized person can be expected to show good organization, simplification of form, and originality of graphic expression. Good organization is reflected in the overall use of space and movement in time (ease of forward movement). Simplification is the use of economic shortcuts, finding economy of time and motion, and seeking what is essential. Originality refers to spontaneity and creativity in the handling of space, form, and movement.

Creativity in writing The ability to produce new forms, to restructure stereotyped situations, to innovate, to redefine, and to improvise. Required is the aspiration to imagine and conceptualize creations, together with the organizational skills for turning such ideas into objective creations.

Graphology The study or description of handwriting in relation to changes from the ordinary which occur in some physical disorders, such as hyperactivity, learning disabilities, and alexithymia; the art or science of inferring a person's personality, character structure, and possibly, aptitudes, from the peculiarities of his or her handwriting.

Intentionality Creativity requires that a person is able to care about a state of future affairs (the realization of a creation), to organize a program to realize this state, and to persevere in this endeavor in spite of distractions, obstacles, and obstructions. On the other hand, the intention to solve a problem can lead to the deliberate and systematic production of ideas that result in creations.

Spoken words are the symbols of mental experience, and written words are the symbols of spoken words.

Aristotle

Graphology, Personality, and Culture

Eleventh century Chinese scholar Kuo Jo Hsu claimed that by using handwriting, he could distinguish "the noble man from the common man from a moral point of view." Efforts to develop graphology as a rational science were underway in eighteenth century Europe and North America, and for well over a century there has been a consistent, yet limited, interest in the relationship between handwriting and personality. Notably in France and Israel, graphology is widely used in personnel selection. This practice has been justly criticized as unfair to potential employees, for its results fail to approach the levels of validity attained by other widely available and less expensive screening devices. Graphology is not a viable method of assessing an individual's potential, and lacks ability to predict on-the-job performance. More generally, the claims of practitioners of graphology that their 'science' is sufficiently developed to have practical reliability and validity has scant support (Edwards and Armitage, 1992).

With respect to the evaluation of personality, graphology has not shown itself to be effective in well-controlled tests. Guides to graphology that describe relevant factors to examine (e.g., slants, zone, pressure, size) and the traits (e.g., character,

personality, moral) they are claimed to 'reveal' lack consistency and await standardization. Attempts by Furnham et al. (2003) to predict psychometrically valid personality measures from reliably measured handwriting factors collected under non-self-conscious conditions have also failed to establish robust relationships between graphology and personality. The claims made for graphology are either not supported, or at best only occasionally and weakly supported. Yet, the possibility of future success cannot be ruled out. Graphology should not be dismissed as mere quackery and pseudo-science, or dismissed along with astrology, parapsychology, palmistry, the Tarot, and other such occult knowledge practices, even though the roots of graphology can be found in sympathetic magical practices.

The invention of writing, as a technique of representing speech by a durable trace, was historically a dramatic leap forward for humanity. Sequential numbering, which requires a system of number signs, is inconceivable without writing, and such a number system is prerequisite for a system of economic exchange. This in turn is a requirement for the development of urbanized societies with developed economies, in which time and value are subject to calculation. Thus, while graphology has a long way to go to establish itself as a way to measure salient aspects of one's personality and character structure, writing has played a crucial role in the development of civilization.

On the individual level, writing is essential to the development of cognitive abilities. The learning of handwriting has the power to initiate reflection and to encourage the higher cognitive processes of analysis and abstraction. Wherever there are students, legible writing is required, attractive script is appreciated,

and both can affect evaluations by teachers and institutional gatekeepers. As text comes to be written directly onto computer keyboards, and as the 'man of letters' comes to be replaced by the 'blogger,' skilled handwriting has waned in importance. Because each person's handwriting is unique, however, graphology can and will long continue to be used in legal systems to detect forgery and ascertain authorship of written text. Handwriting is of interest to cognitive and affective neuroscience, because certain pathologies of brain development and neurochemical processes of brainwork can result in pathologies in speaking, reading, and writing. While humans of all cultures, as far as we know, have the potential for reading and writing, those cultures which remain largely illiterate fall short of developing in their members the most special of left hemisphere functions, which include rational analysis, and which presuppose the measurement of time and money. Literacy, together with numerical cognition, confers ability to question the epistemological and theological doctrines of one's culture and civilization, thereby attaining the potential for developing a rational, enlightened, and scientific understanding of the world. While neuroscientist Joseph Bogen (cited in de Kerckhove and Lumsden, 1988: 442) groused about our own culture being a scholasticized, post-Gutenberg-induced-industrialized computer happy exaggeration of the Graeco-Roman penchant for 'propositionizing,' we must take literacy, reading, and writing seriously as one component of what might be needed in order to avoid a possible broader 'clash of civilizations' promoted by fundamentalists of all kinds. With writing, and handwriting, comes the promise of freedom to think logically and clearly, hopefully in a way that is not limited by the lack of affect and symbolization, which Bogen called 'appositionalizing.' By being taught to decode alphabetic texts, which are both linear and sequential, the brain is encouraged to adopt strategies of sequential analysis for a wide range of other cognitive operations as well. This insight was first expressed in Plato's *Phaedrus*, in his suggestion that the art of writing bears a strong resemblance to the four rules of investigation – examination, division (into kinds or variables), order, and enumeration. This insight was articulated by Descartes, 2000 years later, in his *Discourse on Method*. We find this perennial idea further explored, and grounded in contemporary neurocognitive theory, in Martin Taylor's (1983) model of the bilateral cooperative model of reading.

Creativity: Aspirations and Organization

Creativity requires productive thinking. There is a 'dialectical' aspect to creativity in that it often involves interaction of logical-analytic/propositional and gestalt-synthetic/appositional modes of thought, which are ordinarily lateralized to the left and right sides of the brains of right-handed adults without substantial brain damage. Thinking that integrates these two opposite yet complementary modes of thought is perhaps necessary for creativity, but alone is insufficient because of linkages between creativity and intentionality. On the one hand, creative ideas can be stimulated by the integration of analytic and synthetic thought. But creativity means more than an idea and an aspiration; also required is that something actually be created, a creation.

Graphology, the Study of Handwriting

Proponents of graphology (see Brannan, 2004) maintain that writing can be used to identify a creative personality insofar as writing communicates not only the semantic content of words but also expresses features of the personality structure of the writer. Handwriting is a process of psychomotor gesturing, this gesturing externalizing and thereby giving creative expression to ideas and the contents of inner speech. Qualitative-holistic and quantitative methods of graphological analysis have been developed with the intention of enabling graphologists to make inferences about 'sectors' or 'constellations' of personality structure on the basis of detailed features of handwriting, on the levels of words and letters. One well-known quantitative graphological technique, the Psychogram, was developed by K. Roman and given formalization and elaboration by D. Anthony. The most usual objective of graphology in general, and the Psychogram in particular, is to represent an integrated view of an individual's personality. The forty separate graphic indicators of the Psychogram (organization, rhythm, speed, rightward trend, pressure, etc.) are partitioned, on a conceptual, *a priori*, basis, into eight sectors, including 'intellect, aspirations, and creativity'. Roman wisely cautions that no single component or feature of handwriting can be interpreted without reference to others, even though for purposes of analysis they can be set apart and considered separately, viewing each one by itself. A single feature is significant only in relation to the group to which it belongs. This advice is widely ignored by graphologists. For example, Brannan (2004: 38) does not hesitate to claim that "a relatively heavy *t*-bar is evidence of strong will-power. . . . This trait implies the strength of purpose of the writer" (an inference made about Babe Didrickson [lived 1914–1956], a noted female athlete). Anthony operationally defines the intellect-aspirations-creativity sector of the Psychogram by six quite general features of handwriting samples:

1. good organizational structure;
2. innovative simplification of form;
3. upper zone elaboration ('desire to form, build, or arrange,' e.g., of the letters b, d, f, h, k, l, and t, and capitalized letters);
4. upper zone height;
5. originality, and
6. expressiveness (indicated, most generally, by an overall consistency in effort and direction).

Creativity, Thought, and the Brain

Gestalt-synthetic, holistic thought (in the adult, right-handed person) is usually associated with the functioning of the right cerebral hemisphere (RH) of the human brain, and logical-analytic thought with the left hemisphere (LH). Intentionality, along with planning, monitoring, editing, commanding, and controlling, is associated with the executive-level functioning of the frontal lobes of the brain. The frontal lobes evolved out of, and remain closely linked to, the limbic structures which provide emotional response to images and models, and which, in combination with memory and information about the body and environment, enable the frontal lobes to direct

meaningful, goal-directed actions in the interests of the self. The goal-directed behavioral programs of the frontal lobes extend to intentions and plans. These programs are complex results of social development and are formed with the participation of language, which enables abstraction, categorization, and generalization, and which is much involved in the control and regulation of behaviour.

Dysgraphia and the Split Brain

Dysgraphia – handwriting disability, can come about, as we have seen, as a result of living in a largely preliterate culture. It can also come about as a developmental disorder due to genetic accident, injury, or illness. Dysgraphia seldom occurs in isolation, as it is often concomitant with related disorders such as alexithymia, dyslexia, dyscalculia, parkinsonism, hepatic encephalopathy, aphasia, attention-deficit disorder, and various emotional pathologies. Still-developing dysgraphic students are apt to also have physical disabilities, sensory impairments, mental impairments, or emotional disorders. Dysgraphia stands in the way of academic success. Students with dysgraphia in the United States are eligible for special educational services, and are apt to be placed in categorical classroom programs designed for children with specific learning disabilities.

We can understand creativity through the study of neurological patients with a pathological lack of integration of analytic and synthetic thought. Such a group of patients are the ‘split-brain’ (cerebral commissurotomy, corpus callosotomy) patients who have had the two hemispheres of their brains surgically divided through sectioning of the corpus callosum, a structure containing some 200 million nerve fibers that directly connect the two hemispheres. This radical surgery was carried out as a treatment of last resort for severe, drug-refractory epileptic seizures. Following this operation, patients are limited in their ability to integrate the workings of the two sides of

the brain. The two hemispheres can be of two minds. One of these patients would put his arm around his wife with one hand, while pushing her away with his other hand and arm, a case of true ambivalence.

In a remarkably simple but nonetheless crucial experimental study of eight patients undergoing split-brain surgery, J. Bogen discovered limitations in both their writing and their drawing abilities. Following the operation, the right side of the body is controlled by the LH and vice versa. Therefore, performances carried out by the right hand result from LH activity, and performances carried out by the left hand are related to the activities of the RH. These patients, who were all right-handed, experienced a reduced capacity to write (dysgraphia) with their left hands but not with their right hands. They also experienced a reduced capacity to copy figures (dyscopia) with the right hand, but not with the left. The dysgraphia-dyscopia phenomena are illustrated in **Figure 1** by responses of one of the split-brain patients. To measure dysgraphia, a written model of the word, ‘Sunday’ was presented. The patient was able to copy this word with his right hand (and LH) but could manage only a crude ‘S A’ with his left hand (and RH). His severe dyscopia is illustrated by his effort to copy a cross and a solid cube. He copied the figures quite well with his left hand, but with his right hand showed no configurational ability. It would appear that he started at the top (line segment 1) and then proceeded clockwise. He drew the first seven lines correctly; but at the end of line 7 (the ‘bottom’ line), he made a wrong turn, leftward, instead of up upward and to the right. It is as if the left side of the cross fell off its axis between lines 7 and 8. It appears as if he grasps the figure as a sequence of lines that turn either to the left or right, but made one wrong turn. This could have been an effort at linear direction finding, but it most certainly was not an exercise in gestalt completion. For the cube, it is as if he had merely used his left-hemisphere recognition of a number of connected lines, and then made a visual gesture of stacking some of them up. He showed no configurational ability to recognize the cube as a whole or gestalt.

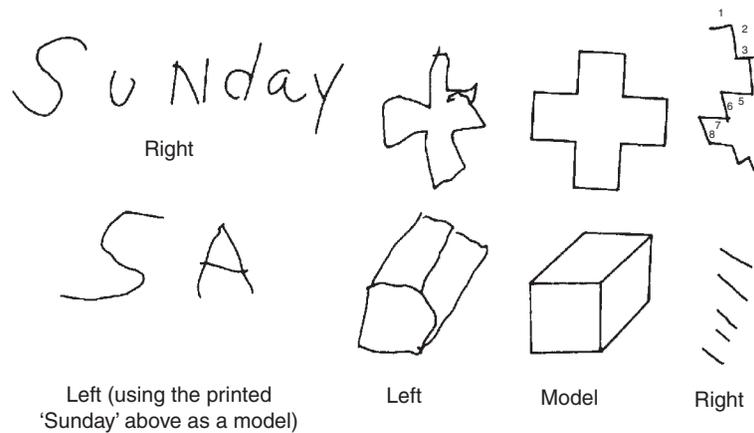

Figure 1 At the left side of the figure, dysgraphia in the left hand (and right hemisphere) illustrated by the inability of a commissurotomy patient to write the word “Sunday” with his left hand (and right hemisphere). At the right, dyscopia in the right hand (and left hemisphere) illustrated by a patient who, while able to copy models of a cross and a cube with his left hand (and right hemisphere), failed to do so with his right hand (and left hemisphere). Reproduced from J Bogen (1969) The other side of the brain I: Dysgraphia and dyscopia following cerebral commissurotomy. *Bulletin of the Los Angeles Neurological Societies*, vol. 34, Figure 5b, p. 83.

Alexithymia, Creativity, and the Split Brain

Klaus Hoppe and J. Bogen found *alexithymia* – a cognitive-affective disturbance involving a lack of words for feelings, in twelve commissurotomy patients. Alexithymia literally means ‘no words for feelings.’ A better term would have been the existing Greek work, *a-thymo-alexia*, which means ‘no feelings for words.’ By analogy, the problem of the color-blind person is not a lack of words for colors, but rather a lack of colors for words. The alexithymic person has difficulty describing his or her feelings to other persons. There is a difficulty in verbally identifying feelings but also in distinguishing feeling from bodily sensations. There is a lack of symbolizations, termed ‘asymbollexia’ by Hoppe in 1985, and an impoverishment of fantasy life, resulting in a utilitarian, operational mode of thinking. The opposite of alexithymia, called ‘symbollexia’ by

Hoppe, is apt to be taken for granted in the everyday world but must be considered a form of creativity in its own right. According to interhemispheric transfer deficit theory, alexithymia results from a physical or functional disconnection of the two hemispheres, such that the cognitive representations of negative affects (of the RH) cannot be articulated in words (by the LH). J. J. Bogen and G. Bogen (1969: 201) have argued that an interaction between the modes of thought of the two sides of the brain is necessary for creative thinking. They suggest that “to demonstrate that division of the corpus callosum leads to a loss of creativity, we need some measure of creativity.”

Handwriting provided such a measure in a further alexithymia study carried out by TenHouten et al. in 1985, which included eight of the twelve split-brained patients of the Hoppe-Bogen study and eight precision-matched control subjects. All 16 subjects were shown a 3-minute videotaped film

Commissurotomy	Normal
AA 1. Baby all for his self in a bed hasn't even his self.	Caa Two toys monkeys hugging The baby disappears An older child swinging
NW Baby was not surprised. By a object around her wheel. Some words	Cnw Then she ran picked her and a car I think, ran

RM YOU DON'T SHOW IT RIGHT IT'S ALL MIXED UP	Crm The baby likes his toys and is secure the baby leaves the crib and his bed
LB 4. Next he played with a blue ball, which rolled into the street, he pursued the ball as a car was coming.	Cib 1. In the first part of each section there was happening?

Figure 2 Selected handwriting specimens of eight commissurotomy patients (left column) and eight precision-matched normal control subjects (right column). Reproduced from TenHouten WD (1994) Creativity, intentionality, and alexithymia: A graphological analysis of split-brained patients and normal controls. In: Runco MD, Hoppe KD, and Shaw M (eds.) *Creativity and Affect*, p. 336. Norwood, NJ: Ablex.

four times. The film's two scenes depicted, with music and visual images but no words, the deaths of a baby and of a boy. After the second showing of this film, all subjects were instructed to write four sentences expressing what they felt about the film. Small samples of the handwriting of the subjects are shown in Figure 2. The commissurotomy patients, in comparison to controls, were described by Psychogram variables as having less form and arrangement in the elaboration of their writing's upper zone and they wrote in a less expressive way. They were relatively constricted in their expression of self, as their graphic gestures lacked individual distinctiveness. Their script lacked rhythm and coordination of movements, organization, and trizonal dynamics. In addition to its arrhythmic quality, their handwriting lacked an effective articulation of the letters with connecting strokes, which according to Anthony, indicates a lack of 'creativity of the graphic expression.' Patients were infirm in their writing stroke (ductus) and showed an arrhythmic alternation of pressure and release. Here they can be said to lack control of sensuous expression. Their writing lacked consistency in the slant of the letters. There is inadequate control over alignment and direction of lines and spaces between lines. And finally, there was a general irregularity in these patients' script. The handwriting samples were scored on the Psychogram by a professional graphologist, Marc Seifer, who was told only the age and sex of the writers (standard procedure in graphology). The six variables classified as indicators of creativity were inter-correlated, with the result that all correlations but those between Organization and Upper Zone Height were positive. A factor analysis of this correlation matrix resulted in a two-factor solution, meaning that there are two latent, abstract concepts which might explain the correlations.

Aspirations and Organization Measurement

The two upper zone variables – Upper Zone Elaboration and Upper Zone Height – joined Expressiveness in the first factor. Anthony defines 'aspiration' as a desire for the realization of values – of "ideals, ambitious intellectuality, power, honour, excellence . . ." (1977: 3). He argues, "Graphologically, it is commonly reflected by the upper zone elaboration . . . and upper zone height (. . . interest and aspirations above the daily routine, the intellectual guiding principle)" (1977: 3). Anthony defines Expressiveness as "those graphic movements which are 'sufficiently distinctive to differentiate one individual from another.' These can include a flair for dynamic design and spontaneous movements on the positive side, or by a stultifying rigidity and static immobility on the negative" (1977: 3). This three-variable factor was named Creative Aspiration. The second factor attracted the other three intellect-aspirations-creativity sector variables: Organization, Simplification, and Originality.

Organization refers to the writer's overall use of space and movement in time (ease of forward motion). Here, the emphasis is on form and design; figure and ground; and unity, coherence, and coordination. If 'creativity' is defined, as in Anthony, as "the ability to produce new forms, to restructure stereotyped situations, to invent or innovate, to redefine, to improvise" (1977: 3), then good organization can be interpreted as a rather global measure of creativity. Anthony states that, "high scores for simplification and originality . . . are indicative of creativity"

(1977: 3). Simplification of form means economic shortcuts in writing, seeking economy of time and motion, and seeking what is essential. Originality has the commonsense meaning of the term, here referring to "spontaneity . . . and creativity in the handling of space, form, and movement." The three variables forming this factor were together named Creative Organization. The person of high creative aspiration is apt to be known for his or her original ideas; the person of high creative organization not only has creative ideas, but possesses the methodological and organizational skills to turn such ideas into objective creations.

Intentionality Measures

The commissurotomy patients, as hypothesized above, showed significantly lower scores for Creative Aspiration and for Creative Organization than did their precision-matched normal controls. They were lower than controls for overall measures of other sectors as well – for Goal Direction, Libidinal Energy, Expression of Feelings, Control, and Script Quality (Form Level and Functional Productivity). A 'second-order' factor analysis, using six sector-level variables, led to the discovery of a possible lack of intentionality in these patients. In both alexithymia and in some psychosomatic disorders there is an impoverished level of relations to objects and goals, and a lack of dynamic energy in relation to these objects. This lack of intentionality degrades one's ability to sustain focus. The data, while only exploratory and based on samples ordinarily considered inadequate for multivariate statistical analysis, suggest that a person predisposed to act with intentionality can be expected to show, in his or her handwriting, the following features:

1. an ability to integrate intentions with actions in a fluent and rhythmic manner;
2. good alignment control, indicated by parallel lines that are unwavering and straight – here reflected in a sense of direction and orderliness – and an effective use of time, all suggesting a functional integrity toward the fulfilment of objectives;
3. writing that shows a naturalness and spontaneity in voluntary control of size, pressure, form, and arrangement;
4. writing that is firm, with rhythmic alternation of tension and release in pressure and stroke (an elastic and flexible stroke shows meaningful functioning, the making of an effective 'impression' on the world); and
5. contractions and release that are balanced and rhythmic in movement, distribution, and form, all of which indicate an ability to perform productively.

Note in this description the importance of rhythm (the strongest single variable for commissurotomy-control group differences). The commissurotomy patients' handwriting had, as global features, lack of coordination and rhythm, intentionality, and goal-directedness. Graphological variables contributing to Intentionality included, in addition to three creativity variables (Upper Zone Elaboration, Upper Zone Height, and Expressiveness): Rhythm, Trizonal Dynamics (psychical energy, goal-oriented behavior), Firmness of Ductus (the control of meaningful functioning, or making an 'impression' on the environment), Connectedness (ability to connect experiences

purposefully), Fluctuation (which integrates intentions with actions in a fluent and rhythmic manner), Slant Consistency, Alignment Control (indicating functional integrity toward the fulfilment of objectives), and Regularity (movement and arrangement volitionally controlled by the writer, an ability to concentrate, and firmness and resolution). On the sector level, data analysis indicated that intentionality is primarily a joint function of two sectors, goal direction and emotional release. An overall measure of intentionality was positively correlated both with Creative Aspiration and with Creative Organization. These results have implications for the study of creativity and of pathological lack of creativity. On the basis of other than graphological analysis, in the same study it was found that following the splitting apart of the left and right hemispheres of the brain, patients had a degraded experience of symbols.

These split-brained patients, in comparison to precision-matched normal control subjects, used few affect-laden words (a face valid index of alexithymia). Their relatively frequent auxiliary verbs suggested a passive and indirect personal style; and they used relatively few adjectives, suggesting speech that is flat, dull, uninvolved, and lacking in color and expression. Further, they were found relatively less apt to fantasize or imagine symbols (of the filmic stimulus). There was an overall lack of creativity in the content of their spoken and written verbal productions. These patients have been described as dull, flat, colorless, inexpressive, passive, indirect, lacking fantasy, unimaginative, unresponsive to symbols, and describing circumstances of events rather than feelings about these events. The evidence suggests, albeit indirectly, a lack of creativity in the content of their spoken and written verbal productions. They symbolized in a discursive way, using mainly secondary-process thought as opposed to a presentational structure consistent with primary-process thought. Hoppe (1985) noticed concreteness in their symbolizations, with an emphasis on stereotypic denotations. The strongest overall result of the handwriting analysis was that, for all of the eight pairs of subjects, patients showed less emotional release than did controls, which replicates the earlier finding of alexithymia following cerebral commissurotomy.

The hypotheses advanced on the basis of graphological variables, distinguishing the handwriting of patients and controls, were consistently supported by other data. The split-brain patients showed a strong dysgraphia in their left hands. They also showed a strong dyscopia in their right hands. Their linear-thinking left hemispheres were not informed by their right hemispheres' affective, expressive, and spatial creative mode of thought. This interhemispheric transfer deficit resulted in what can be termed an *expression dysgraphia* in the right hand, a phenomenon that had not been detected earlier. The split-brained patients did to some extent, however, express and symbolize emotions, primarily in a subconscious, negative way, through their handwriting. The alexithymia of these patients is a matter of degree, and their LHs are hardly devoid of affective expression, especially for positive emotions. Research with split-brained patients shows that their RHs are able to signal their LHs, possibly by means of brainstem connections. In two of these patients researchers found an 'affective aura' rapidly communicated from RH to LH (see TenHouten, 1994; TenHouten et al., 1988). There was in this project a continuity of results based on graphology and

on several other content-analytic measures. The criterion variables, it should be noted, were interpreted not as personality or character attributes, but rather as cognitive structures.

Smith's Study of Handwriting and Creativity

In one other study of relationships between handwriting and creativity in 71 fifth-graders, Willa Smith devised a measure of creativity in 1998, the Graphological Creativity Quotient (GCQ), based on the graphological traits spontaneity, openness, flexibility, intuition, autonomy, self-acceptance, complexity, and perseverance. Not surprisingly, an index based on these eclectic criteria did not predict across several measures of creativity, but a weak positive correlation of 0.30 ($p=0.01$) was found between the GCQ and the Torrance Test of Creative Thinking (TTCT), and between Complexity and TTCT ($p=0.05$), when the other creativity variables were controlled. Generally, the results were weak and nonsignificant.

Handwriting Sensitive to Brain Damage

Cerebral commissurotomy is a radical surgery, but handwriting can be distorted even by minor brain damage, often without the writer being aware of the change in his or her script. It can be hypothesized that insofar as a head injury is potentially life-threatening, it is one's signature that is the aspect of handwriting that is most apt to be affected. As an example, following a left-occipital injury sustained in an automobile accident, my own signature underwent three changes. First, there emerged a greatly simplified, and sometimes eliminated, first *r* of Warren. The dropped *r* was always the leftmost one, as if *rr* symbolized the left and right cerebral hemispheres: this was corrected only with a protracted, conscious effort to do so. Second, a dent emerged at the height in the upper loop of the *t* in Houten. Graphologists uniformly regard the upper zone of script with higher cognitive functioning, so that this upper-zone dented *t* would be interpreted as symbolizing a pathology of higher, cerebral functions. This script feature lasted less than a year. And third, the *en* of Houten was essentially dropped, as were other letters and numbers at the ends of words or number strings. This was likely a manifestation of a mild form of unilateral neglect of the right visual field, not uncommon following left sided occipital lobe damage. It is important that we follow Beyerstein's (1992: 397–398) sage advice, that, just because the brain is responsible for our psychological makeup as well as our writing, it does not follow that "script formation necessarily reveals deep secrets about our personal habits, talents, and predilections." Relationships between minute details of writing and social, psychological, and neurophysiological phenomena would appear to exist, but this is no guarantee that graphology can become an effective evaluative or predictive tool. Certainly, there is no *a priori* basis to assume that writing deserves any special status as a window on personality or character.

From Graphology to Graphonomics

Handwriting analysis will always have a small following on the part of interested persons who are apt to also be practitioners

of nonscientific knowledge practices such as astrology, the Tarot, and the *I Ching*. Persons can indeed experience some insight into the self as a result of having their handwriting 'read' by an adept practitioner of graphology. As one of these authors, Santoy (1994: 230) proudly concluded, "Any novice who has studied this book carefully is now capable of analyzing the handwriting of his friends or acquaintances." To assert that a written *t* with a "short, tapered horizontal stroke" reveals a person with "Caustic humor; sarcasm; destructive tendencies" is not science, but it does possess a kind of synthetic rationality. It is rooted not in science but in sympathetic magic. The problem with this 'key to personality' level of graphology is that, whatever clues are detected about an individual's handwriting script, there is no way to validate that the clues measure what it is claimed they measure, and the same clues can be interpreted in wildly different ways. There is no doubt that graphologists have overestimated the quality and value of graphology. As the same time, there is no doubt that many graphologists are highly insightful, and are able to make use of detailed features of handwritten script to construct a highly useful overview of a person's personality and character structure.

Handwriting is a phenomenon of the world, and as such is subject to scientific investigation. Advances in the study of handwriting, focused both on pathology and productivity of mind, can lead to advances in the scientific study of handwriting, from which cognitive and affective mental structures can be studied in normal and pathological populations and across cultures and writing systems. Handwriting is primarily communicative, and therefore involves social relationships with other societal members. Graphology can be understood only through multi-level analysis, of the mental, the social, and the biological. In fact, such an interdisciplinary enterprise has been underway for two decades, not under the name of graphology but rather as 'graphonomics.' This term, graphonomics, was chosen by an association of psychologists, bioengineers, physiologists, computer scientists, cognitive scientists, and engineers. The International Graphonomics Society was founded in 1985. No graphologists were invited to join this Society, and their conference proceedings cite no graphologists. Moreover, there was no mention of the possibility that handwriting might be correlated with personality. In commenting on this development, Beyerstein (1992: 415n2) observed that, in perusing published works by graphologists, he found that none of the authors "seem conversant with the published research of this

highly relevant scientific organization." The scientific analysis of handwriting, graphonomics, is too important to be left to graphologists.

Katharine Hepburn 1907–2003

E A Gavin, St. Catherine University, St. Paul, MN, USA

© 2011 Elsevier Inc. All rights reserved.

Introduction

Scrolled across the mantel of the fireplace in Katharine Hepburn's childhood home appeared the words, "Listen to the Song of Life." In her autobiography written in her mid-80s, Hepburn recalled the fireside, with her father to the left and mother to the right. This screen memory of the fireside at the Hepburns's will guide our exploration of the long, creative acting career on stage, screen, radio, and television of Katharine Hepburn.

Photograph of Katharine Hepburn supplied with permission from The Connecticut Historical Society, Hartford, Connecticut, USA.

Background

America at the turn of the twentieth century was an exciting time for Katharine Hepburn to be born. The frontier in America had ended in 1890 with railroads and communication lines stretched across the United States. New industries were

springing up, such as the Corning Glassware Works, which her great uncle founded. Suffragettes were working to make it possible for women to vote. The times supported independence and an attitude of hope.

The parents and grandparents of Katharine encouraged their children to aim high in their lives. Excellence was their expectation. Katharine's maternal grandmother, who died when Katharine's mother was a young girl, impressed upon her daughters the importance of higher education to reach their full potential. Katharine's mother earned her baccalaureate degree at Bryn Mawr and later completed a master's degree in art. Katharine's father, the son of an Episcopalian minister, was a physician who specialized in urology and venereal diseases. The Hepburns were role models of achievement for their children.

Katharine's Early Life

To understand how Katharine Hepburn became a highly creative twentieth-century woman, a sketch of her life is essential. By the time Katharine, the second of six children, was born in Hartford, Connecticut, on 12, May 1907, her parents had already established themselves in Hartford as free-thinkers. They challenged the status quo and set progressive goals for the betterment of their community and society at large. Katharine's mother became a powerful leader in the women's suffrage movement and had allied herself with the prominent British suffragette Emmeline Pankhurst, who visited the Hepburn home when Katharine was quite young. When Katharine was 10 years old, her mother became affiliated with the strong suffrage movement led by Alice Paul, who successfully pushed for an amendment to the US Constitution in 1920. This amendment legalized voting privileges for American women. When Katharine was an adolescent, her mother became close to Margaret Sanger, an eminent advocate for birth control. Her mother also worked in the Hartford community to close brothels and to help prostitutes.

Katharine's physician father helped women in his community and elsewhere who, faced with sordid circumstances, contracted venereal diseases that sometimes resulted in death. He became a leading light to improve societal conditions especially for women. In fact, both parents created sparks in the Hartford community and beyond. Ahead of his time, Dr Hepburn strongly advocated physical exercise to promote good health and he modeled this view in his everyday life. After work each day, he joined his own and neighbor children in physical activities.

From an early age Katharine became adept at tumbling, at mastering the trapeze, and even at wrestling. She became a better runner than most boys. She also became a star in swimming and diving and won awards for her success. During her grade school years, Katharine cropped her hair and wore pants (which became a kind of trademark for her throughout her

life). She called herself 'Jimmy' and enjoyed being known as a tomboy. This androgynous side of Katharine reemerged many times during her life. Androgyny is a hallmark of creative individuals. Katharine stayed away from activities, such as needlecraft, which were common among girls in that time and place.

Katharine was fortunate and grateful to have parents who honed habits, attitudes, and values that supported her eventual goal. Her parents modeled and encouraged persistence, hard work, and resilience, key attributes in creative success. Her father challenged his children to be competitive and encouraged his children to pick themselves up after failure, learn from their mistakes, and continue to soldier on. Both parents instilled a sense of freedom in their children. Katharine especially appreciated her parents' high regard for fostering individuality and a sense of freedom.

Katharine's Atypical Adolescent Years

During adolescence Katharine engaged in activities that paved the way for her career in-the-making including organizing and acting in plays. One summer, for example, she and her good friend, Ali Barbour, put together a performance of 'Beauty and The Beast' that mobilized siblings and neighborhood children. The girls charged admission to benefit Navajo Indians of the American Southwest.

Katherine was 14 when she experienced tragedy. She was visiting their mother's friend in Greenwich Village when one morning Katharine found her beloved older brother, Tom, dead of strangulation. The death was initially ruled a suicide, but that cause remained open to speculation.

Tom's tragic death had a huge impact on Katharine's life. During the aftermath of Tom's death, she became even closer to her parents. Katharine dropped out of the school she had attended and avoided contact with people who might raise questions about Tom's death. Instead, she engaged a tutor who prepared her for entrance to Bryn Mawr College at 17.

The Bryn Mawr Years

Bryn Mawr College, a prestigious liberal arts college committed to educating women had stringent standards, and was highly regarded. Katharine's early days at Bryn Mawr College were difficult. Later in life she remarked that she was unaccustomed to "being with a gang of young girls." She described it as "an agony." A well-remembered incident in the college dining hall early in her freshman year became for Katharine "almost the end of me." She overheard a sophisticated New York student refer to her as a "self-conscious beauty." That comment led Katharine to avoid dining room contacts with other students.

Fortunately, Katharine met and joined a group of compatible students. They called themselves 'The Tenement.' With them she felt secure. One of Katharine's new-found friends, Alice Palache, who helped Katharine with her studies, continued to be close to her until Palache's death in her eighties.

During her sophomore year Katharine suffered a 10-day lapse in her studies because of an appendix attack. Afterwards,

the dean wrote a letter to Katharine's father that suggested his daughter consider transferring to a different college where she might do better in her studies. Katharine's supportive father then wrote a letter to the dean, stating that if he had a sick patient in the hospital and did not know what to do for her, he would not send her home. The dean then agreed to keep Katharine as a student.

Katharine managed to get her grades high enough to act in three college plays including the lead role Pandora in a comedy by John Lyly, a forerunner of Shakespeare, called 'The Woman in the Moon.' The play was a huge hit as Katharine assumed the moods of planets, such as war-like Mars and loving Venus. Acting in this successful play confirmed Kate's determination to become an actress.

Katharine broke the news to her parents she wanted to become a professional actress. Her father thought her choice was just one step above being a streetwalker and told her financial support would be cut back if she followed that career. Katharine's mother believed her own progressive, unorthodox work was a far cry from Katharine's choice.

Katharine's parents taught her to be independent so she stood firm, determined to follow her calling. Katharine's father then provided her with a small amount of money. He told her that if things did not work out, she could always return. Perhaps because Katharine's mother strongly believed in freedom of choice, she finally went along with her daughter's decision.

Kate's Earliest Work in Acting

As a beginner in a highly competitive field, Katharine realized that she would have to stand out from others. Her tall angular appearance, her wearing pants, and an oversize man's sweater that she tied behind her with a safety pin, were not new in her demeanor. She had stood out even as a child by wearing pants and boys' attire. Now, as a young woman determined to make her mark, she realized that getting noticed called for a further step and in 1932 and 1933 she deliberately adopted a novel and appropriate tactic; she often appeared in public carrying a live white gibbon that had become her pal.

Talent, however necessary, was of itself insufficient to fulfill Katharine's dream of becoming the greatest actress in the world. She possessed valuable personal attributes, including determination, persistence, resilience, a strong work ethic, and practical common sense. She was also fortunate to have ample personal support from significant people, such as her family and devoted friends.

Katharine Hepburn launched her career known as 'Kate,' the name she kept from that time forward. Her work began on stage in 1928. After playing in 'Summer Stock,' she successfully debuted in Baltimore in 'The Czarina' and later had a small part in 'The Cradle Snatchers.' Kenneth MacKenna, the lead actor in 'The Czarina,' took an interest in helping the young actress. Because MacKenna feared that Kate's high-pitched nasal voice might prove hurtful, he gave her a letter of introduction to Frances Robinson-Duff, an extraordinary coach, who had tutored actresses such as Sarah Bernhardt.

MacKenna recognized that Kate's talent made her stand out, so he recommended her to Edwin Knopf for a small part in the Broadway production of 'The Big Pond.' Instead of getting a small part, Kate got her first big break and was cast for the lead role. However, after one performance of the pre-Broadway tryout at Great Neck, Long Island, New York, Kate was fired. Her coach, Frances Robinson-Duff, gave Kate the bad news that her performance had been too self-contained, she had rushed her lines, and her voice was too high. She also appeared stiff and failed to demonstrate feeling in a believable way. In spite of these failures, however, Robinson-Duff believed that this unusual newcomer had the makings of a remarkable actress. Even at their first meeting, Kate reminded Robinson-Duff of Eleonora Duse, a world-renowned Italian actress, who had recently died. Robinson-Duff and other professionals who understood the requirements for excellence in acting, realized early that this young actress, so different from the common run, would succeed.

Lowes and Highs of Kate's Career During the 1930s

This negative experience didn't stop Kate's ambition. From the beginning to the end of Katharine Hepburn's career, she showed powerful intrinsic motivation. She loved acting, and she did it for its own sake, and for enjoyment. Throughout her career, she worked hard to do her very best and nothing short of steady striving for improvement would satisfy her.

Kate's prodigious productivity in her first ten years of acting is amazing. Before she was 30, she had played roles in approximately 20 stage plays. In just six years, from 1932 to 1938, she starred in 15 films, which included comedies and dramas. She also opened to the imagination of her audience a variety of ways of being and living, especially with regard to women.

A Bill of Divorcement, the first film in which Kate starred, set her on the way to becoming a first-rate film actress. Kate benefited from working with George Cukor, the film's director, and with acting legend, John Barrymore. Both men thought that Kate showed remarkable talent, and both supported her on this maiden voyage. Barrymore saw something in Kate that reminded him of his mother, Georgiana Drew, who he thought was the best actress who ever lived. In late life Kate remarked on her good fortune to have had the privilege to work with Barrymore and Cukor during a vulnerable time in her career.

This early period is punctuated with sporadic criticism and major awards. On stage in New York in 1933 Kate's first performance in *The Lake* resulted in scathing criticism. Dorothy Parker, satirist, screen-writer, and short story writer, said of Kate at that time, "She ran the gamut of emotion from A to B." A few days later *The Lake* closed.

In 1934, Kate won the Academy Award for Best Actress in the film, *Morning Glory*, and just two years later she was nominated for a second Academy Award for her performance in *Alice Adams*. Some of Kate's other films including *Little Women* and *Stage Door* received Academy Award nominations. However, many of her movies in the mid-30 were flops including *Spitfire*, *The Little Minister*, *Sylvia Scarlett* and *Mary of Scotland*. Shortly after she performed in the bomb *Quality Street* a writer in a movie magazine dubbed Kate "box office poison." Perhaps the

major low point in Kate's career followed the filming of *Bringing Up Baby* in which Baby was a live leopard. That film, which opened in 1938, lost money for RKO and Kate's contract was not picked up.

Kate's Relationships: The Intermingling of Early Private and Public Life

In her senior year in college, two young men showed considerable interest in Kate. One of these, Bob McKnight, a student at Yale, proposed but she put him off. A second young man, Ludlow Ogden Smith, was waiting in the wings. 'Luddy' was highly educated and showed broad interests and Kate esteemed him as a good friend and a very nice man. 'Luddy' strongly believed that Kate would become a superb actress, and he was willing to do anything that he could to support her career goals. Kate and 'Luddy' were married in a private ceremony in December 1928.

A few weeks into Kate's first and only marriage, the young couple separated. Kate concluded that her aspirations to become a first-rate actress did not fit with being married. 'Luddy,' who came from an aristocratic, wealthy family, continued to do all he could to be supportive to Kate as her acting career unfolded. They were formally divorced in 1934 but especially during her last years Kate treasured 'Luddy' more and more for his selfless generosity and friendship.

In the meantime, Kate and another student of Frances Robinson-Duff became good friends. The young woman, Laura Harding, an heiress of American Express, moved in with Kate and they shared many conversations that supported Kate's career. They were constant companions and confidantes who moved to Hollywood as Kate's career in films got started and because Laura also knew the acting field well, she was able to provide help and understanding.

During the 1930s Kate also became close to some men, one of which was Kate's first film director, George Cukor. They became dear friends and mutually-valued professional associates. They both recognized the importance of establishing good relationships with everyone who played a role in the film's production, including the stage crew and both favored films that would touch the audience. From 1932 onward, Kate considered George her best friend in Hollywood.

Kate also met men during the 1930s in whom she became interested romantically. One of these was John Ford, a film director and a married man. Chief among Kate's would-be suitors, however, was Leland Hayward, a gifted literary agent who met Kate soon after she arrived in Hollywood. Kate found Leland easygoing and lighthearted and felt that they were well-suited to each other, enjoying his presence in her life. Moreover, Leland liked Laura Harding, Kate's housemate, and he also became a friend of Kate's mother. Leland wanted to marry Kate, but she turned him down. This lovely relationship, in Kate's eyes, lasted nearly four years. However, eventually Leland Hayward moved to the East Coast to help a client, Edna Ferber, who was opening a play called *Stage Door*. Margaret Sullavan played the leading role in the play, which became a hit. The next thing Kate heard from Leland was that he married Sullavan. Kate was thunderstruck by the news, but being resilient, she moved on.

Another major suitor, Howard Hughes, came into Kate's life in 1936 during the filming of *Sylvia Scarlett*. This famous aviator and business mogul landed his amphibian plane along Trancas Beach, the site where 'Sylvia Scarlett' was being filmed. Hughes, a friend of her costar Cary Grant, had wanted to meet Kate for some time. Hughes had been in the audience on a regular basis when Kate went on tour with the play, *Jane Eyre*. Kate soon became involved romantically with the daring aviator who then taught her to fly. Time spent with Hughes also introduced Kate to painting which she enjoyed for many years. Although Kate's romantic relationship with Howard Hughes was over by the early 1940s, their occasional future contacts were cordial.

Kate's Mastering Difficulties at Home and Reinventing Her Image

While visiting her family in 1938 and doing her best to resurrect her career, a hurricane severely damaged the Hepburns's seaside home. Kate was able to salvage some of the best furnishings of the home, but the rest was gone forever. To make matters worse, Kate's brother Dick, who tried unsuccessfully to become a playwright, also caused her trouble. After his first play failed miserably, he wrote another which satirized his family, including Kate and because she believed that Dick's new play could be hurtful to her career and to her family, she and her father did their best to suppress it.

Kate's penchant for taking stands, her questions about accepted societal assumptions, and her 'gumption,' that is, her insistence on being her own person, annoyed some critics. Some scholars think that meeting occasional obstacles, in the case of people who have many positive resources, such as Katharine Hepburn, enhances the development of creativity.

Resurrecting her damaged career, an aim that manifested well Kate's strength of character, was helped when playwright Philip Barry came to the Hepburns's seaside home to confer with her about a script he was writing and a role she would soon play. From the beginning of Kate's career, when she was an understudy for Hope Williams in the stage play *Holiday*, Barry had recognized enormous talent in the young actress. Over the years, as Kate worked with him on occasion, Barry became inspired to write a play with her in mind. Barry's script for *The Philadelphia Story* resulted in a Broadway hit in 1939. Kate recognized making a movie of the play could rebuild her film career. So she managed to buy the rights with the help of Howard Hughes.

Kate's Rise to Fame in the 1940s and 1950s

In 1940, the filmed version of *The Philadelphia Story* electrified audiences as it revealed a new Kate, a person able to express her soft and sentimental side. The reinvented Kate was fully in touch with what was going on in American society at that time. A practical woman who studied all aspects of acting, Kate realized how important it was to get the audience on her side as she moved forward in her career. She was now on her way to becoming a much-loved star.

Just two years later, MGM's film, *Woman of the Year*, brought into Kate's life a celebrated actor and a significant person,

Spencer Tracy. This first film with Tracy was a major hit and won a third Academy Award nomination for Kate. Hepburn and Tracy played a couple who held high-powered jobs and together they discovered a way to reconcile love and work.

Hepburn and Tracy acted together in nine films. They became closely associated with each other both professionally and personally for 26 years despite the fact that Tracy was married. From the record it is evident that Tracy meant the world to Kate. However, the classic New England gentlewoman kept silent publicly regarding her profound love for Tracy until after the death of his widow, Louise, in 1983.

One significant expansion of Kate's repertoire took place in the late 1940s after she was invited to play the character Rosalind in Shakespeare's *As You Like It*. Taking on a major role in a Shakespearean play exhilarated but frightened her. She accepted the challenge, enlisting the help of a British actress, Constance Collier, to serve as her Shakespearean tutor. As Collier worked intensively with Kate, she schooled her in the rhythm and cadence of Shakespeare. Kate's first major performance in a Shakespearean play opened successfully on Broadway in January 1950, followed by a tour. Kate later played a variety of Shakespearean characters on tours in the United States, England, and Australia, and she became known as an acclaimed Shakespearean actress at the American Shakespeare Festival Theatre in Stratford, Connecticut.

By 1950 Kate realized that any failure to work to improve would result in moving backwards. Her professionalism called for steady efforts to improve all aspects of her acting. She believed that L. B. Mayer, her strong supporter at Metro-Goldwyn-Mayer where she acted in ten films during the 1940s, would grant her free rein to do anything she desired on the set. Mayer's belief in her ability bolstered her confidence.

Kate spoke her mind strongly throughout her acting career. She expressed ideas about the arrangement of the set, supported the stage crew and members of the cast, and studied the background and characters of the plays in which she performed. She did not bear fools gladly, but she was ready to help anyone on the set who needed it. Kate's aim to become the best actress in the world never ceased. Her focus in midlife shifted, however, from the fame she desired in her early years to attainment of artistry in acting.

In midlife she faced extraordinary challenges and roles that moved her forward. In 1951 she took on a risky leading role, along with her costar, Humphrey Bogart, in *The African Queen*, which was filmed in the Belgian Congo under the direction of John Huston.

There she experienced some harrowing adventures. For instance, at one place near Murchison Falls, anyone who braved going ashore had to walk through a carpet of crocodiles. She confronted dangerous snakes. Kate also became very ill during filming, caused by polluted bottled water! Nevertheless, Kate was "... moved by the beauty of the country - by its vigor." (Hepburn, 1987: 120) She was also doing what she loved, acting, and she cherished what she described as that remarkable experience. For his performance in *The African Queen*, Bogart won an Oscar while Kate won another nomination as Best Actress. Later during the 1950s Kate received three additional Academy Award nominations for *Summertime*, *The Rainmaker* and *Suddenly Last Summer*.

Kate's Fruitful Golden Years

From ages 55 to 75 Kate accomplished much of her finest work. One of her most celebrated and moving triumphs was for her characterization of Mary Tyrone, the mother of Eugene O'Neill, in his *Long Day's Journey Into Night* in 1962. At the Cannes Film Festival that year, Kate was named Best Actress for playing that extremely touching role. She was also nominated by the Academy as Best Actress. In that emotionally draining film, Kate felt she reached her career high.

Kate was deeply affected by Spencer Tracy's death in 1967, but she continued to work hard. In that year, she received an Academy Award as Best Actress for her last appearance with Tracy in *Guess Who's Coming to Dinner*. She received another Academy Award for *The Lion in Winter* (1968) in which she starred with Peter O'Toole. Next she played the role of Coco Chanel, French fashion designer and perfumer, in the musical *Coco*, which she described as her most challenging and difficult part up to then. Her performance got rave reviews when it opened on Broadway in 1969.

In the same year that Kate performed in *Coco*, she played the lead role in *The Madwoman of Chaillot*. In 1971 she played Hecuba in *'Trojan Women,'* based on the tragedy by Euripides. Later, in 1975, she worked with Laurence Olivier in the televised film version of *Love Among the Ruins*. She received her final Academy Award as Best Actress in 1981 for her performance in *'On Golden Pond.'*

In her eighties, Kate wrote two books, one about her experiences in working on *'The African Queen'* (1987). The other was her autobiography, *Me: Stories of My Life* (1991). Then, in the evening of Kate's life, she acted occasionally in televised plays and made a brief appearance in a film.

The Dying of Some Lights and the Rising of Others in Kate's Latter Years

Some important lights in Kate's life went out during her last years. One was her beloved friend and film director, George Cukor. Her friend dating back to her college days at Bryn Mawr, Alice Palache, and her longtime friend, Laura Harding also died. During these years Kate spent quality time with her former husband and faithful friend, Ludlow Ogden Smith before he, too, died. Next the death of Phyllis Wilbourn, her 'right hand' in late years and a friend for over 40 years, filled Kate with sadness. Finally, Kate experienced the death of her brother Dick.

Fortunately, as many lights went out in Kate's life in old age, significant new lights turned on. One of the presences that entered her life was journalist and friend, Cynthia McFadden, who reminded Kate of herself when she was Cynthia's age. Another was friend and biographer, A. Scott Berg, who spent time with Kate during her last 20 years. These new presences in Kate's life consoled her as she faced the deaths of many people whom she loved. Together with Kate's living family members, McFadden and Berg supported Kate and kept her spirits up as much as possible as she experienced health problems and loneliness.

Kate's Responsiveness to a Flower and to a Question About Life's Purpose

Kate was never more down-to-earth, yet lifted up and inspired, than when she worked in her garden at Fenwick. She loved what she saw and felt and smelled – being close to her flowers and nurturing their growth brought her joy. During her first walk with Scott Berg in Kate's garden at Fenwick, she surprised him by asking "Have you ever looked at Queen Anne's lace, . . . I mean really looked at it, up close, and studied it? . . . Aren't they just thrilling?" (Berg, 2003: 364). Kate went on, "Now how can anybody look at this and not believe there is some higher power, some divine force at work in the universe greater than Man, some god that created it, that created all this, that created us?" (Berg, 2003: 364–365). Kate's sensitivity and responsiveness to a humble flower, that some treat harshly as a weed, revealed two poles to Kate's pondering: The concrete and the transcendent. Her keen response even to a flower evokes a question: Could this quality of spirituality have influenced the luminous quality and artistry in her acting?

Many years later, during his last long conversation with Kate, Berg asked her what she thought life was all about and what our purpose as humans really is. Without hesitation, she answered that our purpose is to work hard, to love someone, to have some fun, and, if we are lucky, to be loved back (Berg, 2003: 366).

Kate's Latest Distinctions

Kate was certainly loved. She received many honors during her final years of life and thereafter.

Hepburn was enshrined like no other female movie star. While her contemporaries faded into obscurity, Kate made the 'Dictionary of Cultural Literacy'. In 1996 she was named one of the one hundred most influential women of *all time*, up there with Eleanor Roosevelt, Marie Curie, Joan of Arc, and (I do not jest) the Virgin Mary. In a Reuters poll in 1999, Hepburn was named the 'greatest' film actress of the twentieth century, paired, fittingly, with the other all-American, John Wayne. (Mann, 2006, xx)

Kate's name, unlike most of her peers, is listed in the biographical section of Webster's collegiate dictionary. The US Postal Service also honored her memory in 2010 by issuing a commemorative postage stamp that bears her image.

Katharine Hepburn and Creativity

Katharine Hepburn's creative gift, her originality and imagination, which manifested itself in her being able to enter the stories and lives of her characters and to make them live for herself and her audience, has long been recognized. For instance, Katharine was able from the script and from her study of the character's situation, to read the mindset of Mary Tyrone, a character based on Eugene O'Neill's mother, and depict a life very different from her own. In the film based on O'Neill's play, *Long Day's Journey Into Night*, Katharine was able to feel and communicate Mary Tyrone's life and story, in a way that stirred the audience, the critics, and herself. She, along with the critics, believed that this

characterization was one of the finest in her career. Like creative musical conductors who through their interpretation of great music are able to stir the audience deeply, Hepburn was able to achieve the same goal in her acting. Again and again she was able to evoke emotions as wide-ranging as deep sorrow and jubilation in herself and her audience. She enabled her audience to empathetically cry or rejoice.

Research literature on creativity also reveals a host of attributes often found in eminent creative people that marked the life of Katharine Hepburn. These include preparedness, resilience, fierce independence, calculated risk-taking, persistence after failure, high productivity, trauma in early life, family support, extraordinary talent, and a network of influential friends and colleagues.

What may well be the major source of Katharine's creativity, that is, her imagination, "a way of knowing things that can be known in no other way" (Berry, 2010: 186), appears to lie at the heart of her greatness. Accessing Katharine's dynamic imagination was something that the science of Hepburn's time could not do. Imagination is *sui generis*, in a class all its own. Katharine's constantly changing consciousness, the handmaiden and very ground of her imagination, is somehow reminiscent of a bird in flight. When it alights momentarily, it can be witnessed only briefly, before it resumes its mysterious flight. Some see imagination "in one of its aspects" (Berry, 2010: 187) as:

... the power by which we sympathize. By its means we may see what it was to be Odysseus or Penelope, or David or Ruth, or what it is to be one's neighbor or one's enemy. By it, we may 'see ourselves as others see us'. It is also the power by which we see the place, the predicament, or the story we are in.

These wise words enable us to see what we could not otherwise see in Katharine's characterizations, that is her ability to communicate the life, the emotions, the predicament of another person. Her ability to sympathize with her character and her character's plight appear to lie at the heart of her creativity in acting (Berry, p. 187).

The Legacy of Katharine Hepburn

Katharine Houghton Hepburn died on 29 June 2003, at the age of 96. She left a legacy that testifies to her highly creative life. It includes her correspondence, transcript of interviews, films,

and records of radio, stage, and television performances. Kate's books and those of others who knew her well, such as A. Scott Berg's, can be easily found in libraries. Her name and works belong to the cultural story of the twentieth century.

Kate, an American original who strove to show through her acting that she understood people, their emotions, and the temper of the times, remains mysterious, unfathomable, and complex. In the end one is left with Kate's screen memory of her family at the fireside, with father to the left and mother to the right, with the words, "Listen to the Song of Life," scrolled across the mantel of the fireplace. This image depicts the motto of Katharine Hepburn, an actress who immersed herself fully in the creative process all her life.

Heuristics: Strategies in Creative Problem Solving

M D Mumford and W B Vessey, The University of Oklahoma, Norman, OK, USA

© 2011 Elsevier Inc. All rights reserved.

This article is a revision of the previous edition article by Michael D Mumford and Dwayne G Norris, volume 2, pp. 807–815, © 1999, Elsevier Inc.

Glossary

Concept selection Choosing relevant or critical concepts to focus on.

Conceptual combination Combination or reorganization of unique and abstract features of concepts relevant to the problem.

Creative thought The production of solutions to novel, complex, and ill-defined problems.

Heuristics The strategies people apply in executing cognitive processes.

Idea evaluation Evaluating and refining ideas relevant to problem solving.

Idea generation Developing and contextualizing ideas that may be valuable in problem solving.

Implementation planning The extensive use of forecasting and development of backup plans.

Information gathering Seeking information that is relevant to solving the problem.

Problem definition Establishing a clear perspective of what the exact problem is.

Solution monitoring Monitoring progress of solution implementation and changes resulting from implementation.

Introduction

In real-world settings, settings where performance matters, creative thinking involves the production of solutions to novel, complex, and ill-defined problems. Creative solutions to these problems are typically characterized by originality, quality, and elegance. These, apparently, straightforward statements, however, broach a question, a fundamental question, to those of us interested in understanding creative performance. What capacities must a person possess that will allow them to produce viable solutions to the kinds of problems that call for creative thought?

In fact, a variety of human capacities appear to represent potentially important influences on peoples' creative problem solving. Creative problems are demanding. As a result, motivation influences peoples' performance in solving the kinds of problems that call for creative thought. Similarly, the complex nature of creative problems suggests that openness, a personality attribute, will prove of value in accounting for creative performance. People, moreover, must search for, and appreciate, the value of creative solutions. Thus values also have been found to influence peoples' creative problem solving.

Although a variety of attributes, personality, motivation, and values to mention a few, influence peoples' creative problem solving, of particular importance is how people think about, and think through, creative problems. Thus students of creative thinking have stressed the importance of knowledge or expertise, the processing activities applied to this knowledge, such as conceptual combination and idea evaluation, and the heuristics, or strategies, people apply in executing these processes. In the present effort, we will examine the role of strategies, or heuristics, in shaping peoples' performance as they work on problems calling for creative thought.

Underlying this goal, however, is a broader concern. More centrally, the strategies people apply in working through problems calling for creative thought exert sizable effects on

subsequent performance. As a result, strategies often provide a basis for this development of effective instructional interventions. Strategies, moreover, often provide a basis for the assessment of creative potential. Thus the identification and analysis of strategies applied in solving creative problems provides a basis for a number of interventions intended to improve creative thinking and enhance our understanding of creative thought.

Knowledge, Processes, and Strategies

It is commonly believed that people cannot produce problem solutions, including creative problem solutions, without knowledge. Knowledge is usually thought to be domain specific – for example knowledge of physics versus knowledge of knitwear design. The acquisition of knowledge within a domain is frequently held to result in the acquisition of expertise. Multiple studies have shown that this acquisition of expertise influences peoples' ability to produce creative problem solutions within a given performance domain.

What should be recognized here, however, is that the acquisition of expertise within a performance domain evidences certain key characteristics. First, experts, as opposed to novices, have more information available. Second, this knowledge is better organized with knowledge organization being based on underlying concepts. Third, relationships among concepts are well defined and articulated resulting in the acquisition of viable mental models. Fourth, well organized mental models facilitate recall of knowledge and recognition of discrepancies, or anomalies, in observations, or events, within this domain.

Although these attributes of expertise all contribute to creative problem solving, if people only had existing knowledge to work with it would be impossible to produce original problem solutions. Recognition of this point has led many scholars to propose models of the processing activities by which people

work with expertise, extensive domain specific knowledge, to produce creative problem solutions. The most widely accepted model of the processes involved in creative thought is a model proposed by Mumford and colleagues.

Mumford and colleagues held that eight critical processing activities are involved in incidents of creative thought:

1. problem definition,
2. information gathering,
3. concept selection,
4. conceptual combination,
5. idea generation,
6. idea evaluation,
7. implementation planning, and
8. solution monitoring.

Within this model execution of an earlier process, for example problem definition, is held to provide an input into the operation of subsequent processes, for example information gathering and idea evaluation. These processes, moreover, are held to operate in a dynamic and recursive fashion over time, with people cycling back to reexecute earlier processes if an optimal solution is not reached at a given stage in a cycle of problem solving activities. Although these processes are held to be involved in most incidents of creative problem solving different processes take on special importance in certain domains. Thus the biological sciences stress information gathering where the social sciences stress conceptual combination.

Over the years, a variety of evidence has been accrued for the validity of this model as a description of the processes underlying creative thinking. For example studies have produced evidence indicating that the processes specified in this model, for example problem definition, conceptual combination, and idea evaluation influences the production of creative problem solutions. Effective execution of these processes has also been found to be related to real-world incidents of creative achievement such as a leader's ability to address critical incidents. Other studies have shown that effective execution of each of these processes makes a unique contribution to predicting performance on creative problem solving tasks. Still other studies have shown that the relationships observed among these processes are, in fact, consistent with this model. Finally, effective execution of these processes has been found to mediate the impact of abilities, such as intelligence and divergent thinking, on creative problem solving. Thus it appears this model provides a valid description of the key processes involved in creative thought.

What should be recognized here, however, is that each of the processes specified in this model represents a complex phenomenon in its own right. One implication of this statement is that any given processing operation may be executed in different ways. For example, in information gathering one might search broadly or one might search in depth. Similarly, in problem definition one might define a problem based on goals sought or, alternatively, the procedures to be applied in problem solving. The particular cognitive operations applied in process execution are what are referred to by the terms heuristics or strategies.

Of course, not all heuristics, or strategies, are likely to prove equally beneficial for effective execution of any given process. Thus a key question confronting students of creativity is what

strategies do, or do not, contribute to effective process execution in creative problem solving efforts. Answers to this question are of interest not only for theoretical reasons but also for practical reasons with regard to the assessment and development of creative talent and the creation of work environments likely to promote creative thought. Accordingly, in the following section we will examine the available evidence bearing on the strategies contributing to effective and ineffective execution of these creative thinking processes.

Process Specific Strategies

One study of process specific strategies examined the strategies contributing to performance during problem definition. The researchers presented 124 undergraduates with four ill-defined problems. Participants were asked to select 4 of 16 alternative definitions of this problem. These alternative problem definitions were varied to reflect definitions stressing key diagnostics, goals, problem solving procedures, and restrictions of varying quality and originality. Subsequently, participants were asked to provide solutions to two advertising and two management problems known to call for creative thought. Solutions to these problems were scored for quality and originality.

When scores on the measures of creative problem solving were correlated with and regressed on the measures of problem definition strategies, it was found that problem definition strategies were effective predictors of the quality and originality of obtained solutions producing multiple correlations in the 0.30 range. More centrally, it was found that people who defined problems in terms of high quality procedures and high quality restrictions tended to produce more creative problem solutions. Use of more original material in problem definition was not related to creative problem solving. Thus use of strategies that result in clear definition of a problem with regard to approach (e.g., procedures, restrictions) but not specific outcomes or concerns (e.g., goals, information) appears to contribute to creative thought. In other words, strategies that result in specification of a viable approach to problems appear to contribute to problem definition.

In a study of the strategies contributing to creativity in information gathering researchers asked 137 undergraduates to produce solutions to the four advertising and management problems which were scored for quality and originality. To measure information gathering strategies participants were presented with a series of four novel, ill-defined problems through web-based administration. They were then presented with a series of cards presenting different types of information bearing on the problem: cards reflecting:

1. key facts,
2. diverse information,
3. information bearing on goals,
4. information bearing on restrictions,
5. information bearing on core concepts,
6. inconsistent information, and
7. irrelevant information.

Time spent reading these cards was used to measure the depth of processing of each information type.

It was found, again, that depth of processing different types of information was strongly related to the quality and

originality of solutions obtained on the creative problem solving tasks producing multiple correlations in the 0.40 range. More centrally, it was found that people who spent more time encoding information bearing on key facts and inconsistent, or anomalous, information produced both higher quality and more original solutions on the creative problem solving tasks. Thus people who employ a focused, albeit open, search strategy, looking for critical information and anomalies during information gathering, are more likely to produce creative problem solutions.

A related study examined the strategies that contribute to creativity in concept selection. Again, the quality and originality of solutions to advertising and management problems provided the basis for assessing creativity. To assess concept selection strategies people were presented with five social innovation problems that might be understood using a number of different concepts. People were then presented with eight key concepts, reflecting general principles, specific actions, long-term actions, and evaluation of actions, where they were asked to select the two concepts they believed to be most useful in problem solving. Again, these strategy measures were found to be effective predictors of creative problem solving producing multiple correlations in the 0.30 range. More centrally, it was found that people who preferred to work with concepts bearing on long-term actions, but not concepts reflecting general principles or specific actions, produced more creative problem solutions. Thus, in concept selection, broad abstract concepts or concepts dictating a specific course of action are of limited value. Rather, creative problem solutions arise from people who prefer to employ concepts guiding long-term actions.

A study of conceptual combination provided evidence indicating that analogical thinking strategies might promote creative problem solving. More specifically, the investigators argued that identification of key features of each relevant concept, mapping the similarities and differences in these features across concepts, and elaboration of the implications of emergent features might account for the success of peoples' conceptual combination efforts. In fact, the findings obtained in this study and others support these propositions with regard to creative problem solving with the notable proviso that people may use metaphors (e.g., birds fly and flight represent freedom) when they are asked to map shared features of highly diverse concepts.

In a more recent study of conceptual combination strategies researchers asked 284 undergraduates to draw aliens. Instructions were given to think of aliens in abstract features or concrete attributes of earth animals. It was found that more original drawings of aliens were obtained when people employed abstract features in thinking about aliens. Thus, in conceptual combination, a search for abstract features linking concepts coupled with elaboration of emergent features of new concepts arising from conceptual combination contributes to creative thought.

Although new concepts provide the basis for generating the new ideas that have been the hallmark of creativity, these new concepts must be used to generate ideas. One set of studies examined the strategies contributing to idea generation. Broadly speaking, their findings indicate that a strategy where the practical implications of emergent features are explored contributes to idea generation. Thus, in a series of studies

they provided participants with abstract forms. They asked participants to imagine using this form and found that more creative ideas are produced when people envision alternative uses of the form. Moreover, creative idea generation improved when people were asked to think about problems associated with use of this object. Thus in idea generation a strategy of contextualizing emergent features to craft potential products and a strategy of identifying restrictions on the application of these products appears beneficial.

Although these strategies contribute to idea generation, multiple ideas will be generated, and, in a real-world context, these ideas must be evaluated. Thus idea evaluation is an important aspect of creative thought. Researchers have argued that idea evaluation is not simply a passive appraisal process but, instead, involves actively working with ideas. To test this proposition, one study asked 148 undergraduates to assume the role of a marketing manager developing an advertising campaign for a new product – the 3D holographic television. The advertising campaigns developed for this new product were appraised for quality, originality, and feasibility. In developing these campaigns people were presented with initial ideas of varying quality and originality. They were instructed to appraise these ideas with respect to innovative or operational efficiency standards and suggest revisions to these ideas with respect to innovative and operating efficiency standards.

It was found that when people were presented with original ideas, use of efficiency evaluations resulted in the production of the most creative advertising campaigns. When, however, people were presented with high quality ideas, use of innovative standards resulted in the production of the most creative advertising campaigns. Thus the most effective strategy in idea evaluation is a compensatory approach where people appraise and revise ideas to remediate deficiencies. Use of this compensatory strategy, moreover, implies that people must recognize unique weaknesses of ideas, and, in fact, other studies have shown that a search for idea deficiencies contributes to creative thought. This idea evaluation apparently requires a search for deficiencies in ideas and express attempts to compensate for these deficiencies.

Presumably, active idea evaluation will result in an idea one can work with to bring a new product, a new picture or a new drug, into the world. However, development of a new product is an inherently complex undertaking. Studies examining planning processes suggest that three critical strategies are involved in planning, including planning creative work. First, the person must mentally simulate the actions required as they unfold over time. Second, they must forecast the effects of various events on effective execution of this model. Third, they must develop back-up plans for opportunistic exploitation of emergent opportunities and to compensate for problems likely to arise in the work.

Some support for the relevance of these strategies has been provided. In one study, researchers asked 174 undergraduates to prepare a plan for operating a new experimental school where they had assumed the role of principal. These plans were evaluated for quality and originality. Prior to preparing these plans, participants were given training in the application of relevant implementation planning strategies (e.g., forecasting). It was found not only that these training interventions to improve strategy application resulted in the production of

more creative plans but that instruction in application of these strategies proved especially beneficial for people evidencing creative ability – high divergent thinking scores. This mental simulation, forecasting, and development of both positive and negative back-up plans appear to represent critical strategies for implementation planning.

Plans and actions, of course, have consequences. Thus monitoring has also been considered a critical process in creative problem solving. Effective monitoring, however, appears to be based at least in part on planning with monitoring markers being formulated with respect to both plans and back-up plans. Thus creative people appear to employ a wider range of plan based markers in monitoring, considering both markers of plan success and back-up plan markers. In addition to searching for a wider array of markers, creative people in monitoring, also appear to focus on crisis events – events that disrupt progress toward long-term goals. Thus broad monitoring and extensive monitoring of crisis events appear to represent two strategies commonly contributing to effective performance among people working on creative tasks.

Cross-Process Strategies

Although many strategies are tied to execution of a particular creative thinking process, some strategies may prove beneficial for execution of multiple processes. For example, one study examined the effects of three cross-process strategies that might contribute to creative thought: brainstorming (generating multiple ideas), hierarchical thinking (finding things in common), and changing perspectives (considering alternative viewpoints). Undergraduates, 92 in all, were given training in the application of one of these strategies, and asked to generate solutions to a creative problem. It was found that the hierarchical strategy, by allowing access to shared features, resulted in the production of the largest number of new ideas. Thus some evidence is available for the value of at least some cross-process strategies. Broadly speaking, five cross-process strategies have received attention in recent years:

1. variability,
2. forecasting,
3. exploration,
4. causal analysis, and
5. meta-cognitive control.

The assumption underlying variability as a strategy is that producing more material, and a wide range of material, will prove beneficial in creative thinking by providing people with more material to work with in execution of creative processes. Although the value of having more material to work with is limited by cognitive processing demands, there is reason to suspect that variability may contribute to creative thinking. For example, in one recent study researchers provided 60 undergraduates with hints as they worked on a computer task. Some hints were intended to encourage variability but others were not. They found that hints that indicated varying specific aspects of the task induced the highest variability in contrast to no hints and a general hint to vary. Other work has shown that increased variability results in improved performance on creative tasks such as painting. However, increased variability

may also require the imposition of standards for selecting the material to be retained in cognitive processing.

The assumption underlying the impact of extensive forecasting on process execution is related to the potential impact of variability. In forecasting people predict the consequences, or implications, of various actions on events. As the forecasting of downstream implications of process execution increase more material is taken into account and critical emergent issues are identified resulting in improved process execution. Thus the extensiveness of forecasting is held to contribute to creative thinking.

In a recent study, researchers asked 149 undergraduates to develop advertising campaigns for a new product – a high energy root beer. These advertising campaigns were the creative product of interest and they were appraised for quality and originality. Prior to preparing these campaigns, study participants were asked to forecast during evaluation of ideas and during implementation planning. Attributes of those forecasts were assessed. One factor which emerged from these attributes was the extensiveness of forecasting. It was found that the extensiveness of forecasting during idea generation, and the extensiveness of forecasting during implementation planning, contributed to the production of higher quality and more original advertising campaigns. Because there is reason to suspect that other processes might also benefit from extensive forecasting, for example extensive forecasting might contribute to the identification of anomalies during information encoding, there is reason to suspect that extensive forecasting might represent a viable cross-process strategy.

One outcome of extensive forecasting is that it permits exploration of a variety of alternatives during process execution. Given the findings of previous studies there is reason to suspect that more extensive exploration of the products produced in execution of all of the cognitive processes underlying creative thinking would prove to be of value. Commonly, the use of an explorative strategy is subsumed under one of two creative thinking styles: (1) exploration versus assimilation; or (2) innovation versus adaptation.

In one study of exploration and assimilation, researchers asked 87 undergraduates to solve two creative problems – the two-string and hatrack problems. Behavioral statements were used to assess peoples' preferences for applying an explorer or an assimilator style in problem solving. For example, people were asked to indicate whether "I prefer to stick to a set of principles when I solve problems" (assimilator) or "I prefer to develop new principles when I solve problems" (explorer). They found that explorers typically produced better solutions to novel problems, although assimilators produced better solutions when working on less novel problems. Thus there is reason to suspect that more extensive exploration will generally contribute to execution of a number of the processes held to underlie creative thought.

One particular value of exploration is that it allows identification of critical causal variables shaping the construction of creative problem solutions. In fact, studies of historically noteworthy cases of social innovation found that intensive analysis of key causes was typically associated with creative efforts. The identification of key causes, moreover, may influence the effective execution of a number of processes such as concept selection, idea generation, and implementation planning.

One recent study examined the effects of causal analysis strategies on solving creative problems. The researchers asked 180 undergraduates to solve six social innovation problems known to call for creative thought. Problem solutions were scored for quality and originality. Prior to starting work on these problems, participants were given training in strategies that would result in better causal analysis. For example, think about causes that have big effects or think about causes that effect multiple outcomes. It was found that training in causal analysis strategies resulted in the production of more creative problem solutions – particularly when the problems presented were more novel. Thus there is reason to suspect that intensive analysis of causes might prove to be a general cross-process strategy contributing to creative thought.

A final set of cross-process strategies that might contribute to creative thought may be found in the area of meta-cognition. Meta-cognitive strategies are employed to organize and structure thinking processes. In a recent study, researchers asked 36 elementary school students to solve a treasure hunt on a deserted island creative thinking problem. After completing their work on this problem, participants were interviewed with respect to meta-cognitive strategies employed during problem solving. It was found that participants who applied a meta-cognitive strategy of mindful learning typically produced more creative problem solutions. Although these findings suggest that a mindful learning strategy may contribute to creative problem solving, and execution of multiple processes held to be involved in creative thought, further research is needed to identify other meta-cognitive strategies that might contribute to creative thought.

Moderators

Taken as a whole, it seems clear prior research has provided a stronger understanding of the strategies, or heuristics, contributing to creative thought. Not only have the strategies contributing to effective execution of critical processes such as conceptual combination, idea generation, and problem definition, been identified, but so too have the strategies, or heuristics, that contribute to effective execution of multiple processes. In this regard, however, it is important to bear in mind another point emerging from recent research. More specifically, a number of variables exist that act to moderate the impact of any given strategy on creative problem solving. Broadly speaking, these moderators fall under two general rubrics: (1) characteristics of the person solving the problem; and (2) characteristics of the problem.

Person Characteristics

People bring to creative problems knowledge and expertise. As noted earlier, strategies are executed with respect to a particular knowledge base. As a result, it can be expected that knowledge and expertise would represent potentially powerful moderators of strategy application. This issue has been examined in a recent study.

In this study, 190 undergraduates were asked to devise a plan for directing a new experimental school with these plans being scored for quality, originality, and elegance.

A conceptual combination task was presented prior to generation of these plans through a consultant's report and a series of strategy execution exercises. In one condition the consultant's report presented concepts, schematic knowledge, and asked participants to apply feature search and mapping processes. In the other condition, cases, experiential knowledge, were presented and participants were asked to apply strength analyses and forecasting strategies. It was found that application of both sets of strategies could result in the production of creative problem solutions. However, when working with schematic knowledge, having more concepts was beneficial. When working with case-based knowledge, having fewer cases was beneficial. Thus knowledge type appears to moderate the effectiveness of applying different strategies.

Not only does the type of knowledge being applied moderate strategy application, with experience people acquire procedural knowledge, knowledge about strategy application, as well as declarative knowledge. Because expertise contributes to the acquisition of procedural knowledge, it can also be expected that expertise would serve to moderate the impact of various strategies on creative problem solving. In fact, prior studies have provided evidence in a comparison of expert and novice designers that strategy shifts are also observed as a function of expertise.

In addition to knowledge, another set of characteristics people bring to creative problems are base abilities such as divergent thinking and intelligence. Given the evidence indicating that abilities influence process execution, it also seems reasonable to expect that abilities will also influence strategy application. In keeping with this observation, a recent study found that abilities, specifically divergent thinking and intelligence, moderated the acquisition, and application, of strategies involved in implementation planning. Similarly, other studies have provided evidence indicating that people lacking requisite abilities often apply suboptimal strategies when working on problems calling for creative thought.

As suggested by our foregoing observations, it appears that application of many of the strategies involved in creative problem solving is, in fact, demanding. The demands made by strategy application, in turn, imply that attributes of the person, for example need for cognition, openness, and the value placed on novelty, which leads people to invest cognitive resources in strategy execution, might contribute to creative problem solving. In a recent study along these lines, researchers examined the effectiveness of peoples' application of forecasting strategies. The researchers manipulated motivation by inducing feelings of high versus low self-efficacy and high versus low implementation intentions. They found that self-efficacy and implementation interventions contributed to the production of more effective forecasts. Thus motivation may influence strategy execution.

Problem Characteristics

Not only can the characteristics of people moderate strategies being applied, and the effectiveness of strategy execution, it also appears that the nature of the problem at hand may prove of some importance in this regard. One potentially important variable in this regard is the domain from which the creative

problem is drawn. Problems drawn from different domains not only emphasize different processes, they may also call for the application of different strategies in process execution. A case in point may be found in contrasting the idea evaluation strategies employed by scientists and leaders. One study on this topic found that scientists in idea evaluation seek early confirmation of ideas. In other words, they look for support. In contrast, leaders, in idea evaluation, seek to appraise ideas based on critical feedback. Thus leaders seek early rejection of nonviable ideas. These examples illustrate our broader point. The domain in which a problem emerges will condition the relevance of various strategies applied in creative problem solving.

Within a domain, the problems presented to people calling for creative thought vary with respect to their complexity and difficulty. These differences in problem complexity and difficulty, in turn, lead to greater demands in the execution of certain processes. As the demands made by process execution increase or decrease, different strategies may be required. This point is illustrated in a series of studies on the strategies involved in execution of the conceptual combination process. In the initial study it was found that feature search and mapping strategies contributed to successful combination and reorganization efforts. However, these strategies were only effective on relatively simple conceptual combination tasks where the concepts involved (e.g., birds, balls) shared certain features. On more complex conceptual combination tasks where shared features were less evident (e.g., birds, furniture) application of these strategies was less effective. Rather, on more demanding conceptual combination problems a search for metaphors was required to execute the conceptual combination process.

A final aspect of the problem that appears to influence the strategies applied pertains to the person's relationship to the problem. People in problem solving interact with the problem. However, these exchanges with the problem may occur in a number of different ways. For example, the problem might be affectively engaging or affectively neutral, it might be challenging or routine, or it might be immediate as opposed to distant. A recent study examined the influence of immediacy and distance of problems by asking people in causal analysis to think about implications of events for friends and families (immediate) versus institutions (distant). The researchers found that causal analysis strategies had stronger effects on creative problem solving when a distant as opposed to an immediate framework was applied during strategy execution.

Conclusions

Our foregoing observations with regard to heuristics, or the strategies people apply in executing the processes involved in creative thought, have a number of noteworthy implications. Perhaps the most important implication arising from these studies involves our basic conception of creative problem solving. Traditionally, creative problem solving has been understood in terms of convergent and divergent thinking. The strategies being applied in executing the processes underlying creative thought, however, suggest this distinction may not hold. For example, idea evaluation and information gather

are considered convergent processes. However, identification of anomalies in information encoding and compensation in idea evaluation suggest that noteworthy 'divergent thinking' may be required. Similarly, problem definition has been viewed as a divergent processing activity. However, the fact that a search for quality procedures and restrictions is critical to execution of this process suggests it may have a distinctly 'convergent' aspect.

Not only do strategy studies have some noteworthy theoretical implications, they have some noteworthy implications for our basic conception of creative thought. Not only are multiple processes involved in creative problem solving, each of these processes calls for application of a number of strategies. Moreover, the strategies that are applied may be process specific or process general. To complicate matters further, the strategies applied in problem solving may vary as a function of both characteristics of the person and characteristics of the problem. This exceptional level of complexity has two important implications. First, there may not be a simple, straightforward, 'recipe' for creative thinking. Second, substantial resources will be required to identify the many varied strategies people can apply in creative problem solving depending on their personal capabilities and the nature of the problem at hand.

Work along these lines, although demanding, may have great value. From a practical perspective, strategies have been shown to be strongly related to creative problem solving performance. The strength of these relationships suggests that strategies might provide a viable framework for both the assessment of creative potential and the design of educational interventions intended to enhance creative potential. From a substantive perspective, the identification of the strategies, or heuristics, contributing to process execution has resulted in a richer, more complete, understanding of creative thinking. We hope the present effort will serve as a stimulus for further work intended to unravel how heuristics shape creative thinking.

Glossary

Associationism The proposition that the mind consists entirely of ideas (words, images, formulae, etc.), each of which is associated with other ideas. Thinking, therefore, is simply a process of moving from one idea to another by way of a chain of associations.

Bicameral mind The concept that the mind is composed of two chambers, one in which desirable innovations are inspired by the gods, and a second chamber in which more mundane thoughts are produced by the person.

Biopsychosocial theory The belief that all human acts are borne of a complex interaction of biological, psychological, and social forces.

Cerebral localization The principle that each of the various human abilities are located in the lobes, which are sections of the brain.

Fundamentalism A movement or point of view characterized by rigid adherence to fundamental or basic principles.

Gestalt German for 'mental patterns or forms.' Gestalts have complex relationships, and are more than merely 'associated' with each other. As mental patterns, they form ideas that are greater than the sum of the parts.

Humanism The belief that humans have the ability to solve problems through their own mental efforts, without having to rely on inspiration from the gods or from God.

Muse A spiritual intermediary for the gods. A person who felt a creative impulse would invoke the appropriate muse for assistance.

Original genius As opposed to mere talent, refers to the ability to create fundamentally new and highly valuable ideas and products.

Paganism The religious belief that many gods play roles in human behavior.

Introduction

What is creativity and how does it work? One group of historians believes that it is a cyclical phenomenon. As Von Fange explains this view:

A close study of dead civilizations indicates that they usually started on their road to glory because of fortuitous circumstances exploited by a strong, inspiring leader. The nation then carried on for a period under its own momentum. Finally, creeping vanity led the people to become enamored of their undisputed superiority; they became so impressed with their past achievements that they lost interest in working for further change. Soon their sons, coddled in the use of all the great things their fathers and grandfathers had pioneered, became as helpless as newborn babes when faced with the harsh reality of an aggressive and changing world (1959: 29).

Although there is some truth in this, there is considerable evidence that in fact, there have been three distinct historical periods in which human understanding of the concept of creativity has differed substantially. From earliest times until the Renaissance, it was widely believed that all desirable innovations were inspired by the gods or by God. Then, sometime during the Renaissance, this view began to give way to the idea that creativity is a matter of genetic inheritance. In the beginning of this century, the debate turned to an argument over the relative contributions of nature versus nurture. In recent decades, there has been growing acceptance of *biopsychosocial theory*, that is, the belief that all creative acts result from a complex interaction of biological, psychological and social forces. How these changes in the popular conception of creativity emerged, however, is far from simple and not without controversy.

Prior to the nineteenth century, very little was written about the nature of creative thinking. Although there had been

extensive theorizing about other human capacities, conjecture about the origins of creative productivity had been impeded by the belief that it is too obscure, too multifaceted, too ethereal to allow for intellectual analysis of its process. The first effective scholarly inquiry was undertaken only a little over a century ago. Research on the creative process was deterred not so much by ignorance as by the conviction that the nature of innovative thinking was already understood: it was thought that it comes as a gift from above.

The Bicameral Mind

The earliest explanation, one that is largely inferred from the writings of Homer and the authors of the Bible, was that the mind is composed of two quite separate chambers (this concept is unrelated to the current knowledge that the brain is composed of two hemispheres). The first scholarly treatise to document this view was written by psychologist Julian Jaynes. He coined the term *bicameral mind* as a label for this phenomenon. Throughout early human history, Jaynes posits, people uniformly believed the chamber of the mind in which new thoughts occur was controlled by the gods. Thus they thought that all creative ideas come from the gods, usually through the mediation of a *muse*, a sort of intermediary for the gods. A person who felt a creative impulse would invoke the appropriate muse for assistance: Calliope for epic and heroic poetry; Clio for history; Erato for love poetry; Euterpe for music and lyric poetry; Melpomene for tragedy; Polyhymnia for songs or hymns to the gods; Terpsichore for dance; Thalia for comedy; and Urania for astronomy. A major function of the mind, then, was as a receptacle for supernatural innovations. It was

believed that the gods projected their ideas from Mount Olympus by inspiring (literally, 'breathing into') this first chamber.

The purpose of the second chamber of the mind was to express inspiration through the more ordinary mechanisms of speech and writing. It was considered to be the public representative of the first chamber. The second chamber also was used to express such mundane thoughts as 'I am hungry.'

The bicameral process is exemplified in the tales of Homer, in which the characters are able to accomplish great acts, but only as directed by the gods. In their most important achievements, Homer's heroes did as they were inspired to do, carrying out the strategies given them. This was no passive act, however. They could choose not to follow the inspiration given them and some did. Thus when they effectively followed the instructions of a god in battle, they were credited with great bravery, but not with the idea for the act. When they wrote a beautiful poem or play, they were admired for having produced it, but mainly because they had been chosen for the honor.

Many early thinkers, Plato and Aristotle among them, believed that the 'creativity' chamber also housed madness when the spirit of the Muse was present. Hans Eysenck cites Plutarch's description of Archimedes, the great geometrician:

... how, continually bewitched by some familiar siren dwelling within him, he forgot his food and neglected the care of his body, and how, when he was dragged by force, as often happened, to the place for bathing and anointing, he would draw geometrical figures in the oil with which his body was anointed, being overcome by great pleasure and in truth inspired of the Muse.

This 'madness' was not the same as insanity, however. As Eysenck points out, "... in Latin there is no linguistic distinction between *madness* and *inspiration*. *Mania* and *furor* are terms that cover many different non-rational states like anger, passion, inspiration, and insanity."

Perhaps the first to challenge the concept of the bicameral mind was the philosopher Aristotle in the fourth century BCE. Although he agreed with his predecessors that inspiration involved madness, he suspected that great insights begin as the result of a person's own thoughts, through a process which has become known as *associationism*. This view proposes that the mind consists entirely of ideas (words, images, formulae, etc.), each of which is associated with other ideas. Thinking, therefore, is simply a process of moving from one idea to another by way of a chain of associations. Aristotle suggested that mental associations are formed between events and objects that occur in the same place, the same time, that are similar, or that are opposites.

For example, the associationist view might speculate that the prehistoric builder who thought of moving huge blocks of temple stones by repeatedly placing wooden rollers in front of the stones got the idea from remembering playing with toy blocks and sticks as a child. The situations may be different, but the method of transportation is similar. Another example would be an imaginative chef's ability to create a delicious new dish by combining ingredients called for in a previously used recipe, but in a different way. At any rate, Aristotle did not spend much time pursuing this insight, and belief in the bicameral mind lived on for several more centuries.

Jaynes states that by the end of the medieval period, speech, writing, and other mental operations grew more complex.

As a result, it was recognized that thought could actually originate within a person's mind, and the notion of the bicameral mind eventually broke down. In its place came self-awareness and thus insight into the human potential to create. After many divergencies, this insight provided the opportunity for the development of scientific discovery.

For this monumental achievement to occur, however, other innovations were required. So many of these innovations come to us from the Greeks in the three centuries before the ascendancy of the Roman Empire, and so few from the medieval Europeans. Both cultures accepted the concept of the bicameral mind, so why was there so great a disparity in the creative output of the two periods? It appears that although they shared the conscious concept of creativity (the 'gift from above' view), the *unconscious concept* held by the two cultures was quite different. In this difference lies the answer to the question, "Why were the accomplishments of these two cultures so disparate?"

Paganism Versus Fundamentalist Religion: The Greeks

During the so-called 'Golden Age' (500–200 BCE), the Greeks invented most of our Western literary and political forms, developed many innovations in the arts, and shaped the disciplines of history, medicine, mathematics, and philosophy. Only portions of their written output still exists, perhaps about a fifth. Not a single one of their public buildings and only a few of their statues remain standing. And yet it is their oratories, plays and histories that are still found worth reading in the world's colleges and universities, and their buildings and sculpture that are emulated more than any other. Historian Daniel Boorstin compares them to other civilizations:

Inquiry for its own sake, merely to know more, philosophy on the Greek model, had no place in [a world view such as the Confucian, Incan, Buddhist, or Christian] tradition. Greek philosophers, beginning with Thales, were men of speculative temperament. What was the world made of? What are the elements and processes by which the world is transformed? Greek philosophy and science were born together, of the passion to know.

To what may we attribute this flourishing of passionate imagination? An insightful hypothesis has been put forth by historian Moses Hadas. He suggests that the Greeks were prolifically creative because they were free of many of the cognitive restraints that afflicted other major civilizations. It is true that they were economically secure and had ample assistance in their daily lives from their slave system but, Hadas argues, their main asset was the absence in their lives of the religious beliefs that fettered most other societies. They believed their ideas were inspired by the gods, but by gods who existed in proliferation and who cared little about the lives of humans. Although they were concerned about displeasing their gods, the Greeks saw no reason to think that self-expression would distress them. After all, the more beautiful or original their creative product, the more likely was it to have been given them by their pleasure-loving gods.

In making this case, Hadas compares classical Greece and its pagan beliefs to medieval Europe and its fundamentalist Christian orientation. He argues that it was not so much the

restrictive teachings of early Christianity or the 'otherworldliness' of the religion that caused inhibition of creative thought throughout the medieval period (the end of the fourth through the twelfth centuries), but its claim to exclusive validity. In its struggle to gain acceptance and then dominance, early Christianity was harsh in its rejection of deviant ideas, which were considered heretical. Beginning with the execution of Arias and continuing through the use of several forms of inquisition, the Church dealt harshly with the progenitors of such thinking.

The polytheistic Greek religion, on the other hand, allowed the individual to exercise choice among various classes of deities. The scope of individual autonomy was infinite, and the Greeks were of the belief that the actions of the gods were unpredictable – they could never assume to know what the gods thought or felt.

Hadas buttressed his case for a sharp distinction between the attitudes of Greek *paganism* and the Christian religion by pointing out what Greek paganism did *not* have:

- churches
- family allegiance to one point of view (members of Greek families were free to choose any god to worship, or none at all)
- strong prejudices against older or newer beliefs
- dogma
- sacred books revealed by a spiritual being, detailing that dogma
- priests
- claims to infallibility
- epic religious stories (e.g., the Garden of Eden, the escape from Egypt)
- a clear concept of sin
- true villains (because many religious views were simultaneously acceptable, persons whose views were diametrically opposed still could respect each other. There were no heretic).

Perhaps the clearest view of the Greek ideal can be seen in their emulation of heroes, as compared to Christian attitudes toward saints. A Greek hero was "any deceased person worthy of a cult, that is, of receiving offerings of flowers or wine on his special anniversary." The offerings are not meant to appease him or her, but to serve the people. For example, Hadas points out, "... we eat cherry pies and chocolate hatchets [on George Washington's birthday] to serve ourselves, not our first president." The main distinction, he argues is that "A man approaches sainthood to the degree that he *suppresses* the impulses of ordinary humanity and assimilates himself to a pattern outside humanity. A man becomes a hero to the degree that he emphasizes his human attributes." Hence Greek pagans were encouraged to perceive excellence as a more readily attainable goal than were medieval Christians.

The single 'sacred source' the Greeks did have was the poetry of Homer. This was the one source of information that all Greek children learned, and its code was therefore accepted with as little question as we accept the facts of the multiplication table. There, it appears, is the explanation for the relentless Greek drive for excellence in all aspects of their lives, and for the quality of their production in the arts and crafts. A person composed music or wrote poetry not merely for self-expression or profit, but as an entry in the national contest for the

approbation of society. The main objective was honor. Even the potters who fashioned the cheapest household bowls took pains to sign their work. When the vases were artfully crafted, both potter and painter signed the bottom. All Greeks knew who designed the Parthenon, but the builders of the great Christian cathedrals remain anonymous. Cathedral architects chose not to put their names on their work because the work was for the greater honor and glory of God, so it would be prideful and disrespectful to display authorship.

From Homer through the Epicureans, we can see that significant and persistent value placed on the self-sufficient individual. To quote Hadas:

The Homeric warrior [knew that] what was decreed for him by a power outside himself he could not alter and need not bother to understand; he was definitely the captain of his soul, but made no pretense of being master of his fate. So the hero of tragedy knew that he must behave well as a man; the disasters that might befall him had no relationship with his own excellence.

Because the gods played so small a role in their daily existence, the Greeks were free to do whatever they wished, so long as it was honorable. The breathing of life into a Greek person's creative process may have been influenced by a heavenly source, yet the credit went to the individual responsible for the creation. Hence the fabulous 300-year-long cornucopia of creativity that was the Golden Age.

This is not to say that the Greeks believed what they were doing was 'creative,' however. Art was "the making of things according to rules," and did not seem to call for innovation (discussed by Tatarkiewicz in 1980).

Paganism Versus Fundamentalist Religion: The Medieval Europeans

As Roman culture died out and was replaced by vibrant new barbarian growths, people forgot many things – how to read, how to think, how to build magnificently – but they remembered and they mourned the lost peace. Call them the people of the Dark Ages if you will, but do not underestimate the desire of these early medieval men and women for the rule of law. (Cahill, 1995)

A squelching of free thought begins in the late Hellenistic period as paganistic Romans come to accept the claims of their all-powerful emperors to have become gods themselves. Under them, Rome became famous for its 'universal' codes of behavior, which covered one's duty to the state. On the other hand, the Romans were not so different from the Greeks in their attitudes toward religious imperatives. It was not until the rise of Christianity, with its fervent devotees, that we see a strict code of behavior, enforced by powers in this world who were exclusively backed by the power of the next.

This extensive change in philosophy was accompanied, and probably abetted by, another sweeping event. Barbarian tribes began attacking the Roman Empire from several sides in the fifth century, and systematically ravaged huge territories. This onslaught eventually destroyed faith in the Roman religion and prepared the ground for a new one.

The most notable group of invaders, the Vandals, deeply penetrated the Empire and nearly destroyed Rome.

The Vandals were a Teutonic tribe that governed their North African kingdom from 439 to 534. Other tribes, such as the Huns, Vikings, and Visigoths, also invaded and pillaged large tracts of the Empire. While in the process of rampaging the lands, and especially the cities they wished to conquer, they destroyed any books or other written materials they could find. They had a savage disregard for intellectual or spiritual enlightenment, being interested only in the spoils of battle and the domination of their victims.

An exception to this was Alaric, who together with his horde of Goths smashed through the gates of Rome at midnight, 24 August 410. He prevented his men from putting the torch to everything, saying that while he wished to destroy the Roman Empire, he had no desire to harm the many Christians who then inhabited the city. Soon a few treasured works hidden in the city were spirited off to Moslem strongholds. Throughout the medieval period other precious tomes were rescued by an unlikely source: the reclusive Christian monks based on secluded islands off the Irish west coast. They secretly made it their business to locate the hidden writing not only of Christians but, amazingly, of the pagan thinkers as well. Not only did the monks preserve these works, but they painstakingly and artistically handcopied the writings in an attempt to perpetuate these obscure pockets of intellectuality. The efforts of these monks must be considered a critical contribution to human creativity, for although the marauders were frequently successful in ravaging the lands, they were never able to destroy the words that would so stimulate thinkers in centuries to come.

The work of these monks is an example of how the Dark Ages' were not totally devoid of creative achievements. The famous *Book of Kells*, produced by the monks over many years, is an exemplar of the level of their creativity. Another such example is the work early in the fifth century of Saint Augustine, Bishop of Hippo. In his brilliant treatise *The City of God*, written between 413 and 426, he argued that Plato and the Greeks were wrong in their belief that life is a series of repetitious cycles. He offered the life of Christ and the subsequent new view of humanity offered by Christianity as a argument against that position. He was probably one of the first to discredit the idea that all creative ideas come straight from God, devout though he was. He was awed by the creative powers of his fellows, in fact, although he could not resist chastising them for the purposes to which such gifts were often put:

... man's invention has brought forth so many and such rare sciences and arts (partly necessary, partly voluntary) that the excellency of his capacity makes the rare goodness of his creation apparent, even when he goes about things that are either superfluous or pernicious, and shows from what an excellent gift he has those inventions and practices of his.

What millions of inventions has he against others, and for himself in poisons, arms engines, stratagems, and such like!

Further evidence of medieval creativity was the work of the Roman Boethius, who served as counselor to Theodoric, King of the Visigoths. This ingenious scholar single-handedly produced the *quadrivium*, which offered explanations of the four 'mathematical' disciplines: arithmetic, music, geometry, and astronomy. Together with the *trivium* (grammar, rhetoric, and logic) later assembled by others, they formed the basic

curriculum for the handful of scholars who struggled to keep knowledge alive during the Middle Ages.

Such contributions notwithstanding, the situation in the Western world in the fifth century was rather grim, as Christopher Dawson so succinctly describes it. He disagrees with Hadas' position that fundamentalism was the major cause of the lack of creative output, however. After all, he argues, the Moslems were as rigidly fundamentalist as the Christians and yet the Moslems made many creative contributions. He ascribes the superiority in creative output of the Greek and Moslem cultures over the medieval Christian culture rather as the result of the Christians having been reduced to a simple agrarian culture by the invasions of numerous outsiders. It may well have been the case that the tight grip of the Church on the minds of the population was welcomed as a consoling relief from the fear of vandalism and starvation alike. In fact, as is so often the case at the macrosocial level, establishing causation is a perilous pursuit. For example, it could well have been that the fundamentalist posture of the medieval Church and the low level of creative output in medieval times were both the result of the destabilized political and economic environments brought about by the widespread vandalism. As Dawson states:

But while there is no reason to suppose that the Dark Ages were dark [solely] because they were religious, it is none the less difficult to exaggerate their darkness, both as regards scientific knowledge and the completeness of the break between the science of antiquity and the science of modern times. Here the traditional view is justified, and it only becomes false when this judgment is extended from the early to the late Middle Ages so as to make the scientific development of Western Europe begin with the Renaissance. In reality the recovery of Greek science and the restoration of the contact with the main tradition of Greek thought was one of the most striking achievements of medieval culture. And it is even more than this: it is the turning point in the history of Western civilization, for it marks the passing of the age-long supremacy of oriental and eastern Mediterranean culture and the beginning of the intellectual leadership of the West. It is, in fact, a far more important and original achievement than anything that the Renaissance itself accomplished. For the Renaissance scholars, in spite of their originality, were carrying on a tradition that had never been entirely lost: the tradition of humanism and classical scholarship that was founded on Cicero and Quintillian. But the rediscovery of Greek thought by the medieval scholars was a new fact in the history of the west: it was the conquest of the new world.

The Renaissance and the Beginnings of Humanism

Dark as the medieval period was, nothing that happened during its 800 years could compete with the catastrophe of the Black Plague which, by the time it ended around 1350, had decimated fully one-third of the population in the West. As a result, however, new emphasis on the individual took place and with it came a loosening of reflexive obedience to clerical rule. Because workers had become so scarce, they found they were in a much stronger bargaining position with the feudal hierarchy as well. This change brought about a shakeup of the entire social structure, and with it a widespread challenge to the belief system of the previous millennium.

For example, artisans began to win acclaim and patronage for themselves. This is similar to the attitude of the ancient

Greeks who took pride in all their creations, from the most minimal to the most spectacular. Painters again signed their artwork, abandoning pious humility for personal pride in their craft. Guilds were formed to foster the growth of individual crafts and skilled trades. The principal source of patronage was no longer the Church, but rather wealthy princes and merchants whose pride in artful possessions was no longer considered a sin. The emphasis in the work of the poets, painters, and philosophers was still on the glory of God, but as reflected in the countless joys of *human* existence.

Also at this time we see widening criticism of what has been considered the acme of Church power, the inquisition. This tribunal, with its witch hunt for heretics and its infamously murderous 'auto-de-fé ("prove your love of God by admitting your guilt!") had exerted a chilling influence over independent thought for many years. As it lost its power, the Holy Roman Empire declined in importance and the papacy was weakened by schism. Among the major causes of this breakdown were the executions by fire of such popular Church critics as Jan Hus and Girolamo Savonarola, and the publication of the 95 theses of Martin Luther, which began the Protestant Reformation. There was a reformation of the Church itself at this time, but it came too late to stave off the winds of change. Simultaneously, the national monarchies increased in strength and prestige. At the beginning of the 1400s, the population of Europe was better off financially than at any time since before the fall of Rome.

Now we see the inauguration of humanistic philosophy, the belief that we ourselves are responsible for much of what happens to us. This view was not generally antimonotheistic, but rather co-monotheistic. The resurgence of creative production on so grand a scale was inspiring, and piqued the curiosity of those who wished to understand the complexities of minds that were capable of such accomplishments.

The term 'renaissance' originally referred to the revival of values and artistic styles of the classical age. By the 1500s, the word had acquired a broader meaning: it was becoming known as one of the great ages of human cultural development, a distinct period signaling the dawn of the modern era. Essentially, a breakdown occurred in the rigid social order that had so dominated societies in Europe, manifesting itself in cultural and intellectual advances. The style of the Renaissance music, literature, and arts is quite distinctive, and ultimately this intellectual and spiritual revolution sparked a drive in the people to release themselves from the medieval traditions. The historian Nicolas Berdyaev describes the period this way:

In the creative upsurge of the Renaissance there occurred such a powerful clash between pagan and Christian elements in human nature as had never occurred before. In this lies the significance of the Renaissance for the world and for eternity. It revealed the activity of the pagan nature of man in creativeness, and at the same time the activity of his Christian nature.

The Christian ideas had been accepted for a long time, but the pagan ideas were rapidly being reintroduced. This came about through the influx of scholars from the Moslem countries, and by the circulation of the magnificent books, produced and kept safe over the centuries by the Irish monks. Spurred by these 'new' old ideas, the best minds experienced a sense of freedom encouraging an inquiry into everything, even

the most cherished of beliefs. From this resurgence sprang the scientific, artistic, philosophical and political revolutions that came to be referred to as the 'Age of Enlightenment.'

The Age of Enlightenment and a Flourishing Humanism

By the beginning of the eighteenth century, the spate of knowledge born of the work of such giants as Copernicus, Galileo, Hobbes, Locke, and Newton solidified belief in the scientific process. Faith in the ability of humans to solve problems through their own mental efforts (known as *humanism*) grew rapidly. Spiritual works such as the Bible waned in their authority, and were viewed with impunity by some scholars as literary efforts rather than as the word of God. The right of individuals to come to their own conclusions began to gain acceptability.

In 1767, the first major inquiry into the creative process took place. William Duff was one of the first to write about the qualities of *original genius* (as distinguished from talent, which is productive but breaks no new ground), and his insights were strikingly similar to more modern attempts to unravel the mysteries of the creative mind. What set Duff apart as an important figure in the study of creativity is that he was the first to suspect the biopsychosocial nature of the process.

Duff was principally interested in determining the cognitive traits that were responsible for the variance he observed in the accomplishments of people. He was not only concerned with hereditary influences, but also with the times in which his subjects lived. As we shall see, it would be quite some time before others would agree that social influences play a role in creativity.

The main qualities that Duff considered fundamental to genius were imagination, judgment, and taste. Any one of these three characteristics alone would not result in the caliber of genius of Shakespeare; rather he thought the combination of the three ingredients to be essential. He argued that imagination contributed the most, in that the mind not only reflects on its own functions, but also organizes its ideas into new associations and combinations of an infinite variety. Duff felt that all discoveries and inventions in science and art were the result of imagination. Judgment, he asserted, is that ability that evaluates ideas or options, and acts as a counterbalance to the influences of imagination. Taste supplements judgment, providing a sense of aesthetic quality to the cold evaluative nature of judgment.

The publication of Duff's work was one of several events that set the stage for scientific research on human thought, which would later prove essential to the demystification of the creative act. Here is a brief list of major Enlightenment milestones that helped break the path:

- The spread of social and philosophical opposition to church and state authority.
- The institution of the British Royal Society, the first research organization.
- A plethora of developments in the natural sciences.
- Separation of the idea of creativity from more ordinary notions of genius (as in "He has a genius for poetry").
- The doctrine of individualism.

- Three enormously influential books: Francis Bacon's *Advancement of Learning*, Adam Smith's *The Wealth of Nations*, and Thomas Malthus' *Essay on Population*.

Robert Albert and Mark Runco have summed up the contributions of this period to a new concept of creativity:

Tedious and tangential as they were at times, nevertheless, the debates through the eighteenth century eventually came to four important acceptable distinctions, which were to become the bedrock of our present-day ideas about creativity: 1. Genius was divorced from the supernatural; 2. Genius, although exceptional, was a potential for every individual; 3. Talent and genius were to be distinguished from each other; 4. Their potential and exercise depend on the political atmosphere at the time (this last distinction would not be recognized for many years, however).

The Debate over Associationist and Gestalt Views

Throughout the nineteenth century, a major shift in the conception of the creative act occurred. With the renunciation of divine inspiration as the sole cause of creativity came a transmigration to what may be the opposite extreme: great men are great because they have inherited a serendipitous combination of genes from their forebears, which produce a mind of intensely fine acuity (decades would pass before the recognition of women of genius). This assumption grew as medical science produced evidence of heritability of physical traits. Moreover, this concept seemed to jibe with the recognition that high level mental ability runs in families.

For a while, a debate raged over just how specific inherited traits might be. Jean Lamarck believed that learned traits could be passed on genetically. Charles Darwin demonstrated that he was wrong, confirming that genetic change occurs not as the result of practicality but through random mutation, over eons of time.

So what explanation did nineteenth-century science offer as to how geniuses formulate their brilliant ideas? A subordinate question was, does a genius search for knowledge elementally (from parts or elements of a problem to the whole), or holistically (from a sense of the whole of the problem to its parts)? Two scientific camps were formed. They have become known as the associationist (a branch of behaviorism) and the *Gestalt* positions. From this seemingly academic debate came one of the greatest advances in our understanding of the creative act itself.

Research on the history of creativity often cites Sir Francis Galton as having conducted the first scientific research on the nature of genius. He was the second great associationist, after Aristotle, and was highly respected in nineteenth-century England as a multifaceted scientist. He was a eugenicist, meteorologist, evolutionist, geographer, anthropologist and statistician, and he probably should be credited as the world's first cognitive psychologist. Building on his friend Charles Darwin's groundbreaking insights of evolution, natural selection (survival of the fittest), general diversity and adaptation, he made inestimable contributions to our thinking about creativity.

One of his most interesting experiments was his attempt to measure the workings of his own mind. The descriptions of his findings have been insightfully analyzed by Crovitz in

his book, *Galton's Walk* (1970). The walk referred to is one taken by Galton down London's Pall Mall, during which he meticulously recorded every thought that crossed his mind. His goal was to:

... show how the whole of these associated ideas, though they are for the most part exceedingly fleeting and obscure, and barely cross the threshold of our consciousness, may be seized, dragged into daylight, and recorded. I shall then treat the records of some experiments statistically, and shall make out what I can of them.

He was awe-stricken by his tabulations:

The general impression they left upon me is like that which many of us have experienced when the basement of our house happens to be under thorough sanitary repairs, and we realize for the first time the complex systems of drains and gas- and water-pipes, flues, and so forth, upon which our comfort depends, but which are usually hidden out of sight, and of whose existence, so long as they acted well, we had never troubled ourselves.

His most important conclusion:

The actors on my mental stage were indeed very numerous, but by no means as numerous as I had imagined. They now seemed to be something like the actors in theatres where large processions are represented, who march off one side of the stage, and going round by the back, come again at the other.

At first glance, this conclusion may not seem earth-shaking, but Galton had actually discovered two principles which have had enormous impact on our thinking about thinking. The first is his notion of 'recurrence.' This holds that the conscious mind is like a plenum. A plenum is a space which is totally filled up with objects. An example would be the ball-bearing ring which supports the fluid motion of wheels. Little balls fill two concentric rings, and roll around in the hub of the wheel, making the wheel spin much more freely than it would otherwise. Each ball can only move by taking the place of the ball in front of it. There is no place else to go. The only possible movement is cyclical movement.

Galton argued that this is what happens in the conscious mind. It is always, at any one point in time, filled up, and thoughts can only follow each other around. He found this positive, because otherwise, he believed, conscious thought would be random and would have no order. Orderliness is essential to logical thought.

However, if this were the only way the mind could process information, there could be no new thoughts, and therefore no creativity. The second and more important discovery Galton made was that new input can come into this plenum from another part of the mind. The source of this input is the unconscious, the 'basement' of the mind. And most important of all, the unconscious can be made conscious through association of thoughts. Thus was discovered the critical notion of 'free association.' The concept was certainly revolutionary: "ideas in the conscious mind are linked to those in the unconscious mind by threads of similarity." At the turn of the century, Sigmund Freud and his associates would bring this notion to fruition.

Of particular note in Galton's research is his use of statistical analyses in the study of individual differences among geniuses. The modern statistical principles of correlation and regression evolved from Galton's findings, gleaned from

biographical sources for his subjects in various fields and their families. This methodology was incorporated into the studies of other researchers who pursued the study of creativity at the onset of the twentieth century and the years to follow.

Galton was convinced that mental capacities are inherited. He believed that these capacities follow certain laws of transmission that can be determined by observation. He examined the hereditary nature of mental abilities in subjects recognized by society as 'geniuses' in an attempt to show that genius is an inherited trait in the same manner that physical features are inherited. In Galton's view, geniuses possess natural ability in terms of intellect and disposition that leads to this reputation, urged on by some internal stimulus that strives to overcome any obstacles.

This definition originated with Galton. Historian Jacques Barzun describes several iterations in the meaning of genius:

In ancient and medieval times, a genius or a demon was a person's guardian spirit, giving good or evil advice on daily affairs. Then genius came to mean a knack of doing a particular thing – a gifted person was said to 'have a genius' for calculation or public speaking. It gradually acquired a more honorific sense. By the 1750s genius was defined by the poet Edward Young as "the power of accomplishing great things without the means generally reputed necessary to that end." This notion fitted Shakespeare's case, for he was thought lacking in discipline, learning and art. He had a wild, untutored genius.

In the next generation came the subtle shift from 'having' genius to 'being' a genius, with no limitation such as Young included in his praise. A genius was now a fully conscious, competent and original 'creator', and only two classes of artists were recognized: the geniuses and the non-geniuses, the second group being dismissed as 'talents'. Unable to create, they followed the path blazed by the geniuses.

For Galton, then, genius resides in persons who are the beneficiaries of exceptional inheritance, especially of brain cells. He refused to believe that early experience or the immediate environment played much of a role in the creative act.

Opposed to Galton and his associates was the other group of theorists, known collectively as Gestalt psychologists. They argued that creativity is a much more complicated process than merely associating ideas in new and different ways. They believed the whole of any idea always amounts to more than merely the sum of its parts, and referred to associationism as 'brick-and-mortar' psychology. Gestalt psychology started with the work of von Ehrenfels, also in the latter half of the nineteenth century. It was founded originally on the concept of 'innate ideas,' that is, thoughts that originate entirely in the conscious or unconscious mind, and do not depend on the senses for their existence.

Max Wertheimer, an early twentieth century Gestaltist, wrote this stinging indictment of his opponents:

In [the associationists] aim to get at the elements of thinking, they cut to pieces living thinking processes, deal with them blind to structure, assuming that the process is an aggregate, a sum of those elements. In dealing with [creative] processes, they can do nothing but dissect them, and thus show a dead picture stripped of all that is alive in them.

The Gestalt position held that creative thinking is the formation and alteration of 'Gestalts,' which is German for 'mental patterns or forms.' The elements of Gestalts have complex relationships, and are far more than merely 'associated' with

each other. Great paintings are made up of elements, all of which are interrelated such that the whole is greater than the sum of the parts.

Wertheimer stated, for example, that creative musicians do not write notes on paper in hopes of achieving new associations. Rather, they conceive of a half-formed idea of the finished piece of music and then work backward to complete the idea. They develop an overview of the entire structure and then rearrange its parts. Creative solutions are often obtained by seeing an existing Gestalt in a new way. This can happen when we change the position from which we view a scene or problem, or when the personal needs that affect perception change.

Imagine that coming back to work after lunch, a person notices the display window of a clothing store. Brightly colored apparel stands out in the foreground. The pastel curtains behind are not so prominent. This individual does not notice at all that the window dresser has left part of a sandwich on the floor. However, suppose he looks at that store window when he is on his way to lunch. The sandwich will leap into the foreground, and he will hardly notice the clothing.

Gestaltists argued that getting a new point of view on the whole of a problem, rather than rearranging its parts, is more likely to produce creativity. Why is a new point of view so hard to achieve? Many impediments exist. First of all, most people do not like problems, because problems are stressful. Distressed thinkers usually react to problems with rigidity.

As is often the case in scientific inquiry, the disagreements between the advocates of the associationist and Gestalt positions still produce wonderful new insights into the process even today. In many ways, the current field of cognitive psychology represents an amalgam of these two positions. Co-existing with the struggle to understand the workings of genius was the zealous effort to reveal the workings of the brain itself. This endeavor also contributed to a new, more scientific understanding of the creative act.

Nineteenth Century Biology of the Brain

It should be no surprise that our knowledge of the way the human brain works is quite recent in the history of medical research. Less than 200 years ago, no one was sure that the various areas of the brain had isolable functions. The first person to suggest this was a German anatomist, Franz Gall, who did so early in the nineteenth century. His research led him to believe that speech is located in the frontal lobes, those sections of each hemisphere located toward the front of the head.

This is the doctrine of *cerebral localization*. Unfortunately, most scientists dismissed his report because he included in it the argument that the shape of the skull reflects the person's personality traits, and so it would be possible to study those traits by examining bumps on the head. This idea became known as 'phrenology,' and has long since been discredited.

Although most doctors branded Gall a quack, he did have some followers. The French professor of medicine, Jean Bouillard, offered a large sum of money to anyone who could produce a patient with damage to the frontal lobes who had no loss of speech. The knowledge of the landscape of the brain

was so primitive in those times, however, that for some years the question remained unresolved.

In 1861, the stalemate ended dramatically. A young French surgeon, Paul Broca, learned of cerebral localization at the meeting of the Society of Anthropology and was reminded of a patient of his who had long suffered from speech impairment and some right side paralysis. Two days after the meeting, the man died. Broca quickly got permission to autopsy his brain, and found what he was looking for: a region of tissue damage (a lesion) on his left frontal lobe. Some months later a similar situation occurred to another patient with the same results. Broca brought this patient's brain with him to the next Society meeting, and created a furor. Many were impressed, but those who dismissed localization accused him of lying.

Interestingly, while everyone noted that in both cases the lesions were frontal, no one seemed to see the *left side* link. Only after eight more autopsies did Broca publicly announce this finding. The notion that the left side of the brain could more powerfully direct mental processes in some persons, and the right side in others, was put forth even later. It came about mostly because it was learned that equal amounts of lesion do not have equal amounts of disruption. By 1868, John Hughlings Jackson, the eminent British neurologist, was guessing that one side may 'lead' the other. Increasingly, there was evidence that the interactions between halves are complex, and different in different people. It was learned that areas involved in speaking are not the same as areas given to understanding the speech of others. The discovery of 'apraxia,' the inability to perform physical functions such as combing one's hair, led to many new hypotheses.

Eventually, it was accepted that most people are right-handed because their left brains are dominant. It was concluded that the right brain had few important functions, serving mainly as a backup to the more powerful left. In the nineteenth-century biological battles, we see the dim beginnings of the debates over how interactions of the two hemispheres across the corpus callosum contribute to creative thinking. The general position of those students of genius and of brain biology was that genetic inheritance rules creative ability. The first scholarly questioning of this position came at the turn of the century from the man some have called the first true psychologist, William James.

Nature and Nurture

William James was the first scientist to make a case for the interaction of the environment with genetic inheritance. As James put it, "The only difference between a muddle-head and a genius is that between extracting wrong characters and right ones. In other words, a muddle-headed person is a genius *spoiled in the making.*" Thus James argued that environment is a more powerful influence than genetic inheritance in determining ability. Whereas Galton claimed that the frequency of creative ability within certain well-known families was due to genetics, James believed that the conditions of one's upbringing, such as the philosophy of the parents, were more important than genes. In his time, he was virtually alone in putting forth this idea.

With Galton and Freud, James was a leader in thinking that the ability to get in touch with one's unconscious ideas is vital to giving birth to originality. This is how he described the process:

Most people probably fall several times a day onto a fit of something like this: the eyes are fixed on vacancy, the sounds of the world melt into confused unity, the attention is dispersed so that the whole body is felt, as it were, at once, and the foreground of consciousness is filled, if by anything, by a sort of solemn surrender to the empty passing of time. In the dim background of our mind we know meanwhile what we ought to be doing: getting up, dressing ourselves, answering the person who has spoken to us, trying to make the next step in our reasoning. But somehow we cannot start; the *pensee de derriex la tête* [literally, 'thoughts of the back of the head'] fails to pierce the shell of lethargy that wraps our state about. Every moment we expect the spell to break, for we know no reason why it should continue. But it does continue, pulse after pulse, and we float with it, until – also without reason that we can discover – an energy is given, something – we know not what – enables us to gather ourselves together, we wink our eyes, we shake our heads, the background-ideas become effective, and the wheels of life go round again.

James clearly recognized the importance to creativity of "thoughts of the back of the mind," but he did not pursue it. If he had, he might have added the third piece to the modern concept of creativity, the psychological element. The progenitor of this element would be Sigmund Freud.

Sigmund Freud and the Psychological View

The chief proponent of the view that creative ability is a personality trait that tends to become fixed by experiences that take place in the first 5 years of life was Sigmund Freud. In general, he and his early psychoanalytic mentees saw creativity as the result of overcoming some traumatic experience, usually one that had happened in childhood.

Often such an experience is buried in the unconscious. Although hidden from conscious awareness, this material could nevertheless have a powerful impact on a person's behavior. In his 1895 book with Josif Breuer, *Studies on Hysteria*, Freud discussed his discovery that the contents of the unconscious could be revealed by suggesting certain key words to patients (as well as by hypnosis). The contents of their unconscious would come forward through their seemingly random associations to those words. These contents are then dealt with by allowing conscious and unconscious ideas to mingle into an innovative resolution of the trauma. The creative act is seen as transforming an unhealthy psychic state into a healthy one.

Freud characterized the unconscious mind as having a weak concept of time and space, and as being largely involved with images rather than words. He saw the unconscious as being limited to a more primitive language that is likely to take place in dreams and in so-called 'Freudian slips.' He also was adamant that creativity almost always stems from original ideas, often first produced in symbolic form, in this nebulous world of the unconscious mind.

Freud's explanation of the creative process depended heavily on his ideas about defense mechanisms, which are unconscious attempts to prevent awareness of unpleasant or

unacceptable ideas. The literature describes almost 50 different kinds. Because defense mechanisms prevent an accurate perception of the world, and because they use up psychic energy, they usually interfere with creative productivity.

Freud firmly believed that people are most motivated to be creative when they cannot directly fulfill their sexual needs. Hence he believed that sublimation is the primary cause of creativity. The link between unconscious sexual needs and creativity begins in the early years of life. Although many people do not think of children as having sexual needs, Freud argued that at the age of four, it is typical for children to develop a physical desire for the parent of the opposite sex. Since this need is virtually never met, sublimation sets in, and the first vestiges of a fertile imagination are born. He traced many specific artistic works to the artist's sublimation. For example, he suggested that Leonardo da Vinci's many paintings of the Madonna resulted from a sublimated longing for sexual fulfillment with a mother figure, having lost his own mother early in his life. As he put it:

Should we not look for the first traces of imaginative activity as early as in childhood? The child's best-loved and most intense occupation is with his play or games. Might we not say that every child at play behaves like a creative writer, in that he creates a world of his own or, rather, rearranges the things of his world in a new way that pleases him?

Some of his followers disagreed with his emphasis on sublimation, ascribing other defense mechanisms as the source of creative thought. For example, Ernst Kris argued that only people who are able to "regress in the service of their egos" into a more childlike mental space are likely to be creatively productive. Thus for Kris, regression was the most productive defense mechanism.

In the writings of James and Freud, we see the beginnings of a biopsychosocial model of creativity. Despite an enormous surge in research on the topic since the middle of this century, however, the fruition of the concepts they pioneered has been seen only recently.

Summary

In conclusion, there have been three distinct stages in the history of the concept of creativity. From prehistory until well into the medieval period, it was generally considered to be a mysterious, supernatural process – a gift from the gods or from God, depending on the religion of the culture (e.g., Greek, Hindu, Egyptian or Incan versus Moslem, Jewish or Christian). As the Renaissance led to humanism, the concept of inherited genius took over. Gradually, psychological and contextual influences received more recognition.

New conceptualizations have proliferated in this century: the cognitive theories of Wallas, Terman, Kohler, Piaget, and Wertheimer, the personality theories of Freud, Jung, Adler, Rank, Rogers, MacKinnon, Barron, Roe, Helson, and Maslow, the research on the brain of Penfield and Sperry, to name only some of the most highly regarded early work. Where are we headed? The biopsychosocial model, which seeks to 'stand on the shoulders of giants' by combining the three essential elements into new explanations, is in the ascendancy. The other articles in this encyclopedia are filled with ideas about the recent past, the present and the future of thinking about creativity. It will be fascinating to see whether these efforts will prove as productive as those of the brilliant foreparents of creativity theory.

Glossary

Content analysis A method of measuring psychological variables by applying objective coding schemes to personal documents (letters, diaries, etc.) and creative products (poetry, musical compositions, etc.). Some content analytical methods have taken the form of computer programs that can directly extract measurements from the primary source material, most frequently written or transcribed text.

Idiographic research Investigations that concentrate on discerning the distinctive features of a specific individual or event. To be distinguished from nomothetic investigations (q.v.).

Multivariate statistics A collection of techniques that permits the simultaneous analysis of numerous variables having a great variety of possible interrelationships. Examples include factor analysis, multiple regression, path analysis, latent variable models, and covariance structure analysis.

Nomothetic research Investigations dedicated to the discovery of general laws, principles, or regularities that transcend the particulars of a given time, place, or person. To be distinguished from idiographic inquiries (q.v.).

Quasi-experimental designs A methodology that permits more powerful causal inferences than traditional correlational methods, but less powerful than conventional experiments. The most common quasi-experimental design in historiometric research is time-series analysis, which allows the inference that the variation in one variable precedes or follows variation in another variable.

Unobtrusive measures Data gathered in such a fashion that the subjects' behaviors, thoughts, and feelings cannot possibly be influenced by the measurements. All measures based on archival data are unobtrusive (or nonreactive). In contrast, laboratory experiments and psychometric assessment techniques lack this quality, and can at least potentially alter the activities of those subjects under investigation.

Background

Historiometric research examines the big names and important happenings that can be considered historic in the sense of 'making history.' For example, the subjects of historiometric studies may involve eminent artists, writers, or scientists (e.g., Leonardo da Vinci, Cervantes, or Einstein) or they may entail major acts of creativity such as musical masterworks or major scientific discoveries (e.g., Beethoven's Fifth Symphony and the heliocentric theory of Copernicus).

The database concerning these historic subjects is compiled from various archival sources, such as histories, biographical dictionaries, encyclopedias, anthologies, and collections. The data may also be derived from the content analysis of creative products, including the computer analysis of music and literature. Because historiometric research concentrates on individuals or products that are highly distinguished, the archival information on these cases is often extremely rich.

The goal of the study is nomothetic rather than idiographic. Nomothetic research involves the quest for general psychological laws or patterns, whereas idiographic research concentrates on those features that are unique to a particular individual or event. Thus, nomothetic research addresses such questions as whether creative development is enhanced when talented individuals are exposed to models of creativity. In contrast, idiographic research might address an issue such as the reason why van Gogh cut off his ear. Hence, in this sense historiometrics has goals comparable to other methods that psychologists use to study creativity, such as psychometrics.

In line with this focus, historiometric research favors multiple-case investigations. Only by obtaining a large sample of eminent personalities or important events can the researcher ensure that the findings are truly general rather than particular. It is rare for a historiometric inquiry to analyze fewer than a dozen cases, and sometimes the sample sizes may run into the thousands. Indeed, the largest number of cases ever examined in a single historiometric inquiry was 15 618 – a very large sample size indeed!

Also consistent with the search for nomothetic results, historiometric research invariably entails quantification. Variables are first quantified from the available archival materials, and then these variables are subjected to statistical analysis. Because the number of variables studied will often be very large, the investigator usually must apply sophisticated multivariate statistics to tease out the complex interrelationships among the variables. The most commonly used statistics are multiple regression and factor analysis, but occasionally one sees studies using path analysis, latent-variable models, time-series analysis, multidimensional scaling, and hierarchical linear models. Needless to say, given the typical sample sizes and the complexity of the statistical analyses, historiometric studies almost invariably must be executed on a computer.

Comparisons

It is important not to confuse historiometric research with several alternative approaches. To begin with, historiometry differs substantially from psychobiographical and psychohistorical studies

of creativity. The latter almost always employ qualitative rather than quantitative methods, and they tend to be idiographic rather than nomothetic in orientation. In addition, psychobiographical and psychohistorical inquiries are very often psychoanalytic in theoretical emphasis. These characteristics are evident in the classic psychobiography of Leonardo da Vinci that was published by Sigmund Freud. Historiometry, in contrast, is a method designed to test hypotheses that might be drawn from any theoretical framework, psychoanalytic or otherwise. An excellent example is Colin Martindale's book *The Clockwork Muse*, in which the author tests a formal model of stylistic change that has roots in psychoanalytic theories of creativity.

Another approach is sometimes confused with historiometry is the comparative. Comparative research takes a modest size sample of individuals or events and then tries to discern consistent patterns or regularities. Although the goal is often nomothetic, the method is qualitative. A good illustration is Howard Gardner's book *Creative Minds*, in which he carefully compares and contrasts the lives of seven eminent individuals. Comparative studies can lead to important insights about creativity and other phenomena but do not share historiometry's capacity for more precise model testing and prediction.

Lastly, historiometry must not be equated with cliometrics. Although the two terms have similar etymologies – both literally mean 'history measurement' – cliometrics has become associated with quantitative research in economic history. Here, the goal is to test a historical question by applying econometric methods and economic theory to archival data. A classic example is the cliometric research on whether slavery was a profitable business in the antebellum US South. Although important, this issue has no psychological content, nor does it concern creative geniuses.

History

Surprisingly, historiometry actually represents the earliest scientific approach to the study of creativity. In 1835 Adolphe Quetelet published a quantitative analysis of eminent English and French playwrights in which he established the relationship between age and creative output. The next important historiometric inquiry was the 1869 book *Hereditary Genius*, in which Francis Galton documented how eminent creativity (and leadership) tends to run in family lineages. Other pioneer historiometric investigations include Alphonse de Candolle's study of eminent scientists and Havelock's study of British geniuses.

However, none of these researchers explicitly identified their work as historiometric, for the term had not yet been invented. The word was not coined until the first decade of the twentieth century, when Frederick Woods, a geneticist, patterned the term after biometrics. Although Woods's own historiometric research focused more on famous leaders than creators, the term was adopted briefly by others. Most notably, Catharine Cox's 1929 study of the *Early Mental Traits of Three Hundred Geniuses* was explicitly labelled a historiometric inquiry. This monumental investigation, which constitutes the second volume of Lewis Terman's *Genetic Studies of Genius*, provided quantitative assessments of the intelligence and personality of famous creators and leaders.

Cox's work inspired other historiometric studies, but unfortunately both the method and the term virtually disappeared from the research literature on creativity. Beginning in the mid-1970s, Dean Keith Simonton began to revive the technique and the name. At present, historiometry seems to represent a relatively rare but nonetheless acceptable approach to the study of creativity. Indeed, from time to time it has attracted the efforts of eminent psychologists whose primary contributions have employed very different methods. Among these holiday historiometricians are James McKeen Cattell, Raymond B. Cattell, B. F. Skinner, Lewis Terman, and Edward L. Thorndike.

Research

One of the reasons that historiometric research may be here to stay is the tremendous amount of important empirical results it has generated. The great diversity of findings may be grouped into two inclusive categories: those concerning the creative individual and those concerning the creative product.

The Creative Individual

The largest proportion of historiometric studies of creativity examines those individuals who have achieved acclaim for their original contributions to some domain. These studies have tended to focus on the following three topics.

Individual differences

Even among eminent creators, the cross-sectional variation in creative success is quite substantial. To appreciate the contrast, we need only compare Newton with William Higgins, Descartes with Henri Duroy, Shakespeare with Chatterton, Michelangelo with Hendrick Bloemaert, Beethoven with Anton Reicha – all pairs of individuals who have rubbed elbows in the same historiometric samples. Much of the contrast in differential reputation can be ascribed to differences in creative output. Accordingly, many studies have examined individual differences in lifetime productivity, including the peculiar skewed (or elitist) distribution of that output. Other studies have examined the personality and intellectual factors responsible for the cross-sectional variation in output and eminence. For example, Cox showed how success required a combination of both high intelligence and unusual motivational persistence. She also demonstrated how the distinctive personality profiles of eminent creators vary according to the domain of creative activity.

Life-span development

Rather than concentrate on individual differences, many historiometricians have studied how creativity develops and manifests itself across the life span. These developmental inquiries fall naturally into two distinct categories. In the first category are those that look for the early antecedents of adulthood creativity. For instance, researchers have examined the impact of such variables as family pedigree, socioeconomic class, childhood precocity, birth order, orphanhood, role models and mentors, crystallizing experiences, and formal education or special training.

In the second category are those developmental studies that scrutinize how creativity varies across the course of the career. Most of these studies are concerned with how the rate of output changes with age. The expected age curves tend to vary systematically according to the specific type of creativity. For example, poets and mathematicians tend to produce masterworks at younger ages than do novelists and earth scientists. Other studies have examined the longitudinal relation between total quantity of output and the odds of producing a masterwork. Significantly, a creator's best work tends to appear in those periods of the career in which he or she is the most prolific overall.

Sociocultural context

Illustrious creators are not randomly distributed across history, nor are they evenly spread across the globe at any one time. On the contrary, creative genius is more prone to appear during 'golden ages,' less likely during 'silver ages,' and supremely unlikely during 'dark ages.' The Golden Age of Greece is a classic example. Such uneven distribution suggests that political, economic, social, and cultural forces may play a major role in the development and manifestation of creative talent. Historiometric investigations have specifically examined such factors as war, political system, ideology, and general intellectual ferment. These studies show that the 'spirit of the times,' or the *zeitgeist*, claims a crucial part in the origination of creative genius. The *zeitgeist* influences not only the number of eminent creators that appears in a given time and place, but also the particular domains in which creativity is most likely to be displayed.

The Creative Product

Because the eminence of a creator is very much contingent on the works he or she contributes to posterity, it is natural for historiometricians to investigate the characteristics of these artifacts of the act of creation. Some of this research has examined scientific discoveries and technological inventions. For example, several studies have been published on the multiples phenomenon where two or more scientists independently (and sometimes simultaneously) arrive at the same idea at about the same time. Classic illustrations include the proposal by Charles Darwin and Wallace of the theory of evolution by natural selection and the invention of the calculus by Newton and Leibnitz. Surprisingly, certain distinguishing features of these events – such as their timing and the number of participants – can actually be accurately predicted using mathematical models.

However, most inquiries into the creative product focus on the arts. Many of these studies are specifically devoted to the determination of the factors responsible for esthetic effectiveness of compositions in literature, music, or the visual arts. For instance, the application of computerized content analysis to classical music has enabled researchers to predict the relative performance frequencies of works in the repertoire. Similar historiometric techniques have had comparable success in the prediction of the differential popularity of literary creations, such as poetry. In addition, several historiometric studies have been concerned with qualitative changes in the nature of the works produced over the course of a career. Of special interest are inquiries into the swan songs of classical composers and the late-period style changes in visual artists. The research

shows that toward the very end of a creator's life the very nature of her or his creative output may undergo a dramatic transformation.

Evaluation

The reason why the behavioral scientists have so many different techniques at their disposal is because no technique is perfect. Each enjoys certain assets, and each suffers from certain liabilities. Historiometry is no exception. It, too, has both advantages and disadvantages. Let us look at the latter before turning to the former.

Disadvantages

Any researcher interested in applying historiometric methods to the study of creativity must often confront one or more of the following four problems.

Causal inference

Methodologists sometimes distinguish between internal and external validity of a technique. The former criterion concerns the security of the causal inferences the method permits. Laboratory experiments enjoy very high internal validity because the experimenter actively manipulates the independent variables and randomly assigns subjects to experimental and control groups. Historiometric research, in contrast, is inherently correlational in nature. The best the researcher can do is to determine how measured variables are associated. Because other unmeasured factors may contaminate the observed relationships, conclusions about causal influence are invariably insecure. Correlation can never be taken to prove causation. Thus, the internal validity of historiometric work is almost always inferior to that found in the experimental literature. For example, one of the oldest debates in the study of creativity is the relationship between genius and madness. What makes this issue especially irksome is the difficulty of determining which of three distinct possibilities is most likely to hold: (a) a proclivity toward psychopathology might make a positive contribution to creativity; (b) exceptional creative achievement might put exceptional strain on creative individuals, thereby making them more disposed to mental and emotional breakdowns; and (c) neither creativity nor psychopathology may have any direct causal relationship with each other but rather might be the consequence of some other factor or factors (e.g., traumatic or unconventional childhood experiences).

Data quality

Because the historiometrician must rely so much on the historical and biographical record, sometimes the available information leaves much to be desired from a scientific standpoint. For example, when Cox attempted to calculate IQ scores for historic personalities, she lamentfully discovered that she had to exclude William Shakespeare from her sample. There exists very little data about the Bard's personal life and virtually nothing about his early years. Even when enough pertinent information could be found in the historical record for a particular individual, Cox found that the reliability coefficients for her IQ assessments could vary substantially from genius to

genius. Moreover, when she wished to estimate 67 personality traits for her subjects, she was obliged to restrict her sample to the 100 famous people about whom the most data were available.

Substantive applicability

Closely related is the fact that some important issues in the scientific study of creativity probably cannot be addressed using historiometric methods. For instance, one of the central questions in the creativity literature is the very nature of the creative process. What is the role of intuition or unconscious processes? What is the function of logical analysis? Yet the biographies and published letters of eminent creators do not contain the necessary information in any systematic fashion, and when the records do, they cannot always be trusted as sources of solid data. For example, Samuel Coleridge's description of the creative process underlying the composition of 'Kubla Khan' is inconsistent with his own unpublished manuscripts that contain the various drafts of the poem. It is now apparent that he distorted his narrative to render the episode more consistent with romantic notions of the creative process.

Labor requirements

Perhaps the most prohibitive drawback of historiometric research is the sheer amount of work required to carry out a project. Collection of the raw data may require many trips to the library and special archives, followed by the arduous coding of qualitative information to get the data in quantitative form. Even after the content analytical, historical, and biographical data have been reduced to numbers, the statistical analyses may consume considerable amounts of time. Historiometric data sets often involve numerous variables with highly complex interrelationships that can only be teased out using the most advanced statistical techniques. As a consequence, it is not uncommon for a major historiometric study to require several *thousands* of hours of effort to produce a single journal article. That is a small payoff in comparison to, say, a laboratory experiment in the area of creative problem solving. Naturally, monograph-length investigations may demand even more time and effort. To offer one dramatic example, Frank Sulloway's book *Born to Rebel* represents the culmination of 26 years of intensive data collection and analysis.

Advantages

The forgoing liabilities notwithstanding, often one or more of these problems can be alleviated if not entirely removed in well-conceived historiometric research. First, multivariate statistics and quasi-experimental designs have immensely increased the power of drawing causal inferences from correlational data. One especially potent inferential tool is time-series analysis. Second, data quality problems can often be handled by the introduction of more sophisticated statistical methods, such as latent-variable models. These permit the explicit incorporation of measurement error into the causal model. Third, the substantive applicability of historiometry can often be greatly extended if the investigator exercises care in selecting the optimal research site. For instance, sometimes a researcher may examine famous creators from non-Western civilizations precisely because the biographical and historical information

is available regarding a particular set of variables. Fourth, if the investigator plans carefully and compiles a rich enough database, it is possible to generate more than one publication from a single data collection. For example, once a researcher decides on using a particular sample of Nobel laureates as the basis for the investigation, he or she can gather a great diversity of biographical, historical, and content analytical data that can be used to test a wide variety of hypotheses.

Besides these extenuating circumstances, researchers often have very strong reasons for adopting historiometric methods for a particular investigation. The following five assets may be the most important from the standpoint of creativity research.

Criterion validity

One of the main problems in studying creativity is how to measure the phenomenon. Some researchers may define creativity in terms of scores on a psychometric instrument, whereas others may rely on judges' evaluations of creative products. Although these conventional assessments have much to recommend them, they are also not without conspicuous limitations. For example, a measure cannot be called a 'creativity test' without first validating the instrument against some more secure criterion of creativity. Perhaps scores on such tests have absolutely nothing to do with real-life creativity. Historiometric research circumvents this problem by studying those individuals who have made a name for themselves precisely for their creative achievements. If the investigator examines persons like Planck, Sartre, Joyce, Picasso, or Stravinsky, we have no other option but to assume that these individuals exhibit creativity. If we were to deny that attribution, the term *creative* would lose all meaning. Hence, historiometric methods take their point of departure at those individuals who best exemplify the phenomenon under investigation.

Variable accessibility

There are many important influences on creativity that for both practical and ethical reasons can only be examined using historiometric methods. If the goal is to determine the sociocultural milieu that best contributes to the development of creative development, it is hard to imagine a better method than to scrutinize the historical record with respect to the coming and going of creative genius. For instance, if we want to test the hypothesis that wartime conditions inhibit the expression of creativity, we probably have no other choice than to conduct a time-series analysis comparing the output of creative products against the magnitude of political violence. Even if the focus is on creative careers, the assets of historiometrics are paramount. The researcher can examine the emergence and manifestation of creative genius from the moment of conception (e.g., family pedigrees) to the moment of death (e.g., swan songs) and everything in between (e.g., birth order, childhood trauma, role models and mentors, education and special training, and career trajectory). Historiometry is thus truly life-span developmental in scope.

Unobtrusive measurement

Ever since the advent of the Heisenberg uncertainty principle in quantum theory, physicists have learned that the very act of measuring a phenomenon may interfere with the phenomenon under scrutiny. A similar consequence often may be seen

in many standard methods in the behavioral sciences. For example, the very act of studying the creative process in the laboratory may distort the observed behavior to such a degree that it becomes unrepresentative of what would happen under more natural conditions. Similarly, the application of psychometric measurement, surveys, and one-to-one interviews to samples of contemporary creators may produce expectancy effects, 'guinea-pig' effects, and other kinds of artificial reactions. Historiometric measurement, in contrast, is totally unobtrusive. The subjects in historiometric inquiries do not know that they are under observation. Indeed, because the subjects are most often deceased, they will never find out the results. Accordingly, the phenomenon of creativity can be investigated without fear of inducing unnatural responses from the subjects of the study.

Cross-cultural and transhistorical invariance

Behavioral scientists seek general laws or principles of behavior that transcend place and time. If an empirical relationship only holds for a particular culture or is merely valid for a single historical period, it cannot have the claim to universality that is the hallmark of all nomothetic science. For example, Newton's law of gravitation holds not only for apples falling from trees in seventeenth-century England but also for all massive bodies in the universe throughout the history of time. One great asset of historiometric research is that it can sample creators from all civilizations of the world and from every major historical period. Hypotheses tested on such diverse samples have a much higher probability of claiming cross-cultural and transhistorical invariance. For instance, one historiometric investigation of literary creativity showed that poets produce their best works at younger ages than prose writers. Furthermore, this differential was shown to be invariant across historical time and geographical origins. Because the sample consisted of hundreds of literary figures drawn from all the world's major literatures from antiquity to the present day, we can have greater confidence that this result is not confined to, say, such nineteenth-century British authors as Keats, Shelley, and Byron.

Unit replicability

One of the peculiarities of historiometric research is that the subjects who compose its samples can all claim a permanent and distinct identity. After all, the individuals under scrutiny have made a lasting name for themselves on the basis of their creative contributions to human culture. As a consequence, it is not uncommon for historiometric studies to identify their subjects by name, listing them either in a table or in an appendix. For instance, Cox listed all 301 geniuses whom she studied along with some of the basic information compiled about each, including the estimated IQ scores. Other times the researcher will give sufficient details about the sampling procedures – such as the precise biographical dictionaries used – that any reader can easily determine who the famous personalities under investigation were. In any case, because the subjects are identified or identifiable, subsequent investigators can study exactly the same individuals, adding new variables and altering the statistical analyses performed. For example, the eminent persons in the Cox study have been re-examined in several follow-up inquiries published over an 80-year period.

This asset of unit replicability allows the historiometrician to improve on previous results in a manner that can accelerate the accumulation of scientific knowledge. Most alternative methods lack this feature. A laboratory experiment can always be replicated in terms of method, but not in terms of subjects. As a consequence, when experiments fail to replicate a previously published finding, it is uncertain whether the contrast may be ascribed to the change of participants in the study. In contrast, when a historiometrician scrutinizes the exact same subjects as analyzed in a previous study and fails to obtain identical results, the cause of the discrepancy can be more easily isolated.

Conclusion

Because historiometry has already been around in the behavioral sciences for more than 170 years, its use will likely continue in the future. The technique has already made considerable contributions to our understanding of creativity in its most historic manifestations. Moreover, the method enjoys many methodological advantages over other research strategies. Above all, it is the technique of choice for anyone who wants to test nomothetic hypotheses about history-making creativity. No alternative method features the same inferential rigor and quantitative precision. Moreover, despite various methodological disadvantages, many of these drawbacks are becoming ever less critical. Certainly statistics for analyzing correlational data are becoming increasingly sophisticated, permitting ever more powerful causal inferences. Even more important, the quality of the data about historic creators is becoming increasingly better with time. After all, creativity is not dead in the world, and each generation will usually produce a new crop of eminent creators that can serve as subjects in future historiometric research. Furthermore, there will probably be more and better information about these forthcoming creative individuals than holds for those born in earlier historical periods. Indeed, historiometric research has actually demonstrated that the reliability coefficients for many variables have increased over time. Finally, with the advent of the internet, the available information has not only become more detailed but also more accessible. The investigator can often download all or most of the data for a particular historiometric inquiry directly from an internet database.

In a sense, the situation for the historiometrician is very similar to that of the astronomer centuries earlier. The first astronomical measurements were rather too imprecise to support anything more than the crudest planetary theories. But as observations became more precise, the archival records collected by astronomers began to encourage the development of increasingly sophisticated theories. I predict that historiometry will enjoy the same historical trend with respect to its own phenomena. In fact, in some respects it has already done so. As mentioned in the section on the method's history, the first historiometric study ever published dates back to 1835. That investigation concerned the relationship between age and creative productivity. Since that pioneering inquiry, many investigators have scrutinized the same question using ever more precise measurement and statistical analysis. Now the cumulative body of evidence on this question has reached the

point that researchers have begun to propose mathematical models that provide rather precise predictions about how creative output changes across the life span. Hence, in this substantive domain at least, historiometrics can indeed provide the foundation for scientific progress in our comprehension of creativity. The same progress should be seen with respect to other topics that attract historiometric inquiry.

General Introduction

Grace Brewster Murray Hopper, an early computer scientist, entered the world of computers as a result of the entry of the United States into the Second World War. An associate professor of mathematics at Vassar College when the Japanese bombed Pearl Harbor, she, like many others, wanted to contribute to the war effort, and her choice was to join the navy. Despite multiple obstacles, she became a WAVE at the end of 1943 and was commissioned a lieutenant (j.g.) in 1944. Her entry into the navy was also her entry into the world of computers; she was assigned to the team working on the Mack 1, the first electromechanical computer, at the Bureau of Ships' Computation Project at Harvard University. As quoted by Charlotte Billings, Hopper described responding to the Mack 1 as "the prettiest gadget" that she had ever seen (p. 49). Hopper remained involved with computing and with the navy for most of the rest of her life. Hopper's creative contributions to computing included the development of the first compiler and of the first nonmathematical programming language, developments which, like many creative contributions, came to be taken for granted but which were unthought of – not merely nonexistent – prior to Hopper's development of them.

Biography

Family

Hopper was born Grace Brewster Murray in New York City on 9 December 1906, the oldest child of Mary Campbell Van Horne Murray and Walter Fletcher Murray. Her parents subsequently had two other children, Mary Campbell Murray and Roger Franklin Murray II, three and five years younger than Grace, respectively.

In some respects, Hopper's family may seem typical of educated families of the era. Her father was an insurance broker, as his own father had been. Her maternal grandfather, John Garrett Van Horne, was a surveyor. One of her great-grandfathers, whom she had met as a very small child, had been a rear admiral in the navy – a fact which Hopper herself would mention during her navy career.

In other respects, however, they were an unusual family. Walter and Mary Murray believed that their daughters as well as their son should be well educated and should be able to support themselves as adults. They also believed that their son as well as their daughters should be able to perform such homely (stereotypically feminine) tasks as cooking and mending. Both parents served as role models for their children. Walter, despite the loss of both of his legs because of problems with circulation, lived a long and active life, serving as an example of perseverance in the face of potentially daunting difficulties, and treated his disability with wry humor (e.g., joking that he changed his socks only when they became dusty). Mary, like her elder daughter, loved mathematics, but

her opportunities for formal study were limited by her era; as Billings (p. 15) noted, "special arrangements" had to be made for Mary to study geometry in high school, and those arrangements precluded her actually sitting in the classroom. Mary also, because of her husband's health problems and her own consequent fear of widowhood, managed the family finances. In both of these ways, she demonstrated to her children that women could be mathematically capable.

All three children graduated from college, and two (Grace and Roger) also earned doctoral degrees. Additionally, all three had careers related to mathematics. Grace was a mathematician and computer scientist, her sister a statistician for an insurance company, and her brother a banker.

Grace remained close to her family as an adult. After she married a man whom she met in Wolfboro, where her family had a summer home, Grace and her husband went to Europe with her family rather than honeymooning alone. As a young couple, they lived near her parents and also bought a house in Wolfboro. Although Grace had no children, she was close to the children and grandchildren of her brother and sister.

Childhood and Early Adulthood

As might be expected given her parents' attitudes, Grace's childhood activities were not limited to those prescribed by the times for little girls. Although she played with dolls, she also played with construction sets; she was an avid reader; and she was an athlete (her athletic experience later played a role in her development of the first compiler).

In adulthood, Hopper was an inveterate story-teller, and she frequently told a story of an episode in her childhood which both indicates her early interest in things mechanical and foreshadows her later response to the Mack 1 as "the prettiest gadget" she had ever seen. She took apart an alarm clock when she was seven years old. Unable to put it back together, she continued taking apart other alarm clocks, trying to use them as models, until she had disassembled every alarm clock in the house.

Grace received her primary and secondary education at academically rigorous schools in New York City and New Jersey. As an undergraduate at Vassar, Grace majored in mathematics and physics and anticipated her later professorial activities by helping other students with mathematics and science. She was skilled at contriving demonstrations which helped make abstract concepts concrete. One example from her undergraduate days was an occasion when she asked one student to climb into a full bathtub to demonstrate for a group the concept of displacement of water. A later example for which she was famous was her distribution of "nanoseconds" at her lectures; the "nanoseconds," literally pieces of wire approximately one foot long, showed how far an electron could travel in one one-billionth of a second (a nanosecond).

Hopper graduated from Vassar with honors and with a grant to support her continued education. She received both

a Master's degree (1930) and the Ph.D. (1934) in mathematics from Yale University. She also married in 1930; her husband, Vincent Hopper, was another academic, an English scholar at New York University.

Hopper began her professorial career while she was a graduate student, appointed an instructor of mathematics at Vassar in 1931. She remained on the Vassar faculty after finishing her doctorate, advancing through the ranks to associate professor by the time she joined the navy in 1943. Her position at Vassar and her husband's at New York University resulted in their living mostly apart, although Vincent did travel to Poughkeepsie on weekends. The Hoppers separated in 1941 and were divorced in 1945.

Second World War and the Navy

Although Hopper wanted to join the navy in the aftermath of the attack on Pearl Harbor, she had multiple obstacles to overcome. In the first place, because professors of mathematics were considered to be essential to the war effort, arranging to leave her faculty position at Vassar was a difficulty. Additionally, Hopper was considered too old (at age 35) and too light (at 5' 6" tall, she weighed 105 pounds) to join the navy. Eventually, however, she was permitted to become a WAVE, attended the Northampton Midshipmen's School, finishing first in her class, and was commissioned a lieutenant (j.g.) in 1944.

Hopper's assignment to the Bureau of Ships' Computation Project at Harvard University was her introduction to computers, and she spent the rest of her career working with computers, sometimes with the navy and sometimes in private industry. Her contributions to the development of computer science will be described in a separate section below.

By the end of the Second World War, Hopper had become a lieutenant. She wished to remain on active duty in the regular navy, but this choice was not open to her. Her age was again the problem. Although she did have the option of returning to her faculty position at Vassar (with a promotion to professor), she chose instead to remain at Harvard to continue working with computers.

The end of the war did not mark the end of Hopper's navy career, however. She remained in the naval reserve, and, as a reserve officer, rose to the rank of commander by 1966. In 1966, however, the navy decided yet again that she was too old to serve. As she told the story to Billings (p. 87), she received a letter from the Chief of Naval Personnel informing her that she had "been on reserve duty for twenty-three years, which was more than twenty. 'I knew that,' Grace said. Another paragraph stated she was sixty years old. 'I knew that too,' she said." Against her own inclination, then, she submitted the requested application for retirement.

As had happened twice before, however, the navy's decision in this case was not final. Hopper shortly was recalled to active duty, not simply reserve duty. The specified term of six months was extended and, by its conclusion, had lasted approximately 20 years. During these years, she headed the Programming Languages Section of the Naval Information Systems Division. Also over these years, she rose in rank to commodore.

In 1986, more than 40 years after the navy first had rejected her because of her age (among other reasons), Hopper was

again requested to retire because of her age, this time for the last time. At her retirement, she held the rank of rear admiral; she was not only the oldest serving officer but also the only former WAVE on active duty. Hopper returned to the private sector on her retirement from the navy. The value that she herself placed on her navy service is revealed not only by the length of her service but by her habitually closing her lectures with a comment on "the privilege and responsibility of serving very proudly in the United States Navy," as she put it in a keynote address published in 1981.

Hopper in the Private Sector

When Hopper was discharged from the navy at the close of the Second World War, she remained at Harvard so that she could continue working with computers. Over the next few years, she, along with the other members of the team, worked on the Mack 2 and the Mack 3, the successors of the "gadget" she had found so appealing in 1944. Because remaining at Harvard was not a viable option for the long term, though, Hopper moved into the private sector, going to work for the Eckert-Mauchly Computer Corporation; she remained with this company, through mergers and takeovers and the accompanying name changes, until her 1971 retirement from what had become the Sperry Corporation. By 1971, of course, she had for several years been back on active duty as a naval officer.

After her second lengthy term of active-duty service, lasting from the mid-1960s through the mid-1980s, Hopper, the navy's opinion notwithstanding, did not consider herself ready to retire. Thus, she returned to the private sector as a senior consultant at Digital Equipment Corporation. In that capacity, she continued to travel and to lecture for the next several years, until 1990. She thus was active nearly until her death on 1 January 1992. Befitting her years of service and her dedication to the navy, she is buried in Arlington National Cemetery.

Hopper, Computers, and Computer Science

When Hopper joined the navy and was assigned to the Bureau of Ships' Computation Project, computers were in their infancy. The Harvard team which she joined was working on the Mack 1, the first electromechanical computer, and she was only the third person (and the first woman) to program this computer. This early computer stands in remarkable contrast to computers of the twenty-first century; a huge machine, it was also hugely slower and less powerful than even an inexpensive modern desk-top computer. Processing speed of readily available twenty-first century personal computers is measured in megahertz or gigahertz; the Mack 1 performed three operations per second. By the standards of the era, however, and in contrast to human computers, the Mack 1 was impressively rapid.

Human-computer interactions in the mid-twentieth century in many respects were even more different from those of the twenty-first century than were the machines themselves. Computer users of the twenty-first century are accustomed to user-friendly operating systems and point-and-click environments. The programmers of the Mack 1, in contrast, wrote the instructions to the computer in machine language. Sets of instructions

to perform specific tasks (programs, in the modern parlance) as well as the data to be processed were punched on paper tape, not stored in the computer. The paper tapes, however, could be kept and could be reused when needed. By making such a collection, Hopper and her colleagues began building a library of programs.

Probably more importantly in terms of the development of computer programming, Hopper and her colleagues collected standard sets of instructions for sets of operations which were common to multiple programs. In the abstract, these standard instruction sets were equivalent to what modern programmers think of as subroutines. In their instantiation, however, they were primitive compared to their modern descendants. Rather than being built into the software or the hardware, these “subroutines” were written on paper and collected in notebooks. In order to use one, a programmer had to copy it by hand into the program being constructed. Although this procedure reduced the mental labor of programming substantially, there still was ample room for human error; in fact, there were now two separate occasions for transcription errors, first in the process of copying subroutines into programs as they were written, and second, as always had been the case, in keypunching the programs once written.

It occurred to Hopper that the problem of transcription errors (along with other problems) could be addressed by using the computer itself to make copies of stored subroutines. This insight eventually led to her development of the first compiler in the early 1950s, while she was working at Eckert-Mauchly. Her idea – and her implementation of it – flew in the face of the conventional wisdom that “computers could only do arithmetic,” as she expressed it in the 1981 keynote address (pp. 13–14). As she described it in the now classic paper, “The Education of a Computer,” by writing this first compiler, called the A-0, she made the computer into its own programmer.

Her refusal to accept conventional wisdom and her rejection of the way things were as the only way they could be were persistent characteristics of hers, and she encouraged others to take unconventional tacks as well, often saying “It is easier to ask forgiveness than it is to get permission” (or some variant of this line). Her office clock, which was numbered and which ran counterclockwise, was a concrete example of her acceptance and her encouragement of novel ideas.

Another characteristic of this first compiler remained impressive – and startling – to her colleagues even after they had accepted that compilers were possible, and that was that the A-0 was a single-pass compiler. As Hopper described the problem in a 1980 oral-history interview,

obviously you couldn't do that, because you'd run into a place where in the flowchart, for instance, you could have two kinds of tests. One would jump back to somewhere you'd been and you knew where you put that program piece, but you would have another test that jumped forward and you haven't processed that yet, so you didn't know where it was going to go (p. 7).

Hopper solved the problem of not knowing where to jump forward to by analogy to a very different domain, using a memory of her experience playing girls' basketball in high school. She built into the compiler a “neutral area,” and, when the compiler needed to jump forward to a place not yet

specified, it would jump instead to the neutral area and put a flag in this neutral area; this flag then would trigger a jump to the appropriate operation once the compiler had progressed that far.

A-0 was a major advance in computer programming, both conceptually and practically. It still was written in machine language, though. In the 1950s, with computers increasingly in commercial use and in use for functions beyond computation, the requirement that computer instructions be written in machine language was hampering the development of needed programs. Hopper was one of the first to consider using forms which looked like natural language (strings like *count* and *divide*) for writing computer programs. For all that programming and programming languages are foreign to most twenty-first century computer users, Hopper's and others' development of high-level programming languages might be considered first steps in the direction of user-friendly computers. Hopper herself, in a 1969 oral-history interview, attributed both the development of the initial compiler and the development of high-level programming languages to the realization that “we had to make it easier for people to use computers” (no page number).

Like the original idea of a compiler, this idea flew in the face of established wisdom. Everyone knew that “computers couldn't understand English words,” as Hopper later put it in the 1981 keynote address (p. 16). Hopper, of course, also knew that computers could not understand English. What was required, however, in her view, simply was another version of a compiler, in this case one which would translate instructions using words (which made sense to people) into machine language (which the computer could process). This new compiler, B-0, was introduced in 1955. With this development, working computer programs could be written using such statements as “INPUT INVENTORY FILE A; PRICE FILE B” and “OUTPUT PRICED INVENTORY FILE C.”

Hopper and her team wrote other versions of the compiler which used French or German words rather than English. This, however, seemed from her later description to have been considered carrying innovation too far for the corporate management. As she said in the 1981 address (p. 17),

it was absolutely obvious [to management] that a respectable American computer, built in Philadelphia, Pennsylvania, could not possibly understand French or German! And it took us four months to say no, no, no, no! We wouldn't think of programming it in anything but English.

Although Hopper's FLOW-MATIC (a name assigned by the marketing department) is no longer in use, it was and is important for several reasons. It was one of the first high-level programming languages to be widely used, and it was the first which was specialized for nonmathematical uses. More importantly, FLOW-MATIC was not only the precursor of but the model for COBOL (Common Business Oriented Language), one of the most important programming languages of the twentieth century and still important in the twenty-first century.

The development of COBOL has often been attributed to Hopper. Although this attribution is false, Hopper's influence on COBOL, both at its outset and later, was substantial. For example, she belonged to the group which initiated the

development of COBOL and provided technical advice to the group which actually constructed the language. Jean Sammet, who was a member of the latter group, wrote in 2000 that

without the existing practical use of Flow-Matic, I doubt that we would have had the courage to develop a language such as Cobol (p. 31).

Over the years after its release, as COBOL was used for various purposes in various sites, programmers at different sites modified the language to fit it to their local needs. The small-scale utility of the resulting different versions of COBOL created problems on a larger scale: Programs written at one site in one version of COBOL might not run – or might not run correctly – at other sites where COBOL had been modified differently. In other words, COBOL ceased to be effectively a common language, becoming instead a family of related languages.

It was to rectify this situation that Hopper was recalled to active duty in the navy in 1967 (only months after she had reluctantly retired from the naval reserve). Making yet another major creative contribution to the development of high-level programming languages, Hopper and the team she directed developed procedures for testing the various versions of COBOL to ensure consistency of performance across the variants. These procedures might be considered to stand in the same relation to COBOL as does the Academie Francaise to the French language.

Awards and Other Marks of Recognition

Hopper's contributions to the navy and to computing were recognized by the navy, by the computer science community, and by the broader community in many ways over the years, beginning early in her career. She was awarded the Naval Ordnance Development Award (1946), the Computer Science Man of the Year award (1969, the first year it was awarded), and the National Medal of Technology (1991). She was named a Distinguished Fellow of the British Computer Society in 1973, the first woman and the first American to be so honored. Her namesakes include the Grace Murray Hopper Award (established 1971; awarded annually at the meeting of the Association of Computing Machinery), the computer center at Brewster Academy (a private school in the community where both she and her parents had summer homes), the Grace Murray Hopper Service Center (a naval data processing center in California), the USS *Hopper* (a highly-computerized destroyer), and the Grace Hopper Celebration of Women in Computing (first held in 1994).

Grace Hopper and Creativity

Grace Hopper grew up in a family with some unconventional attributes, which may have contributed to her own acceptance of alternatives to the usual ways of being and doing. In particular, her mother offered a model of a mathematically competent woman, defying a stereotype much stronger early in the twentieth century but still strong in the early twenty-first century.

Hopper's story of her dismantling of every alarm clock in the house is emblematic of multiple characteristics which are likely contributors to her creative accomplishments as an adult. In the first place, she was curious, and she acted on that curiosity, setting out to discover for herself how an alarm clock went together. Second, she was persistent: She did not stop trying to solve the problem until she ran out of alarm clocks. The story itself is representative of another aspect of her creativity, her consistent use of her own history, personal and professional – her story-telling – to make and to illustrate her points.

Two other characteristics likely to have contributed to her creative accomplishments are distinct but closely related: She had a capacity for moving between the abstract and the concrete, and she had a knack for analogical/metaphorical thinking. Her practical demonstration of the displacement of water to her fellow students at Vassar and her use of lengths of wire to make the concept of a nanosecond comprehensible to those to whom she lectured both are examples of her skill at making the abstract concrete (her story-telling perhaps also falls under this aspect of her creativity). The nanosecond example also demonstrates her use of an analogy between spatial extent and temporal duration, an analogy implicit in much ordinary language usage but made explicit by Hopper's wire "nanoseconds." Her use of an aspect of the rules of girls' basketball as played in her youth to suggest a solution to the problem of forward jumps when compiling a program goes from the concrete to the abstract and also draws on a novel analogy.

Hopper's refusal to be bound by the way things traditionally were done or even by what "everyone knew" also contributed to her creative accomplishments. Both in writing the first compiler and in constructing an early high-level programming language using English words, Hopper made a computer do what "everyone knew" a computer could not do. Last, but not least, in both these cases, Hopper identified a state of affairs of which others also must have been aware as a problem to be solved. Her identification of the problems may be more truly a hallmark of her creativity even than her solution of them. Hopper herself, discussing her achievements in an oral-history interview in 1969, said about A-0 and B-0 that

the realization of what was needed and what could be done was more important than the actual doing of it (no page number).

In some cases, particularly on large-scale projects, creativity may emerge from collaborative rather than from identifiably individual activity. That Hopper and her Mack 1 colleagues realized that programs and subroutines could be collected and reused and that they made and used these collections may be instances of collaborative creativity, as may the later development of validating procedures for COBOL developed by Hopper and her team in the 1960s.

Hopper's frequently offered advice to dare and to do (*Aude et Effice*, in the original and in the form used for the emblem of the USS *Hopper*) was advice which her career exemplifies; Hopper practiced what she preached. She was intellectually daring and highly effective in contributing to the development of her chosen world of computers and computing.

Glossary

Bisociation Arthur Koestler's name for thinking which connects two or more planes. Perceiving a situation, event or idea in two self-consistent but normally unrelated and even incompatible frames of reference. An idea is linked to two associative contexts.

Divergent thinking Producing a large number or wide variety of responses.

Extraversion An enduring personality trait measuring the extent to which a person is socially outgoing or interested in things outside the self.

Fluency The total number of ideas produced.

Gelotophobia Fear of being laughed at.

Humor appreciation Understanding jokes, amusing situations, witticisms, etc., and finding them funny.

Humor production Creating jokes, stories, amusing situations, witticisms, etc., that other people find funny and/or laugh at.

Incongruity Pairing of ideas or situations that are not usually paired.

Psychoticism on H. J. Eysenck's Personality Inventory, a trait which involves being insensitive to others, impulsive, aggressive, etc.

Remote Associates Test (RAT) Sarnoff Mednick's measure of creativity in which respondents are presented with three words and are instructed to find a fourth word which somehow links the first three words together. For example, mouse, sharp, blue, —.

Resolution In creativity the idea that to be creative, an idea, act, or product needs to be appropriate, valuable, to solve a problem, or to fit the requirements of the situation. In humor, resolution of an incongruity means 'solving the problem,' or figuring out how two different ideas are related.

Sense of humor A personality or individual difference variable, in which people are characterized by willingness to smile or laugh, a cheerful disposition, using humor to cope with stressful situations, etc. Many different measures of sense of humor exist.

State-Trait Cheerfulness Inventory (STCI) A personality measure of the sense of humor, developed by Willibald Ruch and his research team, which includes subscales of cheerfulness, seriousness, and bad mood.

Introduction

An important milestone in the recognition of relationships between humor and creativity was provided by Arthur Koestler in 1964. He considered humor, artistic production, and scientific discovery to be forms of creativity because all of them involved a sudden change in the angle of vision on reality. Koestler thought that these three domains of creativity shaded into each other without sharp boundaries.

Over the past 50 years, there has been considerable research on the humor–creativity link. However, there is still little consensus about terminology, nor are measurements of either the humor or the creativity construct widely agreed-upon as definitive. Because terminology is so important to understanding the links between creativity and humor, it is helpful to narrow down the broad concept of 'humor.' We will discuss humor in three ways: understanding humor (humor appreciation), creating humor (humor production), and humor as a personality trait (sense of humor). To some extent, the difference between appreciating humor and producing humor is partly artificial. A person cannot *intentionally* produce humor unless he or she is capable of appreciating humor. However, the opposite is not necessarily true; there are people who claim that they do not or

cannot produce humor, even though they are quite capable of appreciating the humor of others.

The bulk of the literature in the creativity field that deals with humor is focused on humor appreciation, although humor production has received more attention recently. Considerable research has also examined sense of humor as a personality/individual difference variable. A few studies of humor and creativity have used behavioral measures of humor such as smiling or laughing. We will consider all of these types of humor measures. However, we will neither attempt to address 'humor' in the broadest sense, nor to provide a theoretical description of why people laugh and smile. Rather, we will concentrate upon humorous behaviors, personality variables, and cognitions that have been studied in relationship to creativity.

Similarity of Definition

Parallels in the definitions of humor and creativity are readily evident. Both experts and laypersons agree that one of the delineating characteristics of creativity is originality or novelty. Similarly, originality (or its close cousin surprisingness) is also

frequently suggested to be characteristic of humor. Funniness is often found to be related to surprise.

However, simple originality is not enough for the definition of creativity, and surprise is typically not enough for humor once a person is past the 'peek-a-boo' stage. At least one more dimension is needed. In the creativity field, that second dimension has been given many names (appropriate, useful, etc.). The name for this dimension which best links humor and creativity is *resolution* – the notion that to be creative, an idea, act, or product needs to be appropriate, relevant, or to fit the requirements of the situation.

Similarly, in humor appreciation and production, the simply bizarre will not often be seen as funny, but rather as weird or strange. Instead there must be a balance governed by a departure from one idea with the introduction of another idea, different but somehow related and appropriate: a relevant incongruity. Research on linguistic approaches to humor has shown that incongruity-resolution (figuring out how two different ideas are related) can make a significant contribution to funniness. Rod Martin illustrated the concept of incongruity resolution with this joke:

"Is the doctor at home?" the patient asked in his bronchial whisper.
"No," the doctor's young and pretty wife whispered in reply. "Come right in." (2007: 90)

The listener must resolve the incongruity of the initial expectation that the patient is seeking the doctor's care for his hoarseness, and the additional inference that perhaps it's not the doctor's company that the patient is seeking.

Thus, surprise is just part of the story. Some research has shown that relatively predictable punchlines are funnier. And incongruity recognition (rather than resolution) may be a better description of the process. Resolution sometimes increases funniness, but it depends on circumstances and personality.

Similarity of Cognitive Processes

An important way in which humor and creativity are similar lies in the cognitive processes involved. The classic incongruity theories of humor say that humor arises from the pairing of ideas or situations that are not usually paired. As discussed earlier, information-processing models of humor focus on the resolution of incongruities.

In linking humor and creativity, Koestler coined the term 'bisociation' to describe the mixing of ideas involved when a person abruptly perceives as similar two habitually-incompatible contexts. Understanding a joke requires the given data to be transformed or reinterpreted. A simple example is a pun, where two different meanings of a word or phrase are brought together simultaneously (e.g., a fake book entitled *Proper Use of Sunscreen* by Justin Casey Burns). Other names have been used for the same concept that Koestler named bisociation. For example, in the creativity field, Sarnoff Mednick called it 'remote association,' and D. N. Perkins called it 'contrary recognition.'

Humor comprehension and creativity should be similar because both require the ability to link disparities. Humor often depends upon unusual associations, so a person's ability

to generate and understand humor would seem to depend, at least partly, upon ideational fluency (the ability to produce many ideas to fulfill certain requirements, such as thinking of possible uses for a brick, or for a paperclip). Ideational fluency has been said by many authors to be an important component of creativity.

J. P. Guilford used a similar concept in his multidimensional theory of the structure of intellect. He proposed that there are five different types of mental operations, among them convergent and divergent thinking. In his theory, divergent thinking was defined as producing a variety of responses, in which the product is not completely determined by the information given to the respondent. Guilford considered that semantic transformations (puns) are evidence of divergent thinking, as well as one important source of wit and humor. He said that such transformations do not necessarily produce humor, but they often produce delight as well as surprise – an 'aha' moment or a 'eureka experience.'

Over time, divergent thinking has come to be considered almost synonymous with creativity. Tests have been devised to measure divergent thinking, the most widely-used of which are the Torrance Tests of Creative Thinking. Such tests are often considered to be measures of creativity, and adults and children who score high on them are considered to be 'creative.' As we will discuss later, several of these creativity tests assign points for humor, as Guilford did.

Convergent thinking has received somewhat less attention in the creativity literature. Mednick's Remote Associates Test (RAT), although sometimes considered to be a measure of divergent thinking, is scored with correct answers. In addition, the RAT correlates positively with standard tests of intelligence, which also measure convergent thinking. Thus, the RAT seems to be a better measure of convergent thinking than divergent thinking.

Logically, it is possible that humor production is more strongly related to divergent thinking, whereas humor appreciation might be more strongly related to convergent thinking. Some evidence that humor production is related to divergent thinking was provided by research of Peter Derks. Participants made up funny captions for still photographs from old movies, and their responses were judged by peers. Results showed that the best captions for people instructed to give quantity and not be critical were rated funnier than for those aiming for quality. There was also an indication of improved quality of the captions as the participants continued to make them up. Providing even more evidence for divergent thinking, the participants showed no evidence of running out of ideas for more than 10 minutes, regardless of whether caption production was guided by a goal of quantity or quality. Originality was also high, because <1% of the captions were duplicates.

Emotional Similarities

In both the creativity and humor fields, emotional themes of delight, surprise, and enjoyment are found. As noted earlier, Guilford discussed the delight and surprise that often accompanied divergent thinking in the form of semantic transformations. Frank Wicker stated that enjoyment of humor is in part an aesthetic enjoyment of a creative product. Several classic theories, including Freud's, emphasized the relaxing and

emotion-relieving characteristics of humor. Unfortunately, these theories are typically not consistent in whether they refer to the humor producer, the humor appreciator, or both. But in any case, relaxation, emotional release or 'liberation' from the bounds of rational thinking are consistent themes in classic humor theories. Thus, the joy of discovery seems to be a fairly common emotional theme in both humor and creativity. The discovery can be tiny or grand, but is typically accompanied by some delight, surprise, and enjoyment.

A second important area related to emotional similarities between the fields of humor and creativity lies in the research examining the effects of mood. Generally, results reliably show that individuals in positive mood states are more creative on a range of tasks. Some research shows that engaging in creative tasks can lead to a good mood. It is possible that positive mood could result in a self-instruction to be less critical; if that were true, one would expect greater ideational fluency as a result of lower self-censorship of ideas.

In 2006, Allan Filipowicz reviewed a considerable amount of the literature about the effects of positive mood (also called positive affect) upon creativity; his conclusion was that positive mood generally leads to higher creativity, but occasionally to lower creativity. In this body of research, positive mood has been manipulated in several different ways: by winning a small prize, being given a cookie or candy, being asked to imagine pleasant experiences, etc. But a complication in quite a few studies of the effects of positive mood upon creativity is that mood is induced by having participants watch humorous videos, or exposing them to other forms of humor in order to improve their moods. This is troublesome methodologically when we try to examine emotional similarities between humor and creativity, because the difference, if any, between humor and good mood is unclear.

The above research on the effects of mood has often focused on mood as a transitory experience, or a psychological *state*. Another related topic is the concept of positive affect as a psychological *trait*, or a long-lasting attribute of one's personality. For example, in 2008, Tammy Pannels and Amy Claxton Kozbelt and Nishioka concentrated on happiness as a positive personality characteristic; their findings were consistent with several theories suggesting that happiness should have a direct positive effect upon creative cognitive processes. Specifically, these authors found a moderate positive correlation (0.34) between happiness scores and creative ideation scores. Trait happiness might be considered to be related to the trait of cheerfulness, which has been studied quite extensively by Willibald Ruch and his colleagues in their development of the State-Trait-Cheerfulness Inventory (STCI), one of many measures of sense of humor. Interestingly, in one study using the STCI discussed by Ruch, the 'seriousness' scale was a better predictor of humor production (e.g., creating captions for cartoons) than the cheerfulness scale, although seriousness was associated with lower humor production.

Sense of Humor and Creative Personality

The topic of personality characteristics leads us to another dimension in which humor and creativity are seen to demonstrate similarities. The creative person, including characteristics of the creative personality, has been more widely studied in

the entire field than any of the other 'Four Ps' of creativity (the others are process, product, and 'press' or environment). Some examples of the many traits said to be typical of the creative person are originality, openness to experience, tolerance for ambiguity, self-confidence, unconventionality, and independence. Not surprisingly, many of the same characteristics are often linked to a person with a good sense of humor. Some researchers have found that extraversion, or the extent to which a person is socially outgoing, is correlated with self-reported sense of humor; however, the research evidence is somewhat mixed. The personality trait of psychoticism (being impulsive, aggressive, and insensitive to others) has been more consistently linked to sense of humor.

Despite a great deal of progress in the assessment of sense of humor, Ruch stated that there is still no standard measurement of sense of humor or theoretical framework upon which investigators generally agree. A complicating issue is that humor has been included in several measures which attempted to assess creative personality or creative potential, thus assuming that humor is a simply part of the creative personality and not conceptually distinct. For example, the Creative Personality Scale for the Adjective Check List includes 'humorous' (along with 'original' and 'clever') among its 18 items positively related to creativity.

Nonetheless, the definition of humor has been clarified by personality research. In 2008, Ruch demonstrated that nonsense and incongruity resolution appeal to different types of people, with nonsense more entertaining to the liberal, flexible, more creative individuals.

Social Factors

Israeli researcher Avner Ziv examined the possible relationship between humor and creativity in numerous studies. In discussing intentional humor (humor created by a person in order to be enjoyed by other people), he emphasized that humor is a form of communication. The communicator is the humorist (humor creator), the message is the joke or story (the creative product), and the listener is the humor appreciator. 'Humor production' is what we recommend calling humor creation in order to facilitate clarity of terminology.

Humor most often occurs naturally in social situations. When we analyze the cognitive and social processes that occur in a situation in which humor is produced, we see that the jester must typically utilize information quickly for the product (joke or witticism) to be successful. A scientist or an artist who is creating is usually not under such immediate time constraints. For a humor producer, not only must the incongruity be recognized, but the immediate interests and the intellect of the audience must be considered in formulating the communication. A successful new joke requires making a product, and communicating that product in such a way as to allow someone else to appreciate its 'artistry.' Stand-up comics plan their routines and modify them based on the feedback that they receive from audiences over time.

Many theorists and researchers in the field of humor have noted the importance of considering the audience in understanding the phenomenon of humor production. Research has been facilitated because the success of a humorous production can be readily and immediately identified by audience

laughter. For example, a classic study measured humor production by crediting a subject with a successful witticism when at least two other group members laughed; results indicated that persons who were spontaneously humorous were also spontaneously creative. In 2007, Martin investigated a further role of social interaction; he measured aggression and affiliation as humor styles and found that they differentiated individuals' preferences. Clearly the jester must keep the audience in mind, while the artist and scientist may be less immediately concerned.

During 2008, Ruch and his colleagues studied the sense of humor in depth, and developed several measures of different aspects of the sense of humor, including wittiness, originality of punch lines created, etc. Ruch pointed out that one can be witty without necessarily producing new humor; telling jokes and funny stories may require abilities such as a humor repertoire, social needs, and performance skills. Trait cheerfulness, as one measure of sense of humor, emphasizes its entertainment (or social) aspects.

In creativity, social factors may affect the scientist or the artist. In particular, scientific and artistic products must be recognized by others (such as journal editors or theatergoers) to be considered successful. Their work is judged within a societal milieu, which changes over time. An important social dimension in creativity, as well as humor, is the implicit or explicit evaluation of the creative idea or product. Not surprisingly, in 2009 Proyer and Ruch found that fear of being laughed at (called gelotophobia) accompanied reduced self-ratings of creativity and curiosity, and reduced peer ratings of curiosity. In a broader sense, social factors are part of the 'press,' or environment in which creativity takes place.

Another social factor to be considered is whether humor facilitates group problem solving. If a humorous atmosphere aids individual originality by increasing freedom and breaking boundaries, then it should also be helpful to groups. One study by Firestien and McCowan in 1988 found that groups trained in creative problem solving did indeed produce more ideas while showing more signs of humor, but inferring causality is a problem in that study because the groups were self-selected. Another study by Pollio and Bainum in 1983 composed groups by choosing individuals who had been more or less witty in earlier problem solving tasks, but the effect of having witty participants was not consistently positive. For groups, then, the value of humor is not as clear as for the individual. A sensible speculation is that humor, while it may 'break the ice' and relax the atmosphere in a group, can also consume time, distract group members from the task, etc. The relative impact of humor's potential positive and negative effects in groups is not well-investigated.

Relationship to Play

Playful behaviors have been linked to both creativity and humor. Play, although not synonymous with humor by any means, is related to humor through its association with light-hearted behavior, laughter, etc. In 2007, Martin noted that social play is an important way in which humor can be enjoyed entirely for its own sake. Indeed, he stated that the very definition of humor is based upon the distinction between playful and serious.

In the creativity literature, it is also common to find the theme of playfulness mentioned as being characteristic of

creativity or creative people. Both researchers and theorists have noted that play and creativity have similarities. In particular, play often involves symbolic transformations in which objects and actions are used in new or unusual ways, akin to the novel, imaginative combinations of ideas involved in creative thinking.

Survey of Research

Humor as a Form of Creativity

In surveying the humor-creativity literature, it is clear that several authors have assumed that humor is simply a type of creativity without examining the basis for that assumption. In fact, some studies of creativity have used the production of captions for a cartoon, drawing, or picture as the only measure of creativity. Valuable information can, however, be obtained from this approach. As mentioned earlier, Derks asked college students to make up funny captions for still photographs from old movies, and these responses were judged by peers. In a subsequent study in 1988 over half the captions were evaluated as 'relevant incongruities,' that is, attempts at humor. More recently Kozbelt and Nishioka used similar results to argue that humor production is divergent. They also found that humor appreciation depended on insight aided by hints and was, therefore, convergent.

The production of story titles or cartoon captions has a long history in the measurement of creativity. Guilford discussed 'cleverness tests' to measure originality, which he considered to be part of the concept of divergent thinking. The most commonly used was plot titles, in which participants made up titles for a short (one-paragraph) story, and the responses were judged for cleverness. Cartoons from magazines were also used, and participants were instructed to write punch lines for each one. The riddles task called for two solutions to each riddle, one of which was supposed to be clever; people quite commonly produced puns when instructed to be clever.

Besides Guilford, other classical theorists in the field of creativity have mentioned humor as being a characteristic of creativity or creative persons. For example, E. Paul Torrance noted that the work of creative children is characterized by humor and playfulness. His scoring instructions for the Torrance Tests of Creative Thinking include assigning a point to humor in assessing the Originality and Interest scores. Other tests of creative potential, such as Urban's Test for Creative Thinking-Drawing Production, include humor as one of the evaluation criteria.

Humor as a Correlate of Creativity

Many researchers have recognized the multifaceted nature of both humor and creativity. Therefore, attempts to predict creativity from humor (or vice versa) have employed a large variety of tests of both constructs. Humor has been measured by such things as appreciation tests (usually rating cartoons or jokes for funniness), writing cartoon captions which are judged for funniness, teacher ratings of sense of humor or humorous attitude, writing humorous definitions, completing jokes, peer nominations of individuals as funny, humor knowledge, humor reasoning ability, observer ratings of laughs/smiles/

behavioral attempts at humor, judges' ratings of how clever or humorous a product was, and many different tests of the sense of humor.

Creativity has also been measured in numerous ways, for example, the Torrance Tests of Creative Thinking (the most commonly used), the Remote Associates Test, Guilford's Plot Titles, teacher ratings, word atypicality, the Asymmetrical Preference Test, observer ratings, Wallach and Kogan's ideational creativity, Getzels and Jackson's Word Association Test, infrequency, and the originality subtest of the Comprehensive Aptitude Test Battery.

Obviously, there is little agreement about how best to measure either humor or creativity. Despite this lack of agreement on measurement, however, a meta-analysis conducted by O'Quin showed a fairly consistent tendency to find modest positive relationships (average correlation of 0.34) between measures of humor and measures of creativity. The lack of common agreement on measurement in one sense adds to the richness of the fields. Researchers bring different assumptions and theoretical views to their work. However, it also leads to unclear definitions of concepts, ambiguity of conceptualization, and consequently little forward momentum in the accumulation of knowledge about the humor-creativity relationship. When neither concept is clearly defined nor measured, little research progress is made.

Despite these limitations, there are many interesting studies in the humor-creativity literature. During 1974, for example, Ward and Cox asked judges to assess both the creativity and the humorousness of products created by entrants in a radio station contest. The radio listeners had been asked to send in 'humorous and original little green things.' Ward and Cox found high positive correlations between judges' independent ratings of originality and humor. Relatively few studies in the humor-creativity literature have directly examined creative products.

Numerous other studies have been conducted on the humor-creativity relationship. A frequent humor measure used, whether alone or in conjunction with additional tests, is nomination by others for being funny. For example, teachers may be asked to rate children on how often they produce humor in the classroom, and/or peers may be asked to nominate the 'funniest in the class,' or to identify the class clowns. The students in these studies vary from preschool age to college undergraduates. The creativity measures across these studies are also numerous, although some variation of Unusual Uses is the most common. The size of the correlations varies from study to study, but is usually positive. Several experiments have tested both male and female subjects, and similar results (small to moderate positive relationships between measures of humor and measures of creativity) are found for both sexes, with a slight tendency for the correlation to be higher for females.

Research on the relationship of humor to age was reviewed by Martin in 2007. For example, preadolescent children often define humor as involving funny actions and joke-telling, and adolescents tend to emphasize witty verbal skills. For younger children, humor initiation was unrelated to classroom behavior; however, by grade 7, children who engaged in more humor initiation were more disruptive in class and received more reprimands from the teacher. But by grade 11, humor in the classroom was no longer associated with acting-out behaviors

and was instead related to being popular with peers. Most of the research on developmental aspects of humor is cross-sectional in nature, so it is not possible to determine whether the child who is humorous in kindergarten continues to make his or her peers laugh in high school.

Most of the age-related research on the creativity-humor relationship showed that humor appreciation, comprehension, and production were moderately positively related to measures of divergent thinking and to general social competency. But the type of measurement was crucial. When humor was defined as making their peers laugh (i.e., being a class clown), it tended to be related to less positive outcomes, such as disruptive classroom behavior, aggressiveness, and a conflicted relationship with authority figures.

Comparing Humor Production and Humor Appreciation

When looking specifically at studies assessing the production of humor, the correlations with creativity are also moderate. Many of these experiments used samples of young adults, most often college students, but even preschoolers have been studied. There is no agreement across these studies about how to measure humor production (e.g., making up humorous captions for TAT cards, a Make-a-Joke test, funniness of slogans, cartoon captions, observer or teacher ratings of humor production). Similarly, no consistency exists for measures of creativity, although RAT scores and Unusual Uses have been the most frequently employed. To summarize the results of several studies, the correlations between humor production and a variety of creativity measures is about the same moderate size and positive direction as the correlation of other measures of humor, such as humor appreciation and sense of humor, with creativity.

Another way to examine humor production is to study professional humor producers, such as comedians and comedy writers. Kaufman and Kozbelt reviewed the literature on this topic in 2009. They concluded there was some evidence that professional humor producers (including writers) were creative and verbally intelligent, and that comedians tend to have overcome adversity in life and use humor as a coping mechanism. However, they also noted a dearth of empirically sound research.

Some authors have suggested that humor appreciation is not as close to the rigorous definition of creativity as humor production because the former appears to need cognitive processes that are less similar. But there is little difference in the size of the statistical relationships. Why? Humor production involves creating or making humor, and thus seems conceptually closer to the concept of creativity than humor appreciation. Perhaps this conceptualization is simply wrong. Another possibility is that the wide variety of measures used for both humor and creativity has obscured true differences in the size of the relationships. A third possibility is that the correlation between humor appreciation and creativity comes about more indirectly, maybe through humor's facilitation of a relaxing 'game-like' atmosphere. Let us look further at the latter possibility.

Humor as a Producer of Creativity

Theoretically, humor should have two related effects on thinking that would facilitate creativity. First, the cheerful mood

associated with humor should reduce tension and anxiety. In a state of relaxation, individuals would show less fixation and rigidity in their responses to problem solving situations. Second, beyond the reduced rigidity, there might also be a wider range of options that could be considered. The cognitive network could be expanded due to priming by the incongruous.

There is research evidence that both these factors can contribute to a relationship between humor and creativity. Many research reports in the humor–creativity literature have actually manipulated humor as an independent variable. In these studies, exposure to humor (typically in the form of cartoons, comedy films, or records) facilitated creativity or problem-solving in one or more forms (e.g., RAT score, unusual word associations, unusual uses, word atypicality).

Ziv has carried out several studies with humor as an independent variable. In one of his classic studies, some classrooms of Israeli adolescents listened to a comedy record; others did not. After the humor experience, there was an increase in creative performance on the Torrance tests of unusual uses and just suppose. The increase in divergent thinking was most marked for originality.

Psychologist Alice Isen and her colleagues have conducted numerous experiments demonstrating that positive emotion facilitates creativity. Although humor was not usually the focus of this research, in many of Isen's studies, positive emotion was manipulated by exposing participants to a comedy film. More generally, the effects of positive emotion have been widely studied; for example, Barbara Frederickson established the Positive Emotions and Psychophysiology Lab, whose web site summarizes a great deal of this research.

In the same vein, positive mood has been found to enhance flexibility and original thinking. Instructions, however, have been found to over ride the effect. In 1968, Liam Hudson told students to pretend to be a wild, free-wheeling artist and found the instructions increased unusual uses. Karen Gasper instructed participants to 'seek freely' and that all responses were acceptable in generating problem solutions. What had been a significant effect of mood was eliminated. Thus, it is possible that much of the effect of mood on creativity may be a result of self instruction.

A question left unanswered by these studies on humor as a producer of creativity is the duration of the effect. All the tests reported above were immediate; a humor experience was followed right away by creative tasks or problems to be solved. A fruitful testing ground for further research on this topic might be workshops or conferences that evoke humor to enhance creativity.

Methodological Issues

A problem for the comparison of creativity and humor, and an indication of their relevance to each other, is the recurrent inclusion of humor or funniness as an element in the scoring of creativity tests. When humor is one of the ways to get points on a creativity test, such as the widely-used Torrance Tests of Creative Thinking, it is easy to see how that may inappropriately inflate the humor–creativity relationship.

There is also evidence that alerting respondents to the possibility of humorous answers may positively affect their creativity scores. Ziv has found that instructions to 'be funny'

do, in fact, improve performance and originality on tests of unusual uses. Wallach and Kogan also suggested that a game-like, rather than a test-like, atmosphere will improve creativity test scores.

A second important methodological issue for both the humor and creativity literatures concerns validity of measurement. Kerr and Gagliardi reviewed the literature on creativity measurements during 2003 and criticized commonly used creativity instruments, such as measures of divergent thinking, for lacking predictive validity by failing to predict future behavior. Thus, people who score highly on tests of divergent thinking do not necessarily create products generally associated with the work of creative people such as artists, musicians, writers, etc. Few studies in the creativity–humor literature examined actual creative products rather than spur-of-the-moment creativity tests.

The state of affairs with regard to validity in the humor literature is somewhat better; at least criteria such as laughter and smiling are relatively objective. Humor production can be measured by the simple and obvious criterion of creating something judged by others to be humorous. Despite this relative advantage, however, the wide variety of humor measures chosen by researchers reveals that there is little agreement as to exactly what constitutes humor production and humor appreciation. Ruch discussed the lack of agreement on measures of sense of humor, pointing out that the plethora of approaches led to a hodge-podge of often-conflicting results.

Discussion

Unresolved Questions

First, can the effects of humor on creativity be more simply explained by positive affect or good mood? Is humor just a stronger laboratory manipulation of positive mood than most laboratory manipulations, or does humor make some unique contribution? A great deal of research has been conducted on the effects of mood. Isen and her colleagues found in 1987 that comedy films led participants to be more creative, compared to emotionally neutral or negative films, but they also found similar results with nonhumorous methods of producing positive emotion. Thus, one might infer that the creativity-enhancing effects of exposure to humor may simply be due to the effects of positive emotion upon cognition, rather than the idea that activation of multiple schemas in humor produces cognitive flexibility.

This question is not fully settled, however. Filipowicz used humorous videos in 2006 to induce positive emotion, and found that surprisingness fully explained its relationship to creativity. A 'game-like' atmosphere seems to facilitate optimal creative performance; humor and laughter can lead to such a relaxed, positive, game-like state. Another possibility is that 'game-like' conditions could produce self-instruction to reduce inhibition and a too-careful selection of responses caused by a fear of evaluation. But it has not become clear that humor manipulations of positive mood contribute to creativity above and beyond the effects of positive emotion.

Second, to what extent is humor appreciation different from humor production, and how are they related to sense of humor? Looking across many studies, the relationships among these three concepts are typically only modest, and in some

cases, no higher than their relationships to other constructs, such as creativity. Logically, it seems that one can certainly be an appreciator of humor without also being a producer, but the reverse does not seem at all likely. It is hard to imagine a humor producer who is not also capable of humor appreciation. However, comedians do not necessarily respond when comedic events are produced by others. To the best of our understanding, humor appreciation can exist without production, but humor production is much less likely to exist without the ability to appreciate humor. As we discussed earlier, it appears that humor production should be more closely related to creativity, but the research literature is not particularly supportive of this proposition. Humor production includes the social need for the audience to 'be there,' whereas creativity varies widely in audience relevance; that may provide a partial explanation. It is also possible, although research evidence is still inconclusive, that humor production is more strongly related to divergent thinking, whereas humor appreciation might be more strongly related to convergent thinking.

Third, to what extent is humor truly separate from creativity? Murdock and Ganim concluded in 1993, after reviewing theories that addressed both humor and creativity, that humor was sufficiently integrated to be considered a subset of creativity. However, our review of the broader empirical literature leads us to disagree with their conclusion. Rather, humor and creativity seem to be two interdisciplinary areas which overlap most clearly in the area of humor production. While it is possible to argue, based on the literature, that humor appreciation itself requires some creativity, humor production is logically more directly related to creativity. Our view is that greater creativity is required to make a joke, cartoon, or other form of humor, than simply to understand the same thing when it is made by another person.

However, another possibility is that humor and creativity are related because of their mutual correlation with another construct, such as intelligence, verbal ability, or cheerful personality. For example, in 1991 Feingold and Mazzella linked humor comprehension and humor cognition to intelligence in their theory of wittiness. It is also clear that some of the creativity measures typically employed in the literature (e.g., the RAT) place a premium on verbal ability or vocabulary.

Another possible candidate for one of the links in the relationship between humor and creativity is personality. Research by Kohler and Ruch in 1996 indicated that cartoon caption production, but not humor appreciation, showed low but significant positive correlations with the personality variables of extraversion and psychoticism. Ruch and his colleagues have devoted a great deal of attention to developing and testing different measures of the sense of humor, most recently the cheerful disposition, measured with the State-Trait Cheerfulness Inventory. The notion tying these measures to creativity is that the individual with a sense of humor is skilled in rapid cognitive or perceptual switches in frame of reference, an ability which is presumed to be important in creativity as well.

Summary and Suggestions

If creativity can be defined as 'successful originality,' then Eliot Oring's definition of humor as 'appropriate incongruity' seems a plausible parallel. For creativity the problem is to define

success and originality. For humor, 'appropriate' relates to the experience, personality, and circumstance of the individual and/or the group. 'Incongruity' plays a similar cognitive role to originality. A creative product is not always (or even usually) funny, and a funny idea is creative only in a very special way, involving originality and a resolution that takes social, human factors into account.

Granted, humor and creativity share similar cognitive, social, and emotional processes that give the two parallel psychological implications. Creativity requires flexible examination of the connections among ideas, and humor depends on the selection and evaluation of different associations at different levels of analysis. However, originality without resolution usually not considered creative. A joke that leaves the incongruity unresolved is nonsense, but might still be funny. Production of ideas is necessary for both humor and creativity, and evaluation of those ideas is critical (although not always acknowledged) for both. Creativity and humor do require similar cognitive processes, but the specific applications are different.

As discussed earlier, a major problem in investigating the humor-creativity link is a lack of clarity in defining the two constructs. Humor is sometimes considered to be a form of creativity. Creativity measures sometimes assign points for humor or include tasks that involve humor. Such confounds must be removed before the 'true' nature of the relationship between the two constructs can be thoroughly examined.

In addition, there still remain problems with basic theories in both fields. Many years ago, authors bemoaned the lack of a single and widely-accepted theory of creativity to focus research. Despite a tremendous surge in creativity research in the past 60 years, no absolute consensus or over-arching theory of creativity has yet been reached. To an extent, the abundant creativity exhibited by authors in the field of creativity research has impeded progress in that field. The pressure to be novel, which exists in many disciplines but seems to be particularly prevalent in creativity, often leads to reinventions, reimagining, and renaming of 'old' concepts. This leads to a subsequent lack of resolution, lack of agreement on the meaning of constructs, etc. Some choose to interpret the proliferation of hundreds of creativity models and instruments, only some of which are psychometrically sound, as indicative of a dynamic field rather than a handicap.

Similarly, there is no single theory of humor. As we have discussed, even basic differences such as those between humor appreciation and humor production have not always been made clear by either theorists or empirical investigators. Well-known humor researcher Victor Raskin has spoken of the problem of reinventing the wheel; he pointed out that first-timers in the study of humor, often established experts in their own fields, sometimes begin humor research without any idea of the vast body of knowledge that already exists. A number of 'new' theories are proposed each year that are indeed new to the author, but not necessarily to the discipline.

The interface between the fields of humor and creativity is thus clouded by these perplexities. Creativity researchers are often not familiar with the breadth of research and measures in the humor literature; for humor researchers, the reverse is also true. Sometimes, experts in one domain impose their own ways of thinking on another domain, which may yield insights which are original, but are not high in resolution.

Perhaps one day, a general unified theory of cognition will encompass both humor and creativity. Until then, we need more precise definitions and measures. Rather than simply saying 'humor,' researchers and theorists must be clear as to what, in the broad array of cognitions and behaviors that can be encompassed by that term, they mean. In the short run, rather than trying to come up with a grand and complete theory of humor, we need more 'mini-theories' to help explain individual phenomena. Similarly, in the creativity literature, researchers should be more aware that a vast amount of humor research exists, only a small part of which overlaps with 'creativity.' Equally important to furthering progress is to begin to converge on clear, precise and psychometrically sound measures in both domains.

Imagination

M Taylor, University of Oregon, Eugene, OR, USA

© 2011 Elsevier Inc. All rights reserved.

Glossary

Default network The regions of the brain that remain active during rest periods; a psychological baseline that is active when external tasks do not require conscious supervision.

Imaginary companion An invented character that is talked about or interacted with on a regular basis.

Imagination The multifaceted capacity to transcend one's current time, place and/or circumstance in one's mind.

Mental time travel The capacity to project oneself back in time to re-live past events of one's life or forward in time to pre-live hypothetical events in the future.

Mind wandering A shift of attention away from a primary task toward internal information, including daydreams about fictional worlds, as well as memories and plans related to actual experiences.

Introduction

In common usage, 'creative' and 'imaginative' often serve as synonyms to describe innovative ideas/objects or the people who are responsible for them (e.g., "she is so creative/imaginative"). However, in the psychological research 'imagination' is becoming a broader term that encompasses the multi-faceted capacity to transcend our current time, place and/or circumstance to think about what might have been, plan and anticipate the future, create fictional worlds, become absorbed in the narratives created by others, and consider remote and close alternatives to actual experiences. With this definition, imagination includes everyday mundane thoughts (e.g., plans for tonight's dinner), as well as the creative insights that lead to progress in art and science. This definition also distinguishes imagination from imagery, with the latter being a tool of the imagination rather than equated with it.

The capacity to depart mentally from our current time, place and/or circumstance emerges early in childhood, develops substantially during the preschool years, and is inextricably linked with our understanding of reality throughout life. Theories that highlight imagination date to the earliest days in the history of psychology, but in recent years, the study of human imagination has moved from the margins of mainstream psychology to assume a more central role. This change is partly due to the findings of brain imaging studies that have revealed the close connection between the neural patterns for imagining a behavior and actually performing it. The science of imagination has also been elevated by studies that have identified a particular neural response associated with periods in which the participants are not involved in any experimental task, the so-called 'default network' that is believed to be associated with thoughts that are turned inward. In addition, there are many

new studies that show how imaginative processes have real world effects on our behavior and that introduce new concepts such as 'mental time travel' that have highlighted the role of imagination in everyday thought and united subtopics of research (e.g., counterfactual thinking and planning for the future). There is currently a renewed appreciation for the value of fictional narratives in enhancing our capacity for empathy and social inference and for the role of simulation in thinking about the future, remembering the past, taking another person's perspective and thinking about what does not exist. The connections between childhood imagination and highly valued adult behaviors (e.g., creative writing) are being re-examined and more generally, research on imagination is shifting from a story of decline after early childhood to a story of continuing enrichment in adulthood. Some theorists have proposed that imagination is the leading candidate for the 'spark' that distinguishes human beings from other animals.

The study of imagination is broad in scope, cross-cutting traditional areas in psychology and extending into other fields as well (e.g., philosophy, literature). Here I have focused on some of the interconnected topics that are driving research investigations: (1) pretend play, simulation, and emotion; (2) narrative, fiction, and testimony; (3) mind wandering, mental time travel, and counterfactual thinking; and (4) imagination and autism spectrum disorders.

Pretend Play, Simulation, and Emotion

Pretend Play

Pretend play provides some of the earliest evidence of imagination, as well as a potential training ground for its

development. Young children understand pretense in other people by 18 months or earlier and at two years are able to act in accord with requests for pretend actions (e.g., dry off a stuffed pig that had been soaked with imaginary tea). The first spontaneous acts of pretend play (simple actions directed toward the self) occur in the second year of life followed by pretend actions directed towards another individual (e.g., pretending to feed a doll) and the acting out of scenarios in which the other is the initiator of the action (e.g., animating a doll who feeds a stuffed animal). Once children start to incorporate the behavior of others into their pretend play, they quickly start to attribute thoughts and feelings to imaginary others and to produce narratives to accompany their actions.

In western cultures, children do not simply imitate or reproduce the characters and events they have encountered; they exhibit a striking ability and inclination to invent imaginary characters and act out fantasy scenarios. Sometimes their pretend play involves social contexts in which young children's activities are scaffolded by mature play partners (parents, older children) or coordinated with the pretending of peers, but they also pretend when they are alone. Imaginary companions – the characters created by children that are talked about or interacted with on a regular basis – provide particularly interesting examples of developing imaginative skills because they are usually created spontaneously by young children and can assume important roles in children's lives.

Imaginary companions provide evidence of children's early developing capacity to create elaborated and idiosyncratic fantasies. Imaginary companions are diverse in form and function. They vary in size from a speck to ten feet or taller, can be newborn infants or ancient (e.g., 1000 years old), are every possible species, and may even be from another planet. They differ in vividness, personality development, longevity, and activities. Sometimes they are completely invisible and sometimes children use props to represent them, including a variety of idiosyncratic objects (a leaf, a stick, a finger, etc.), as well as toys such as dolls and stuffed animals (if the child treats the toy as having a distinct personality and talks and listens to it on a regular basis). It is not unusual for three-year-old children to have imaginary companions and by the time children are seven, as many as two-thirds have had some experience with them. In some cases, children move from having imaginary companions to the creation of 'paracosms' – private, elaborate, and enduring imaginary societies or worlds.

A number of studies have investigated personality and other types of possible differences between children with and without imaginary companions. The emerging view is that, in most respects, the similarities between the two groups are more striking than the differences. However, fantasy activities during the preschool period are related to a number of positive social characteristics. For example, high fantasy children are rated by teachers as showing higher levels of energy, concentration, self-reliance, and tolerance for frustration. Young children who create imaginary companions show higher levels of positive affect, social competence, and creativity. Jean Piaget described imaginary companions as distorted assimilations of reality to the child's own ego, but research indicates that having an imaginary companion is positively associated with performance on cognitive tasks that require accommodation of

thought to reality. Rather than promoting an exclusive focus on the child's own subjective experience, pretend play involving imaginary companions is related to a greater ability to adopt the perspective of another person.

Later Forms of Imaginary Relationships

Imaginary companions and other types of pretend play become less common in later life, but philosophers have pointed to the continuity of childhood pretending with adult activities involving drama, film, art, internet role play games, and fiction (both reading and writing). Adult novelists, playwrights, and screenwriters provide interesting examples of adults who are preoccupied with the production of fantasy and there is a growing literature investigating the psychological significance of these activities. More generally, imagined interactions continue beyond childhood in various guises, from intellectual exercises such as imagined conversations with historical figures to more fully developed and maintained fantasies. The social worlds of many people can be described as including individuals whom they know only through television, books, movies, and other forms of media, as well as the people they interact with face-to-face in their everyday lives. The experience of having a personal 'parasocial' relationship with a famous individual who has never actually been encountered in real life is quite common and can go beyond interest and admiration to involve imagined conversations, meetings, and extended interactions. Other types of imagined interactions are important in rehearsing messages, managing emotions, and coping with life events. Recently researchers have found that imagined interactions with members of a minority group can reduce the individual's level of prejudice.

Emotional Responses to Fiction and Pretend Play

The pretend play of children has several features that are significant for understanding the fundamental role of imagination in human thought. First and foremost is children's emotional investment in their pretend activities. For example, children often become afraid when engaged in scary pretend play and they claim to love their imaginary companions. Throughout life, the capacity of fantasy to engage our emotions is one of the most intriguing and potentially significant characteristics of our imagination. The affective response to imagining a pretend scenario seems to closely track the affective response that would occur if the person came to believe that the scenario was real.

In the past, children's emotional reactions to fictional characters and scenarios were sometimes interpreted as reflecting an immature understanding of the distinction between fantasy and reality. However, research evidence suggests that children have fewer problems with the fantasy/reality distinction than has previously been supposed. Currently, emotional reactions to fantasy in childhood are viewed as similar in many respects to adult emotional responses to fantasy. The child who retreats from a scary game of monster is akin to the adult who stops reading a novel when it becomes too creepy. In both cases, the emotion elicited by the fantasy crossed the line of what was experienced as pleasurable, but the individuals were not

necessarily confused about the reality of the situation. The emotional reactions simply reflect the human capacity to react emotionally to fantasy, rather than a breakdown of the boundary between fantasy and reality.

The capacity to experience emotional reactions to imagined events is consistent with the view that an important function of pretend play is the management of emotion. In their pretend play, children explore real-life themes and challenges that are significant to them and discover new insights and understanding. Thus, children can benefit in real life from their pretend play, for example, deriving real emotional support from an imaginary companion that increases the child's resilience. The influence of imagination on real behavior is not limited to children. Clinical research indicates that throughout life, we are able to explore emotional space via our imaginations in a way that provides insight into the real life emotional experiences of ourselves and others. This is the basis for many types of clinical interventions in which adults use imagined interactions or scenarios in therapy to cope with trauma, anxiety, or other types of problems.

The Simulation of Experience

Why do we have emotional systems that can be driven by fictional as well as real input? One answer is that the ability to produce and comprehend acts of pretense is a consequence of the early development of the simulation process that underlies our understanding of the real actions and thoughts of other people. There are different accounts of how simulation might work, but the basic idea is that information about the person and the situation is fed into the same system that determines our own reactions to events and the output of the simulation is attributed to the other person. The process of simulation is of crucial importance for interpersonal understanding, decision-making, and communication. Simulative processes are involved when we consider how someone might feel if he or she lost a job or how we might feel in the future in that scenario. What is particularly important about simulation from the point of view of research on imagination is that the system underlying the processing of real life events can also be driven by fictional input. Thus, simulation theory provides a link between imagination and our understanding of reality.

The discovery of the mirror neuron system in macaque monkeys has special significance for simulation accounts. Mirror neurons fire when one performs an act and also when that same act is observed being performed by others. Some only fire when there is a close match in the form of the action, but others are less specialized, firing for actions that have the same goal or intention. If observations of others activate one's own internal representations of the perceived actions, intentions, and emotions, as research on mirror neurons suggests, this system might allow for the direct experiential detection and understanding of mental states in other people. Neuroscientists vary in their appraisal of the promise and current state of research investigating a human analog of the mirror neuron system; however, what is known about the mirror neuron system has an impressively close fit with the simulation account of how we understand other minds. Thus, the discovery of mirror neurons has increased the prominence

of simulation theory, and along with it, elevated the study of how fictional content in role play, narrative, and mental time travel is processed.

Narrative, Fiction, and Testimony

In addition to pretend play, the production and comprehension of narratives are activities that explicitly display children's early developing capacity to imagine scenarios beyond their immediate experience. Narratives are stories with sequences of causally linked events that unfold over time involving characters and a point of view. The earliest narratives may be those that are implicit in the context of pretend play, with parents sometimes telling a story to accompany the children's pretend actions. By three years of age the children themselves start to narrate their pretend play, a development that enriches its thematic possibilities. In both pretend play and narrative, children create characters, imagine a scene, and develop plot lines that include goals, conflicts, and/or problems to be resolved. The research on character representation suggests that pretend play and storytelling have somewhat different developmental origins and trajectories, but that these two activities become increasingly coordinated in middle childhood.

Narrative and Social Understanding

The ability to create narratives and to comprehend the stories of other people provides an important vehicle for reflecting on experiences in adults as well as children. In adults, the extension of experience beyond personal circumstance that is possible through narrative is believed to promote deep insight into human behavior and contribute to the development of wisdom. Experimental research shows that readers follow a narrative by adopting a psychological vantage point within the narrative – taking the visual, spatial, and mental perspectives of a main character and tracking the perspectives of multiple characters. Some theorists have suggested that these simulations of a character's emotional reactions to the events in a story help to develop the reader's 'theory of mind' – the understanding of people's behaviors as reflecting their beliefs, desires, and other mental states. This hypothesis has received empirical support from research showing a relation between reading fiction and higher scores on tests of interpersonal understanding.

There are several possible overlapping explanations for the relation between reading fiction and interpersonal understanding in the real world. Fictional narratives provide an abstraction of social experience in which attention can be focused on nuances of social interaction that might be overlooked in real life. Thus the reader is guided to attend to the important parts of the interaction. In addition, the author's commentary on the unfolding events might provide insight into behavior that in real life might be misunderstood. Perhaps the benefits derived from reading fiction are primarily due to the extensive practice in the type of simulation that is used in real life encounters. There also is a structure to fiction that some theorists have suggested could help reorganize and make sense out of real life experiences. More research is needed to understand how reading fiction can affect real life social behavior, but current

work in this area suggests that the consumption of fictional narratives has significance beyond 'mere entertainment' by enhancing empathy and social inference in real life.

Learning Real World Knowledge from Testimony

In addition to connections with theory of mind and social understanding, the ability to immerse oneself in a narrative is fundamental to our acquisition of real world factual knowledge. This point is sometimes overlooked, but the capacity to learn from what other people tell us (i.e., referred to as 'testimony' in the literature) relies upon imagination. Much of our historical and scientific knowledge concerns events or entities that have not or could not be personally observed. The acquisition of knowledge requires 'testimony' when there is no possibility for first-hand experience. Thus our capacity to understand narratives outside of our experience is involved in our learning about Ancient Rome, black holes, micro-organisms, and the Milky Way. Developmental research on imagination has recently extended beyond fictional content to investigate children's ability to learn factual information from what they are told, including simple statements and descriptions as well as more fully formed narratives.

Children's success in learning via testimony depends upon their ability to evaluate such information and from an early age, children have been shown to assess the reliability of information acquired from what other people say and to construct a mental model of the world that incorporates these claims. Importantly, this developmental research connects the work of the imagination more generally with the acquisition of knowledge about the real world, rather than conceptualizing imagination as concerned primarily with fiction or fantasy content. Our ability to imagine what we are told about but have never seen also plays an important role in the acquisition of religious beliefs. On this vein, some have argued that the development of pretending and narrative in childhood lays the groundwork for the capacity to have religious faith.

Mind Wandering, Mental Time Travel, and Counterfactual Thinking

In the past, 'daydreaming' (i.e., shifts in the contents of one's thoughts away from an immediate task to unrelated images or thoughts) has tended to be associated with fantasy content and the suggestion of psychopathology. For example, individual differences in 'fantasy proneness' are correlated with a history of trauma and considered to be a risk factor for emotional or cognitive problems. However, daydreaming is only one part of the construct of fantasy proneness and currently, the mind's tendency to wander is being taken more seriously as a fundamental aspect of everyday thought rather than a marker of possible pathology. This idea dates to William James or earlier and was extensively researched by Jerome Singer and his colleagues, but recent advances in cognitive and social psychology, along with the development of brain imaging techniques, have led to an increased interest in mind wandering and the development of theories for why we have evolved minds that tend to wander from the task at hand. The research on mind wandering demonstrates not only the capacity to mentally

transcend our current time, place, and/or circumstance, but a surprising propensity to do so. Mind wandering is ubiquitous rather than exceptional. As the mind wanders, remote associations are brought together into consciousness and, thus, mind wandering is likely to play an important role in facilitating creative breakthroughs.

A variety of terms with partially overlapping meanings are associated with this type of research, including 'default network,' 'mental time travel,' 'stimulus independent thinking,' as well as 'mind wandering.' The large literatures on counterfactual thinking and on dissociation are also relevant to this topic. These concepts all share a connection with earlier work on daydreaming, but vary in numerous ways, including the extent that they suggest a particular type of content and whether the thoughts are intentional or spontaneous. In what follows I briefly discuss a subset of these ideas and findings.

The Default Network

Recent brain imaging studies indicate that we have a particular pattern of neural activation that occurs during 'rest' periods when participants are not doing anything (e.g., sitting in a chair with no assigned task). The 'default network' is the term given to this psychological baseline from which people depart when attention is required to perform a task and to which they return when the external task no longer requires conscious attention. The default network turns off and on, depending upon how focused we need to be to complete different tasks; its activation has been interpreted as signaling mind wandering. For example, people who report more mind wandering during a task also show more activation of the default network. In addition, the default network is more active during conditions in which the task has been well practiced than when the task is novel. The default network varies somewhat from person to person; some people tend to show a pattern suggesting thoughts about the past whereas other people tend to wander to thoughts about the future. This finding points to the potential of brain imaging research in this area to shed light on individual differences as well as general processes. There is much more to be learned about the default network, but the basic finding of a recurring neural pattern associated with mind wandering has been partly responsible for making off-task thoughts a focus of research rather than dismissed as experimental noise.

Mind Wandering and Mental Time Travel

The term 'mind wandering' refers to a shift of attention away from a primary task toward internal information, including daydreams about fictional worlds, as well memories and plans related to actual experiences. Mind wandering can occur without intention or even awareness that one's mind has wandered. Individuals often fail to notice that their immediate goal of task completion has been temporarily displaced by another concern. As our minds wander from a present task toward unrelated inner thoughts, fantasies, feelings, and other musings, we shift our attention among competing goals, including goals that were being pursued outside of conscious awareness.

Why do we have minds that wander away from the tasks that we are performing, often without conscious awareness? There are a variety of explanations (e.g., the importance of multi-tasking, maintaining an optimal level of arousal, etc.), but most researchers include the benefits of relating current thoughts to past experiences and future plans. This type of mind wandering is sometimes referred to as 'mental time travel,' a term that suggests more intentionality than mind wandering and tends to be more associated with content about the self – the person mentally projects him or herself back in time to mull over past events or forward in time to anticipate and plan for future ones. This process helps to give coherence to one's past, present, and future experiences and contributes to a concept of self as persisting over time.

Early signs of mental time travel include children's anticipation of future events in pretend play and narrative activities. Mental time travel occurs in other contexts as well, indicating that a sense of self that extends in time from the past through the present and into the future (the 'temporally extended self'), is in place by the end of the preschool period. By five years of age, there is considerable flexibility and foresight in children's ability to mentally project themselves forward in time to make plans for the future and to explain their choices by referring to future states. An awareness of the future is also demonstrated in children's performance on prospective memory tasks (e.g., following through on a plan to do something in the future) and delay of gratification tasks.

An important finding of this research is that children's performance on tasks assessing the past self is correlated with performance on tasks assessing the future self. This developmental synchrony between the capacity to project oneself mentally into the past and into the future is consistent with neurophysiological evidence that thinking about the future and the past are closely related. On some accounts, mental time travel is said to have evolved primarily because it increased the capacity to act in the present to increase future survival chances. Thus the capacity to think about the past is secondary. Similarly, some theorists have claimed that the reason we have the capacity to imagine fictional worlds is because of the significance of being able to anticipate the possible consequences of future courses of action. On this view, the evolution of an ability to simulate the emotional consequences of hypothetical events that could actually happen in the future allows for emotional reactions to purely fictional events.

Counterfactual Thinking

Mental departures from our current time, place and/or circumstance include many varieties of counterfactual thoughts about alternatives to the actual events of one's life. The integration of thoughts about what is currently happening with thoughts about what could have happened helps to make sense of events and plan for the future. Mind wandering and mental time travel can involve content that is remote from everyday experiences, but the imagination is closely tied to reality when we engage in many types of counterfactual thinking. With our imaginations we reconstruct and reinterpret past experiences in light of present understanding. This process involves the generation of counterfactual premises, the simulation of how an alternative past might have resulted in a

different outcome in the present and the integration of that information with actual events and outcomes. Counterfactual thinking is believed to underlie everyday causal understanding of our experiences, as well as the capacity to plan for the future. Thus, the work on counterfactuals rests upon the idea that imagination is rational and closely tied to our understanding of reality.

An important component of counterfactual reasoning is the capacity to anticipate the emotional consequences of different courses of actions, often by linking past experiences with hypothetical future possibilities. Imagining different possibilities for future outcomes can be accompanied by worry about past negative outcomes and plans for preventative action. In addition, the capacity to compare actual outcomes with counterfactual alternatives provides the foundation for moral reasoning and judgment.

There is a large literature investigating the types of counterfactuals that are most common and their effects on our understanding of everyday events and our emotional reactions to them. For example, although it is possible to generate a large number of counterfactuals for most scenarios (e.g., close vs. remote, concerning actions vs. failure to act), this is not what people do. Usually a very small number of possibilities are generated when people consider alternatives to reality. When they think about how an event might have turned out, most people are influenced by counterfactuals that are close plausible alternatives to what actually did happen. In addition, counterfactuals involving the most recent step in a causal sequence are common. People can easily imagine a causal sequence that is missing the last step and so counterfactuals in which the last event did not occur are particularly likely to influence our reasoning. Another find from this literature is that most counterfactual thinking occurs after a negative event. How might it have been prevented? How could it have been avoided? This type of thinking is particularly likely to help individuals learn from experience.

Counterfactual reasoning underlies our understanding of causal relations and thus helps us build causal models of the world that are used to understand ongoing events and to imagine fictional possibilities. We also gain insight into the emotional consequences of various scenarios when we transform the facts of our experiences into alternative realities and experience the emotions associated with those counterfactual possibilities. Some types of emotional experiences are particularly dependent upon our ability to generate counterfactual accounts of past experiences. For example, thoughts about what might/should have been give rise to shame, guilt, relief, and regret (e.g., "If only I hadn't been rushed, I would have noticed the red light. . ."). The experience of regret requires the consideration both of reality and a more positive counterfactual. Although developmental research indicates that preschool children can think counterfactually in some contexts, children's capacity to report which characters in a story might experience regret indicates that an adult-like processing of counterfactuals might be in place around seven years of age.

Some research has focused on the limits on our ability to anticipate the emotional reactions to future events. For example, research on 'affective forecasting' indicates that although people can predict whether they will react positively or negatively to a future event, they are not very accurate in

predicting the intensity and duration of their emotional reactions. We tend to overestimate how much we will think about the event in the future, underestimate the extent that other events will influence our thoughts and feelings, and fail to anticipate the extent that we will be able to adjust emotionally to even very negative events (e.g., diagnosis of a serious illness). Biases in the imagined experiences of counterfactual pasts and hypothetical futures are an important direction for future research. More generally, the extent to which thoughts about the counterfactual past and the hypothetical future permeate our thinking in the present and influence our actions is an important area of research showing the role of imagination in everyday cognition.

Imagination and Autism Spectrum Disorders

Disturbances of imagination are associated with many types of mental illness and neurological disorders. Our capacity to imagine alternatives to our current experience can lead to the development of worldviews that are not shared with other people and difficulties in distinguishing fantasy from reality (e.g., the delusions of a person with paranoid schizophrenia). Sometimes the association between mental illness and imagination is framed as enhanced creativity – interpreted by some as the silver lining to the experience of depression, schizophrenia, or, most recently, bipolar disorder. Disorders that increase the flood of thoughts and mind wandering can lead to original ideas, but in most cases such products do not have the utility in addition to novelty that characterizes creativity. On the other hand, some have argued that the ideas generated during a bout of mania, for example, can be usefully developed during periods of mental health when the individual is not experiencing symptoms.

For other disorders, there appear to be deficits of imagination, most notably in the autism spectrum disorders. A deficit in imagination is widely considered to be one of the triad of symptoms that characterizes people with autism (the other two being problems with socialization and communication). In general, research on autism spectrum disorders has been very informative about typical and atypical functioning, and has the potential to provide new insights about imagination. There is still much to learn about how imagination functions in individuals on the autism spectrum, but some of research findings suggest connections with the topics discussed in this essay. For example, children on the autism spectrum tend to not spontaneously engage in pretend play. However, they have less difficulty comprehending the pretend acts of others than producing their own, which suggests their difficulty is in generating play ideas rather than difficulty understanding the underlying representations. Other types of tasks suggest that children on the autism spectrum have particular difficulty in imagining something that does not exist in the real world. For example, whereas children with cognitive delays are able to produce drawings of a person who could not exist (e.g., a person with two heads) and imagine scary things that are fictional (e.g., monsters), children on the autism spectrum struggle with these types of tasks. In addition, first person accounts from high functioning adults on the autism spectrum indicate that the problem with generativity might be specific to

the unreal or impossible rather than a more general problem with generating any type of new idea. High functioning adults with autism also express difficulty understanding fictional narratives about interpersonal scenarios. Future research with this population is a very promising direction for the development of more elaborated theories about the development of imagination and its role in understanding the world.

Conclusion

The study of imagination is currently somewhat fragmented, spread across developmental, social, clinical, and cognitive psychology, as well as neuroscience and other disciplines. Much of the research on imagination has focused on children and their developing capacities for pretend play and narrative. Children's thoughts about the nonactual and the fictional in these activities are seen as helping them process real-life events and enriching their understanding of self and other. In addition their ability to follow narratives is crucial in the acquisition of real world knowledge from the testimony of other people.

There is also growing recognition that fantasy activities such as reading fiction have real world consequences for adults. The exploration of emotional space via simulation in fiction leads to real world insight and affects behavior. There is likely to be an increased number of studies comparing the processing of fiction and real life social scenarios and investigating the relation between reading fiction and social abilities. In this area, brain imaging research is helping to disentangle the way information about the self and other is processed and could yield new insight about the development of simulation and the neural correlates of different components of imagination. In addition imaging research on the default network has contributed to the growing recognition of the prevalence and importance of mind wandering.

The development of children's imagination is facilitated when they have some amount of unstructured time and are provided with a few props, space, and the encouragement of a supportive adult – conditions that vary considerably as a function of religious, economic, ethnic, and family context. The influence of culture has not been discussed here, but cultural studies of pretend play in nonwestern societies are raising many questions about imagination. For example, children raised in Mayan communities in the Yucatan do not engage in the types of fantasy pretend play that are so common in Euro-American children. The form and frequency of pretending and the extent that children are private about their fantasy lives are clearly influenced by the cultural perspective of their community and this perspective needs to be taken into account in future research.

There are many questions about imagination that are unanswered and many issues to be resolved, but there has been a surge of interest in this area of research and some progress has been made. In general, the advances of the past decade or so emphasize that imaginative processes are fundamental to everyday thought throughout life and are inextricably linked to our understanding of reality.

Glossary

Discriminant validity The distinctiveness of creativity from related characteristics and talents (e.g., intelligence).

Explicit theories Opinions and views held by scientists. They are explicit in the sense that they are shared with other scientists and testable.

Implicit theories Opinions and views held by people other than scientists. They are often personal rather than shared, and they may not be in a form that allows testing.

Personal explicit theories These are the implicit theories that are held by scientists. They are personal and thus implicit, but because they can influence the research of the scientist, they are explicit as well.

Social validity A psychometric technique relying on judgments given by parents, teachers, or others who are important in the lives of the research subjects (e.g., children). The assumption is that these judgments will have more ecological meaning than will test scores and judgments given by trained professionals.

Tacit knowledge Personal understanding about the world. Often we know something about the world (e.g., gravity pulls objects toward earth), yet many of us cannot give a precise explanation for why this is the case. Our knowledge is in that sense tacit.

Introduction

Good scientific theories are testable. Hypotheses are easy to draw from them, and they are precise enough to know if data support or refute them. In this sense scientific theories must be explicit. They are made explicit to share, as well as to test. Scientists share ideas by publishing them, along with the results from their investigations. Other scientists can then attempt to replicate or utilize the research. Science is a social endeavor. Implicit theories, on the other hand, reflect the opinions held by parents, teachers, children, managers, and others who need not articulate their views. Although implicit theories are manifested in opinions and expectations, they are largely personal. They reflect a kind of tacit knowledge, which is quite common. Often we know something about the world (e.g., gravity pulls objects toward earth), yet many of us cannot give a precise explanation for why this is the case (other than referring to the mass of the earth or Newton's observation of an apple falling from a tree). Implicit theories allow us to judge creative behavior even if we cannot define creativity.

Implicit theories are important because they are related to the standards used in making many judgments – including judgments about creativity. They are also related to expectations, and a corpus of research has demonstrated the impact of expectations on development and behavior. Teachers' expectations, for example, may actually influence the rate of learning by students. Parental implicit theories and expectations are similarly important. If a parent has reasonable expectations for his or her child, for example, the child will be more appropriately challenged. The parent will give the child activities and tasks that require some effort, but they will not be so difficult that the child is frustrated. Most of the research on implicit theories has focused on the opinions of teachers and parents. A few isolated studies have been conducted with other samples. Some research has, for instance, been conducted with

managers in organizations. Their implicit theories presumably are important in that these will influence what expectations they hold for their employees. The most recent research has examined the implicit theories held by scientists who are studying creativity. These were labeled 'personal explicit theories' because they are both implicit and explicit. The reasonable assumption here is that the implicit theories of scientists influence their thinking and the development of their explicit theories. This is analogous to what was noted above about parents' and teachers' expectations reflecting their implicit theories, only for scientists the expectations influence their work and research.

Methods Used in the Study of Implicit Theories

The methods used to study implicit theories vary. One method utilizes the social validation technology. Social validity was developed in the clinical setting as a means of ensuring that treatment outcomes would be meaningful in the natural environment. Treatment outcomes are frequently validated, but often this validation process relies on judgments of therapists. Social validation is based on the judgments of parents, teachers, and individuals who are likely to be involved in the lives of the client in the natural environment. They are, then, based on implicit theories rather than on explicit theories. Social validation requires two phases. First the sample whose implicit theories are of interest receive openended questions (e.g., what characteristics are shared by creative individuals?). The most commonly nominated characteristics are identified and placed on a questionnaire. This can be used in the second phase of the research to obtain ratings about particular individuals. The ratings on the questionnaire are usually categorical (e.g., Likert) but allow parametric statistical techniques to test group differences or relationships with other variables.

There is some subjectivity involved when the implicit theories of the individual are being compiled. Different individuals may express their implicit theories in different ways, so two individuals may both believe that creative persons are always original, but one of them describes this as being prone to novelty and the other as characterized by unusual behavior. The researcher attempting to identify the most commonly nominated characteristics may have difficulty determining which nominations refer to the same trait and which do not. Is 'original' the same as 'novel,' 'unique,' and 'unusual'? We cannot be certain, even if we consult a standard dictionary, because we are dealing with implicit theories. One person may say 'original' and mean the same thing someone else means when he or she says 'novel.'

For this reason the first phase of social validation work may avoid open-ended questions. In Mark Runco's work with parents and teachers, the Adjective Check List was used in the first phase. This contains 300 adjectives, alphabetically arranged, and the individuals nominating traits simply choose which of those 300 are descriptive of creativity. The range of possible traits may be slightly truncated with this technique but it does avoid the subjectivity mentioned above. (Social validation using the Adjective Check List has not been conducted on anything other than creativity. Social validation is a part of some clinical assessments, but there the 'significant others' are given the open-ended questions in the first phase of the research.)

Another advantage of the Adjective Check List is that it facilitates comparisons with explicit theories. This is because it contains several creativity scales. In fact, the Adjective Check List also has a social desirability scale, and this too has been used in the research examining the traits suggested by the implicit theories of creativity. This particular comparison is interesting because previous research indicates that teachers' views of the 'ideal student' contain traits such as conforming, considerate, and so on – traits which may be unrelated to creativity. The creative student may daydream, only concentrate on intrinsically motivating tasks (rather than assignments), and do things in an original fashion. One socially valid measure is the Parental Evaluation of Children's Creativity (revised). It was constructed from the traits parents most agreed on when asked to use the Adjective Check List to describe creative children. It contains 75 items, but only 24 of them (32%) are part of the scale that is relevant to social desirability. (The Adjective Check List scale used for social desirability is the 'Favorable traits' scale.)

Empirical Research on Implicit Theories and Group Differences

Runco and colleagues have found that parents and teachers believe creative children to be active, adventurous, alert, ambitious, artistic, capable, curious, dreamy, energetic, enthusiastic, and imaginative. There were, however, differences between these groups. Teachers pointed to cheerful, easy-going, emotional, friendly, and spontaneous as characteristic of creativity. Parents chose enterprising, impulsive, industrious, progressive, resourceful, and self-confident.

Artists have been found to distinguish between artistic creativity, scientific creativity, everyday creativity, and 'noncreativity.' Imagination, emotion, and expressiveness were tied to

artistic creativity, while 'patient' and 'thorough' were tied to scientific creativity. Clearly, the domain differences that are recognized in explicit theories of creativity are also recognized in implicit theories. The social validation technique has also been used to empirically examine sixth- and seventh-grade children's implicit theories about creativity. In the first phase of the investigation the students were required to 'list synonyms of creativity, behaviors they observed in peers they considered to be creative, and personality traits common to creative peers.' Helen Miller and Janet Sawyers identified the most common items and placed them in their Students' Self-Evaluation of Creativity. They added several items (e.g., Conforming) to minimize the chance of response sets. These negative items were theoretically antithetical to creativity. As was the case with the implicit theories of artists, some of the characteristics nominated by the children (e.g., Imaginative and Interested in Many Things) are entirely consistent with explicit theories of creativity. Some of them reflect unfortunate biases. The item Artistic, for example, reflects the widely held but incorrect assumption that creativity is only possible in the arts.

Ratings from a second group of students (fifth-grade students) on this new instrument were correlated with originality scores on divergent thinking tests. They were also unrelated to the IQ, which gives the self-report some discriminant validity. Robert Sternberg has also reported evidence for the discriminant validity of implicit theories of creativity. He found differences among people's conceptions of creativity, intelligence, and wisdom.

Creativity is associated with certain traits (e.g., originality and intrinsic motivation) and is inhibited by other traits (e.g., conformity and conventionality). For this reason those describing their implicit theories should be asked about traits that are related to creativity and those that are unrelated to creativity. The latter question may be asked something like, "what traits are uncommon in creative people," or "what traits are found only in uncreative persons?" Runco and colleagues did exactly this. They then constructed two indices in the ratings obtained from mothers, fathers, and children. One was indicative of creativity and one contained contraindicative items. These showed good agreement among the groups. In particular, the indicative index of the mothers was positively related to that of the fathers, but negatively associated with both the mothers' and the fathers' contraindicative ratings.
